Isolated hydrogen centres are difficult to study directly in semiconducting materials, yet an awareness of hydrogen behaviour is essential to enable its effects on electrical properties, diffusion and growth processes to be understood. One way of building up atomistic pictures of hydrogen behaviour is through observation of its analogue *muonium*, formed by implantation of positive muons. Implanted into a semiconducting material, muons behave like light proton isotopes, mimicking protons, isolated hydrogen or hydride ion species depending on how many electrons they pick up. Observation of muon and muonium (the isolated hydrogen atom analogue, μ^+e^- , Mu) behaviour therefore enables analogous hydrogen behaviour to be deduced [1].

The technique of μ SR—muon spin rotation, relaxation or resonance—involves implantation of spin polarised, positive muons followed by observation of the time evolution of the muon polarisation in the sample after implantation. Muons are unstable particles,

decaying after an average lifetime of 2.2 μ s to produce a positron, which is preferentially emitted in the instantaneous direction of the muon's spin at time of decay. Detection of these positrons therefore allows the evolution of the muon polarisation in the sample to be followed after implantation, informing on muon behaviour.

Observation of the muon response in semiconducting materials has enabled models of hydrogen behaviour to be built up. In silicon and germanium at low temperatures, three muon states are formed: a diamagnetic state (μ^+ or μ^-); a paramagnetic, isotropic muonium state which moves rapidly between tetrahedral sites (Mu_T); and an axially symmetric, immobile bond-centred paramagnetic species (Mu_{BC}). Detailed models for the dynamics of these states have been developed (for example [2]). Muons have recently provided the first experimental confirmation of a predicted shallow donor hydrogen state in ZnO [3], together with observation of shallow donor states in other II–VI materials [4].

The interaction between hydrogen and interstitial oxygen in Si is of particular interest, because of the ability of H to catalyse oxygen diffusion. The precise mechanism for this is not well understood, however, although it is believed that H adopts a bond centred site

near to oxygen atoms in the Si lattice [5,6]. Comparison of the muon response between float zone and Czochralski material may enable information on oxygen–hydrogen interactions to be deduced.

This current study also includes data from a bulk, Cz-grown $\text{Si}_{1-x}\text{Ge}_x$ alloy. The recently developed ability to grow alloy material by the Czochralski technique [7] has opened up the possibility of exploring the bulk properties of this technologically important material. A more detailed comparison of alloy material with Cz-Si will be presented elsewhere; however, the alloy results shown here are the first presentation of the muon response from $\text{Si}_{1-x}\text{Ge}_x$ material.

2. Experimental

Muon behaviour in three samples is described: 300 μm thick, $\langle 111 \rangle$ oriented, 5 cm diameter prime undoped Czochralski silicon from Virginia Semiconductor, with n-type character and a measured resistivity of $885 \Omega \text{cm}^{-1}$ ($5 \times 10^{12} \text{ carriers cm}^{-2}$); 330 μm thick, $\langle 111 \rangle$ oriented, 10 cm diameter float zone silicon from ShinEtsu Handotai with n-type character and a measured resistivity of $3300 \Omega \text{cm}^{-1}$ ($1.5 \times 10^{12} \text{ carriers cm}^{-2}$); and $\langle 100 \rangle$ undoped Czochralski $\text{Si}_{0.91}\text{Ge}_{0.09}$ grown by Prof. I. Yonenaga in the form of a single wafer 2.5 cm across and about 500 μm in thickness.

Muon measurements were made at the ISIS pulsed muon facility. The muon spectrometers enable decay positrons to be detected using an array of scintillator detectors arranged in two groups, one forward and one backward of the initial muon polarisation direction. Forming the normalised difference in positron counts between these two detector groups enables a direct measurement of the time evolution of the muon polarisation in the sample after implantation to be made. Samples were mounted in exchange gas ^4He cryostats to allow temperatures from 5–300 K to be accessed.

Fig. 1 shows a typical plot of the muon polarisation as a function of time after muon implantation. This plot was taken from the Cz-Si sample at 25 K in an applied longitudinal field of 525 G. This plot was formed using

$$P = \frac{1}{a_0} \frac{F(t) - \alpha B(t)}{F(t) + \alpha B(t)},$$

where F and B are respectively the counts in the detectors forward and backward of the initial muon polarisation direction, and α is a factor to correct for small differences in efficiency and solid angle between the forward and backward detector sets. a_0 is the forward–backward detector asymmetry corresponding to full polarisation, typically about 0.24 on the ISIS muon instruments.

Fig. 1. Muon polarisation as a function of time in the Cz-Si sample at 24.8 K and a longitudinal field of 525 G. The exponential decrease is due to Mu_T relaxation; the oscillations are due to Mu_{BC} states with symmetry axis parallel to the field direction.

The features of the polarisation plot show the behaviour of the muon species in the sample. The main features in Fig. 1 are an overall decrease of the polarisation with time down to a constant value, on which is superimposed an oscillatory component. Dynamical processes involving muonium lead to an exponential relaxation of the muon polarisation after implantation; Fig. 1 has been fitted with a single exponential decay. States not involved in relaxation processes contribute a constant component. The oscillatory term in Fig. 1 is due to particular transitions within one of the muonium species, and can be fitted with a sinusoidal term whose amplitude decreases with time. All of the longitudinal field data in the current paper have been fitted with a single exponential decay (allowing the amplitude and relaxation rate of the component to be extracted) and a constant component, together with a single oscillatory term where needed.

3. Results

Fig. 2 shows the measured relaxation rate in applied longitudinal field as a function of temperature for the Cz-Si, $\text{Cz-Si}_{0.91}\text{Ge}_{0.09}$ and Fz-Si samples. For the $\langle 111 \rangle$ Cz-Si and Fz-Si samples, the applied field was 525 G. This field was chosen to allow oscillations caused by the avoidance of a level crossing in the Mu_{BC} energy levels, in Mu_{BC} species with symmetry axis parallel to the applied field diagram, to be observed; these can be seen in Fig. 1. Longitudinal field measurements at 525 G therefore allowed a very direct way of monitoring the behaviour of Mu_{BC} as a function of temperature. For the $\text{Cz-Si}_{0.91}\text{Ge}_{0.09}$ sample, the applied field was 100 G.

Fig. 2. Longitudinal field relaxation rate as a function of temperature from the Cz-Si and Fz-Si samples (both 525 G longitudinal field) and the Cz-Si_{0.91}Ge_{0.09} alloy material (100 G field).

The float zone silicon shows a small relaxation between 10 K and 30 K of about $0.3 \mu\text{s}^{-1}$; the rate stays low until above 100 K. The Cz-Si shows a similar behaviour below about 17 K, but then exhibits a very strong relaxation rising to a peak of $2\text{--}3 \mu\text{s}^{-1}$ at 40 K. Measurements as a function of applied field show the relaxing species to be Mu_T ; this is confirmed by the fact that the Mu_BC longitudinal field oscillations show little change over the temperature range shown in Fig. 2. Shown also in Fig. 2 is the relaxation rate from the Cz-Si_{0.91}Ge_{0.09} sample. This also exhibits a significant peak at around 40 K, again from the Mu_T species. The amplitudes of the relaxing components in the Cz-Si and Cz-Si_{0.91}Ge_{0.09} samples show peaks at around 30 K before falling to low values above 40 K.

Transverse field measurements can reveal the behaviour of promptly formed diamagnetic species—either μ^+ or μ^- —although delayed diamagnetic formation (for example, resulting from conversion of a paramagnetic species) is not seen in transverse data. Fig. 3 shows the transverse field amplitudes for the three samples as a function of temperature. Over the whole temperature region of Fig. 2 there is no significant increase in the prompt diamagnetic fractions in any of the samples. The rise shown by all three above 200 K is the result of Mu_BC ionisation.

Delayed formation of muon states can be seen using radio-frequency μSR . RF- μSR involves application of a static, longitudinal field to the sample, together with an RF pulse applied for the duration of data taking. Depolarisation is observed as the static field is swept through the resonance condition—in the case described here, the signal from diamagnetic muons has been measured. Fig. 4 shows the RF diamagnetic amplitude as a function of temperature for the three samples. At

Fig. 3. Transverse field diamagnetic fractions as a function of temperature from the Cz-Si and Fz-Si samples (20 G transverse field used) and Si_{0.91}Ge_{0.09} alloy material (80 G field used).

Fig. 4. Radio-frequency μSR diamagnetic fractions as a function of temperature from the Cz-Si, Fz-Si and Si_{0.91}Ge_{0.09} alloy materials.

low temperatures, below 100 K, there is no change in the signal from the Fz-Si; above 100 K, Mu_BC ionisation to a diamagnetic state is observed. In the two Cz samples, a significant increase in the diamagnetic signal is observed, starting at around 50 K. The diamagnetic species observed cannot be formed promptly, as it would appear in the transverse field data of Fig. 3 if so.

4. Discussion

The results described above reveal a Mu_T behaviour seen in the Cz samples that is not observed in the Fz-Si. The strong Mu_T relaxation seen at around 40 K, immediately followed by a rise in the RF diamagnetic amplitude, together with the transverse field diamagnetic

signal showing no change, all point to the mobile Mu_T species being involved in a process which initially leads to its relaxation, then to its conversion to a diamagnetic species. Whilst the temperature regime of this behaviour is around the region of donor ionisation, the carrier concentrations of the Cz-Si and Fz-Si are similar, so that such different behaviour between the samples based on donor behaviour would be surprising. The Mu_{BC} species in the Cz-Si is unaffected over the whole temperature range of Fig. 2 since no changes are observed in its longitudinal field precession signal. The visibility of this Mu_{BC} oscillation signal and the fact that it shows no temperature dependence is evidence that free carriers are not producing any spin-exchange relaxation, as would be seen at higher n-type doping levels. It seems likely that the Mu_T relaxation seen in the Cz samples is caused by interactions with oxygen impurity in this material; this would explain its absence in the Fz-Si. Previous authors [5,6] have reported the association of a bond centred Mu or H species with bond centred oxygen in Si. It is possible that the presence of oxygen facilitates the site change of muonium between the tetrahedral cage centres and the bond centres. The resultant modulation of hyperfine parameters in the course of diffusion is then the cause of the enhanced spin relaxation or depolarisation. A reduction in ionisation energy for bond centred muonium at these extrinsic sites, i.e. at the centre of a pre-stretched Si-Si bond, would then lead to the delayed formation of a diamagnetic species as seen in the RF data.

This paper is also the first time the muon response in a $\text{Si}_{1-x}\text{Ge}_x$ alloy has been reported. A more detailed analysis of the dealing specifically with the $\text{Si}_{0.91}\text{Ge}_{0.09}$ alloy material and with other alloy compositions will be presented in a future paper. In particular, whilst the transverse field diamagnetic plot (Fig. 3) suggests that the ionisation temperature for Mu_{BC} in the alloy material is relatively unaffected by the presence of 9% Ge, the RF diamagnetic behaviour for the alloy material shown in Fig. 4 is more complex in the 100–200 K region than in the Cz-Si and Fz-Si material and requires further investigation.

Abstract

It has been shown that during irradiation, the V_2 and $V_2\text{Ge}$ centers are formed and the absorption band that peaked at about 5560 cm^{-1} in as-irradiated $\text{Si}_{1-x}\text{Ge}_x$ samples is the superposition of two bands corresponding to the absorption by the V_2^0 and $V_2\text{Ge}$ centers. The contribution of the V_2^0 component to the absorption band in as-irradiated samples increases as the germanium content increases. A thermostability of the $V_2\text{Ge}$ centers is shown to be essentially higher than the one of the divacancy in silicon and increases with the germanium content. © 2001 Elsevier Science B.V. 1. Introduction

It is known that the doping of semiconductors with isovalent impurities (IVI) can be employed to control defect–impurity interaction processes, which occur both during growth and under various external actions. Depending on the ratio of the covalent radii of the IVI and matrix atoms, they can suppress or enhance the effects associated with vacancies (V) or with interstitials (I) and change the reaction channels that are characteristic of Si. For example, the carbon in the Si interacts effectively with the I at irradiation and forms numerous defects of the I-type. The Ge and Sn influence the reactions involving the V. Earlier, we showed that a localization of the vacancy + oxygen (VO) centers near the Ge atom in the Si takes place [1]. In this paper, we report new data on the interaction of the divacancies with the Ge atoms in the $\text{Si}_{1-x}\text{Ge}_x$.

The divacancy (V_2) is known to be one of the main radiation defects both in single crystals and in thin layers of Si and $\text{Si}_{1-x}\text{Ge}_x$. It may be formed either as a primary radiation defect during irradiation or as a secondary defect as a result of the interaction of vacancies that

occurred during their thermally activated migration. The properties of the V_2 in the Si have been studied widely. The V_2 in the Si is known to be in four charge states, namely V_2^- , V_2 , V_2^+ , and V_2^{2+} [2–6]. Three absorption bands peaked at about 2500, 2760, and 5560 cm^{-1} correspond to the states V_2^- , V_2^+ , and V_2^0 , respectively. There are some papers on the V_2 in the $\text{Si}_{1-x}\text{Ge}_x$ solid solution. In Ref. [7], the V_2^0 in polycrystalline $\text{Si}_{1-x}\text{Ge}_x$ irradiated with neutrons and protons have been studied. It was found that, as the Ge concentration is increased, the 5560 cm^{-1} absorption band shifts to the low frequency side and this shift is supposed to correlate with the composition-related change in the lattice parameter. The authors also had marked the rise of the thermal stability of the V_2 in the Si-rich solid solutions and the decrease of the thermal stability in the Ge-rich samples. But in Refs. [8,9], in investigations of $\text{Si}_{1-x}\text{Ge}_x$ thin layers, it was shown that the thermal stability of the V_2 is not affected by variations in the composition of the $\text{Si}_{1-x}\text{Ge}_x$.

To the present day, the properties of the V_2 in the $\text{Si}_{1-x}\text{Ge}_x$ single crystals have been studied at Ge content less than 1 at%. Here, we report new data on the peculiarities of the V_2 formation (estimated on the 5560 cm^{-1} (V_2^0) absorption band) in the $\text{Si}_{1-x}\text{Ge}_x$ single crystals with the Ge content as high as 15 at%.

2. Experimental results and discussion

The samples of boron-doped $\text{Si}_{1-x}\text{Ge}_x$ single crystals grown by the Czochralski method in the Institute of Crystal Growth (Berlin, Germany) [10,11] were investigated. The oxygen and carbon contents determined using infrared absorption lines 1107 and 604 cm^{-1} were $(7-9) \times 10^{17}$ and $(2-3) \times 10^{16}\text{ cm}^{-3}$, respectively. The Ge content was measured using the X-ray microanalyzer JCSA-733 and varied from 2 to 15 at%. To analyze the peculiarities of the Ge influence the properties of the V_2 the samples of Si that did not contain Ge and whose parameters were close to those of the $\text{Si}_{1-x}\text{Ge}_x$ were investigated.

The samples were irradiated by fast electrons with the energy 4 MeV at temperatures of about 300 and 90 K for doses $(3.5-6) \times 10^{17}\text{ e cm}^{-2}$. The samples were investigated just after irradiation and after following isochronous annealing ($t = 20\text{ min}$) in the temperature range $100-400^\circ\text{C}$. The processes of the formation and annealing of the divacancies (V_2^0 and V_2^+) and their dependence on the Ge content were studied by infrared Fourier spectroscopy.

The absorption spectra obtained for the samples irradiated at $T \approx 300\text{ K}$ with a dose $F_e \approx 5 \times 10^{17}\text{ e cm}^{-2}$ are shown in Fig. 1a, and the dependence of the band maximum position on the Ge content in Fig. 1b. As can be seen, a gradual shift of the V_2^0 absorption band towards low frequencies was observed at the increase of Ge content in the samples. The estimations of the V_2 concentrations from the intensity of the 5560 cm^{-1} band have shown that there is no noticeable influence of the Ge content on the efficiency of the V_2 formation. Note that previously, we have observed the decrease in the formation efficiency of the VO centers in these crystals [1].

Interesting features in the behavior of the V_2^0 absorption band were observed in the samples subjected to isochronous annealing. The results obtained for the crystals with the Ge content 3.5 at% are shown in Fig. 2a. One can see that in the temperature range $150-240^\circ\text{C}$, the high frequency wing of the absorption band anneals out, the maximum of the band shifts gradually to the lower frequency side, and the intensity of the band somewhat rises (Fig. 2a, curve 3 or V_2^*). These changes are observed in the same range of the annealing temperatures for all concentrations of the Ge used in the investigations. However, it should be noted that the shift of the absorption band on annealing decreases as the Ge content increases (Fig. 2b). In the reference Si samples, a larger part of the V_2 are annealed out in the temperature range of $150-240^\circ\text{C}$ (Fig. 3, curve 1) with the synchronous formation of additional VO centers. For all investigated $\text{Si}_{1-x}\text{Ge}_x$ samples no changes in the VO absorption region were observed after annealing in the temperature range $150-240^\circ\text{C}$.

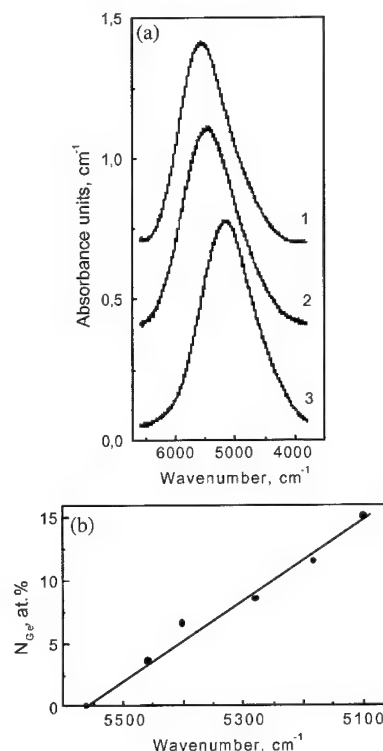

Fig. 1. The absorption spectra near 5560 cm^{-1} for the Si and $\text{Si}_{1-x}\text{Ge}_x$ measured at 300 K (a) and dependence of the band maximum position on the Ge content in the $\text{Si}_{1-x}\text{Ge}_x$ (b). $F_e \approx 5 \times 10^{17}\text{ e cm}^{-2}$. N_{Ge} (at%) for (a): 1—0; 2—3.5, and 3—11.5.

For higher annealing temperature ($T > 240^\circ\text{C}$), the intensity of the absorption band V_2^* at first does not change but later decreases gradually as a whole without any change in the maximum position (Fig. 2a, curves 4–7). The annealing behavior of the V_2^* band for the samples under investigation is shown in Fig. 3 (curves 2–5). As can be seen from Fig. 3, the annealing temperature of the V_2^* is higher than the one of the V_2 in Si and increases with increasing Ge content in the samples. These observations do not correlate with the results obtained by DLTS in Refs. [8,9], where it was shown that the thermal stability of the divacancies does not depend on the composition of the samples.

The V_2 are known to diffuse over the Si lattice during the annealing until they are trapped by the sinks. The diffusing V_2 effectively interact with the impurities with a formation of the complexes [1,12–14]. The observed features of the transformations of the band that peaked at about 5560 cm^{-1} on annealing of $\text{Si}_{1-x}\text{Ge}_x$ in the range of $150-240^\circ\text{C}$ (the annealing of the high frequency wing of the absorption band, shift of the band maximum position, increase in the

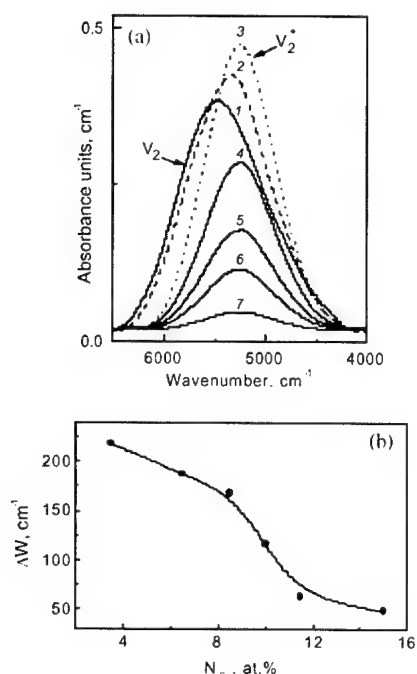

Fig. 2. The behavior of the absorption band near 5560 cm^{-1} during annealing of irradiated $\text{Si}_{0.965}\text{Ge}_{0.035}$ (a) and dependence of the band shift on the Ge content in the $\text{Si}_{1-x}\text{Ge}_x$ (b). T_{ann} ($^{\circ}\text{C}$) for (a): 1—before annealing; 2—180; 3—240; 4—310; 5—320; 6—330, and 7—335.

Fig. 3. The relative change in the intensity (I/I_0) of the absorption bands V_2^0 in the Si (1) and the V_2^+ in the $\text{Si}_{1-x}\text{Ge}_x$ (2–5) at annealing. N_{Ge} (at%): 2—3.5; 3—6.5; 4—8.5, and 5—11.5.

intensity and the absence of the negative annealing stage of the VO centers) enable one to suggest that the observed V_2^+ can be tentatively assigned to a new defect. Taking into account the fact that the Ge content in the samples under investigation is much larger than the concentration of all possible sinks one can assume that the diffusing V_2 interact with the Ge atoms and form $V_2\text{Ge}$ centers. As a result, V_2^+ absorption band appears.

The decomposition of the absorption band that peaked at about 5560 cm^{-1} in as-irradiated $\text{Si}_{1-x}\text{Ge}_x$ samples shows that it is complicated and consists of two bands. One of the bands corresponds to the V_2^0 while another one corresponds to the V_2^+ centers detected. The contribution of the V_2^+ component to the absorption band increases as the Ge content increases, and at the Ge concentration about 15 at%, the contribution of the V_2^0 in the band peaked at about 5560 cm^{-1} is very small. This is probably the reason for the diminishing of the absorption band shift at annealing in the temperature range $150\text{--}240^{\circ}\text{C}$ with the increasing Ge content in the samples (Fig. 2b). Thus, the facts obtained testify that the V_2^+ are formed during the irradiation also. Since the Ge atoms are the effective sinks for vacancies, the latter move towards the Ge atoms during irradiation and, evidently, associate with them into $V_2\text{Ge}$.

To confirm the complex structure of the absorption band that peaked in the vicinity of 5560 cm^{-1} in as-irradiated $\text{Si}_{1-x}\text{Ge}_x$, we have studied the samples irradiated at $T \leq 90\text{ K}$. At such irradiation temperatures, it is known that the GeV centers are effectively formed and almost all vacancies are captured by the Ge atoms. The last factor influences the formation rate of secondary V-related defects [15]. Fig. 4 shows the obtained spectra (measured at $T = 4.2\text{ K}$) for Si and $\text{Si}_{0.965}\text{Ge}_{0.035}$ irradiated with a dose of $6 \times 10^{17}\text{ e cm}^{-2}$ at $T \leq 90\text{ K}$. As can be seen, the band at $\sim 835\text{ cm}^{-1}$, corresponding to the VO centers is not observed in as-irradiated $\text{Si}_{0.965}\text{Ge}_{0.035}$ samples. However, any Ge noticeably influence absorption band that peaked at about 5560 cm^{-1} is not observed, although the efficiency of the secondary V_2 formation due to the vacancy–vacancy interactions in the CZ material is known to be lower than the efficiency of the VO formation at the energies and irradiation doses under investigation. Moreover, due to the high Ge content, the efficiency

Fig. 4. The absorption spectra of the Si (2) and the $\text{Si}_{0.965}\text{Ge}_{0.035}$ (1) irradiated at $T \leq 90\text{ K}$ at a dose of $6 \times 10^{17}\text{ e cm}^{-2}$.

of the GeV centers formation is essentially larger than that for the secondary VO and V_2 centers. Thus, the influence of the Ge formation on the V_2 should be observed.

In the last experiment, we had the possibility of study the two charge states V_2^0 and V_2^+ (absorption band near 2760 cm^{-1} and its phonon-assisted high-energy satellite in Fig. 4) simultaneously. As it is seen from Fig. 4, the V_2^+ absorption band in the $\text{Si}_{0.965}\text{Ge}_{0.035}$ is shifted at $\sim 20\text{ cm}^{-1}$ to low frequencies as compared to the Si (note, that the 5560 cm^{-1} band shifts by $\sim 100\text{ cm}^{-1}$), some broaden, and the intensity of this band is lower than in the Si. A comparison of the areas under the V_2^+ curves shows that the concentration of the divacancies decreases in the $\text{Si}_{1-x}\text{Ge}_x$ as compared to the Si. As it has already been mentioned above, this decrease should be observed at low-temperature irradiation. Then we have carried out an isochronal annealing of samples and found that the annealing of the V_2^+ related absorption bands in the $\text{Si}_{1-x}\text{Ge}_x$ is similar to that in the Si. This band disappears in the temperature range of $180\text{--}260^\circ\text{C}$. This correlates with the results reported in Refs. [8,9]. All these obtained facts confirm our suggestion that the origin of the band that peaked at about 5560 cm^{-1} band is a complex one.

Thus, the experimental data obtained prove that the V_2 characteristic for the Si and complexes of the V_2 with the Ge atoms ($V_2\text{Ge}$) are formed in the $\text{Si}_{1-x}\text{Ge}_x$ single crystals during irradiation. The absorption band peaked at about 5560 cm^{-1} in as-irradiated $\text{Si}_{1-x}\text{Ge}_x$ is the superposition of two bands corresponding to absorption by these two centers. Note that the formation of the $V_2\text{Ge}$ during irradiation is, probably, one of the reasons for the suppression of the VO formation efficiency observed earlier [1].

High resolution minority carrier transient spectroscopy of defects in Si and Si/SiGe quantum wells

J.H. Evans-Freeman*, M.A. Gad

Centre for Electronic Materials, Department of Electrical Engineering and Electronics, UMIST, P.O. Box 88, Sackville St. Manchester, M60 1QD, UK

Abstract

High resolution Laplace minority carrier transient spectroscopy (LMCTS) has been used to study defects in gas source molecular beam epitaxy grown Si/Si_{0.855}Ge_{0.145} strained quantum wells. In LMCTS, the minority carrier emission transient is analysed and detailed emission properties of minority carrier traps which have similar energy can be characterised. The technique was evaluated by comparing LMCTS of a Au:H hole trap, G3, in n-type silicon with Laplace deep level transient spectroscopy of the same trap in p-type silicon. Both techniques confirm that this level consists of two states, as previously suggested in the literature. MCTS was then applied to the n-type Si/SiGe quantum well sample, and five-hole traps were observed. A level at 95 K in the MCTS spectrum was identified as a possible candidate for hole emission from the quantum wells. LMCTS showed that the emission rate of this hole trap exhibited only a slight temperature dependence compared to that exhibited by hole states associated with isolated point defects. This is attributed to holes tunnelling out of the quantum well assisted by the electric field present in the experiment. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Deep level transient spectroscopy (DLTS) is a commonly used technique to characterise the electrical activity of defects in semiconductors [1]. It yields a universal signature of the enthalpy of deep levels, but has some drawbacks. Only defect states in one half of the band gap can be easily characterised, and closely spaced energy levels are not resolvable because of the poor time constant resolution; both these problems have been addressed in recent years. To characterise deep states throughout the whole band gap, a complementary technique, minority carrier transient spectroscopy

(MCTS) [2] was developed, in which thermally stimulated minority carrier emission is measured and processed in the same way as DLTS. As an example of its use, it was reported [3] that Au:H complexes in silicon produce four deep levels, two in the upper half of the band gap and two in the lower, established by examining n- and p-type silicon [3]. The application of MCTS meant that all four new levels were observed in n-type Si [4]. MCTS can also be used to measure activation energies and capture cross sections, and can be combined with DLTS to examine carrier dynamics at recombination centres [5] but is difficult to use for depth profiling [6].

The problem of closely spaced levels has been addressed by the development of algorithms for analysing the components in the capacitance transient [7,8], and these have been used with considerable success to resolve some long standing defect problems in silicon

[9–16]. This technique is termed Laplace DLTS (LDLTS) and produces an output of intensity as a function of emission rate.

In this paper, we report on application of the same algorithms to minority carrier emission transients, which we call Laplace MCTS (LMCTS). The technique is verified by applying it to minority carrier traps in n-type Si containing Au:H complexes. Earlier work had suggested that one of the Au:H states, G3, consisted of two closely spaced levels [3,4], based on detailed capture cross-section measurements [4]. G3 is a hole trap, therefore we have compared LMCTS of this trap in n-type Si with LDLTS of the trap in p-type Si. We have then applied the technique for the examination of hole emission from strained Si/SiGe/Si quantum wells (QWs). The majority of the band offset is in the valence band [17] and we have used MCTS and LMCTS to detect thermally stimulated hole emission from the wells. The results are compared with PL quenching experiments which yield the hole confinement energy.

2. Experimental

The samples containing Au:H complexes were either n-type CZ Si doped with $2 \times 10^{15} \text{ cm}^{-3}$ phosphorus or p-type Si doped with $2 \times 10^{15} \text{ cm}^{-3}$ boron. The gold diffusion and introduction of hydrogen (by wet chemical etching), is described elsewhere [4]. Gold Schottky diodes were evaporated onto the n-type Si, and titanium Schottky diodes were sputtered onto the p-type Si. The SiGe/Si QW structure was grown by gas source molecular beam epitaxy and consisted of 10 strained $\text{Si}_{0.855}\text{Ge}_{0.145}/\text{Si}$ QWs grown on a Si substrate. The Si cap layer was 199.8 nm, the wells were 5.7 nm thick, the barriers were 55 nm thick, and the layer was n-type because of a residual phosphorus level of about $1 \times 10^{16} \text{ cm}^{-3}$.

For the MCTS and LMCTS measurements, thin (20 nm) Au diodes were evaporated. Electrical measurements were carried out in a closed cycle cryostat between temperatures of 300 and 20 K. In MCTS, above band gap light is incident on the semitransparent Schottky diode, and creates electron-hole pairs. The wavelength of the light ensures that the extinction depth is greater than the depletion region width. Majority carriers are rejected from the depletion region, and it is predominantly minority carriers that are available for capture in the region. In the LMCTS experiment, the capacitance transient due to minority carrier emission was recorded up to 10,000 times at a fixed temperature in a high stability cryostat. For the photoluminescence (PL) measurements, the sample was attached to a cold finger inside a closed cycle cryostat and excited by using the 514.2 nm line of an argon ion laser. The signal was

detected using a liquid nitrogen cooled Ge detector and analysed by conventional lock-in techniques.

3. Results and discussion

When silicon containing Au:H complexes was characterised by DLTS and MCTS (not shown) the expected traps G1–G4 [3] due to Au:H complexes, and the Au acceptor and donor states were observed. In earlier work [3,4], it was noted that G3, at $E_v + 0.47 \text{ eV}$, exhibited different behaviour from the levels G1, G2 and G4. The annealing behaviour was different [3] and it exhibited a two-stage capture process [4]. The existence of two closely spaced levels in G3 is confirmed here by carrying out LDLTS and LMCTS. Fig. 1(a) shows LMCTS carried out at 225 K and Fig. 1(b) shows the LDLTS recorded at the same temperature in p-type Si. In both spectra two emission rates are observed. The relative intensities of the two emission rates are different between the n- and p-type samples, but this may reflect the differences observed and reported previously regarding G3 when it is in n- or p-type Si. These spectra confirm that LMCTS yields the same information at LDLTS.

Turning to the strained QW layer, PL at 5 K layer showed very clear zero phonon, transverse optical and transverse acoustic phonon peaks [18,19]. The hole confinement energy can be found by examining the PL quenching as a function of temperature [20]. This yielded an activation energy for thermal emission out of the wells of 110 meV, which is the depth above the Si valence band of the $n = 1$ heavy hole confined state.

Fig. 1. (a) LMCTS carried out at 225 K of the trap G3 associated with Au:H complexes in n-type silicon, and (b) LDLTS of the same defect recorded at the same temperature in p-type Si.

In MCTS and LMCTS, the QWs capture holes during the fill pulse, the fill pulse creates a photocurrent through the diode, and the hole quasi-Fermi level varies with photon flux [6]. The calculation is further complicated by the presence of the QWs, because the quasi-Fermi level in them will depend upon the fraction of injected holes that are captured and reside in the wells. Difficulties in the calculation of the emission rates can easily be overcome if a few simple assumptions are made [21]. It can be assumed that all captured carriers will reside in the lowest confined energy state. This means that the experimental conditions are the same as during the PL experiment. It can also be assumed that the quasi-Fermi level in the QWs lies several kT above the confined heavy hole state, and will not affect the carrier dynamics during the emission process [22]. Hence, the emission rate for the holes out of the wells depends only upon the difference between the confined hole state energy and the valence band in the Si barrier.

It has been reported that at low temperatures (≤ 100 K) and relatively modest electric fields, $\geq 30 \text{ kVcm}^{-1}$, a plateau can be observed in the DLTS due to a constant emission rate of carriers out of QWs. This is attributed to tunnelling through a triangular potential barrier between the QW and the relevant carrier band [22]. Fig. 2 shows the MCTS spectrum of the Si_{0.855}Ge_{0.145}/Si MQW, in two halves for clarity. As an example of a point defect in this system, Fig. 3 shows the LMCTS spectra measured between 30 and 38 K, and shows that two emission rates are present. An Arrhenius plot of these two states, taken from the LDLTS data, yields activation energies of 50 ± 3 and 35 ± 3 meV. Both defects exhibit exponential filling, hence can be attributed to point defects. No Poole–Frenkel effect was observed.

The broad feature in Fig. 2 between 85 and 100 K is a strong candidate for the QW signal. The feature is

Fig. 2. MCTS spectrum of the Si_{0.855}Ge_{0.145}/Si MQW sample, spectrum in two halves for clarity, at a rate window of 200 s^{-1} . The feature proposed to be due to hole tunnelling out of the wells is indicated.

almost plateau-like, in accordance with Ref. [22], and no other features in the MCTS spectrum have an activation energy of 110 meV. Fig. 4 shows the emission rate of this deep state between 100 and 112.3 K, and it is nearly constant. The best fit of the emission rate to temperature was by assuming a square root dependence upon the temperature, rather than a Boltzmann relationship. Other defects in the LMCTS spectrum of this sample do not exhibit this behaviour, and we therefore conclude that we are observing direct evidence of holes tunnelling out of SiGe QWs into the cladding layers.

Fig. 3. Shows the LMCTS spectra of the Si_{0.855}Ge_{0.145}/Si MQW sample measured between 30 and 38 K.

Fig. 4. LMCTS of the QW-related state, showing the nearly constant emission rate between 100 and 112.3 K.

4. Conclusions

A technique which uses the same analytical approach to the capacitance transient as LDLTS but examines the detailed emission properties of minority carrier traps, LMCTS, has been described. In LMCTS, minority carriers are injected into a depletion region by the application of a light pulse of suitable wavelength. LDLTS and LMCTS are complementary because traps in the whole of the band gap can be accessed in semiconductors of one polarity. To verify the technique, LMCTS in n-type Si containing Au:H complexes was compared to LDLTS of p-type Si containing the same complexes, and found to yield the same results. The LMCTS technique was then applied to n-type Si which contains 10 Si_{0.855}Ge_{0.145} strained QWs. Several hole traps were observed, but it was possible to identify a candidate for hole emission out of the QWs. When examined by LMCTS over a temperature range of 102–116 K, it was found that the emission rate for holes out of the QWs was only weakly dependent upon temperature. This indicates that this defect is not point-defect-like, and it is suggested that the nearly constant emission rate is due to holes tunnelling out of the QW. This is the first direct observation of this effect, which up till now could only be inferred from conventional DLTS spectra.

Abstract

We have introduced S donors into SiGe alloys as probe atoms for a spectroscopic investigation of the local environment of these donors. Even for low Ge content ($x = 2.4\%$), we already observe strongly broadened lines for the intra-centre transitions, whereas the onset of the photo-ionisation stays at approximately the same energy, in contrast to expectations from a linear extrapolation of the impurity level from values of the pure compounds or from deformation potentials. We thus conclude that the S centres seen are located in the neighbourhood of significantly lower Ge content suggesting that Ge clusters may exist with much higher Ge content which, however, cannot be resolved in the photo-conductivity spectra. This finding, together with the observed line broadening demonstrates strong, non-statistical fluctuations in the alloy distribution. © 2001 Elsevier Science B.V. All rights reserved.

PACS: 61.66.Dk; 71.55.Ak

1. Introduction

It is quite common practice to describe alloys in terms of the so-called virtual crystal (VC) approximation. Within this VC model, it is assumed that all parameters of the alloy can be interpolated between the values of the pure constituents. There is, however, in general, very often a substantial mismatch in the bond length of the constituents and a tendency for phase segregation and cluster formation. As a consequence, there are substantial fluctuations of various parameters impairing the quality of the material with respect to both its optical and its transport properties. Proper characterisation methods are therefore needed in order to find ways for

optimising the material preparation. In this paper, we investigate the homogeneity of $\text{Si}_{1-x}\text{Ge}_x$ alloys for low x values ($x < 0.1$) making use of the photo-ionisation properties of chalcogen donors which are considered as local probes for their environment.

We investigated the influence of Ge contents in SiGe alloys on the highly localised states of deep impurities in silicon, in particular sulphur, using photothermal ionisation spectroscopy (PTIS). Chalcogen impurities in pure Si exhibit extremely sharp lines in the photo-conductivity spectra due to intra-centre transitions to excited states in the photo-conductivity spectra [1]. If these sharp lines could also be found in the alloys, one might be able to observe “alloy splitting” as it has been observed, e.g. for the DX centres in AlGaAs [2,3]. Due to the highly localised nature of the ground state of the DX centre, centres formed by substitutional donors exhibit different ground state energies depending on the different numbers of Al neighbours. For a group IV

*Corresponding author. Tel.: +43-732-2468-9649; fax: +43-732-2468-9696.

E-mail address: gudrun.kocher@jk.uni-linz.ac.at (G. Kocher).

donor, like Si_{Ga} , there are four possibilities: it can have $i = 0, \dots, 3$ Al neighbours after relaxation and the others will be Ga. Therefore, we expect a 4-fold splitting of the ground state which manifests itself in different emission energies. Here, the excited states are delocalized and thus they cause only broadening. The relative strength of the transitions gives a measure of the abundance of centres with different i . Consequently, in principle, it is possible to obtain information on the statistical distribution of the nearest neighbours.

For this work, we chose high quality, dislocation free bulk crystals of $\text{Si}_{1-x}\text{Ge}_x$ that show much lower line width in their rocking curves than MBE grown samples. We could not resolve, however, the intra-centre transitions even for the lowest Ge content investigated (2.4%). The photo-ionisation edge shows strong broadening but no shift in photon energy. We conclude thus that Ge clusters are formed and the VC approximation does not apply to SiGe alloys.

2. Experimental

$\text{Si}_{1-x}\text{Ge}_x$ wafers (bulk material) with low Ge content ($x \leq 0.1$) and either p- (boron) or n-type (phosphorous) doping between 10^{13} and 10^{15} cm^{-3} were additionally doped with sulphur (S) by means of diffusion. After the usual cleaning procedures, the samples were introduced into the first of two connected chambers of a quartz ampoule. In the second part, a mixture of Si-powder and S (approx. 100:1) was introduced. After evacuation and sealing off, the samples were put into a furnace for approx. 60 h at a diffusion temperature of 1100°C . In order to observe any line spectra due to S, p-type starting material had to be compensated which limits the initial doping level to less than about 10^{15} cm^{-3} (solid solubility of sulphur in Si).

Ohmic contacts were obtained by rubbing-on gallium. For the PTIS measurements, the sample itself was used as detector in a BOMEM DA8.22 Fourier spectrometer equipped with a Globar lamp and a KBr beamsplitter.

3. Discussion and conclusions

Typical PTIS spectra are given in Fig. 1 showing the threshold behaviour of the photo-ionisation for both Si and SiGe and there are sharp lines for pure Si ($x = 0$) which are superimposed on the absorption edge. For Si:S, we can clearly resolve the most prominent lines from the intra-centre transitions; the transitions to the excited states $1s(T_2)$, $2p_0$ and $2p_{\pm}$, respectively, are labelled 1, 2 and 3 (see Fig. 1). For a detailed discussion of these lines see Ref. [1]. This spectrum has been identified as that of isolated, substitutional S^0 . For a Ge concentration of 2.4%, the sharp lines are already

Fig. 1. Photo conductivity spectra for Si:S (lower trace) and SiGe:S with 2.4% Ge (middle trace) and 5.5% Ge (upper trace).

Table 1

Values of $-E_D$ as a function of Ge contents x for different methods

Ge content x	Experiment	Deformation potential	Linear extrapolation
0	318 [1]	318	318
0.024		329	322.3
0.055		341	328
0.1		360	335.2
1	280 [6]	280	280

completely smeared out and the ionisation edge appears broadened. The onset of the transitions into the continuum appears to stay at approximately the same energetic position (Fig. 1). This holds for a Ge content up to 10%.

The lattice mismatch between silicon and germanium is about 4% and drastically alters the band structure due to the built-in strain in the epitaxially grown $\text{Si}_{1-x}\text{Ge}_x$ films. In bulk crystals, strain will rather be induced statistically around some mean value. According to Herzog [4], the average lattice constant varies with Ge content x as

$$a_{av}(x) = 0.002733x^2 + 0.01992x + 0.5431(\text{nm}). \quad (1)$$

Using a_{av} , one can calculate the shift of the conduction band minima at the Δ -point using the deformation potential for the Δ_1 conduction band minimum [5]. Assuming that the deep ground state is hardly affected by the change in lattice constant, we obtain a value for the shift of E_D relative to the Δ_1 minimum (see Table 1). Another method to estimate the shift of the deep sulphur levels due to increasing Ge content would be a simple linear extrapolation (Fig. 2) using the experimentally

Fig. 2. Schematic diagram of the L- and A-conduction band edge as a function of x in $\text{Si}_{1-x}\text{Ge}_x$ alloys; in addition a linear extrapolation is given for the ground state level of S^0 between the values for the pure Si [1] and Ge [6]. The four dashed lines indicate the expected alloy splitting.

determined values for pure silicon [1] and pure germanium [6] as starting points which gives a shift of $\alpha = 1.72 \text{ meV per \% Ge}$.

In this extrapolation, we did not take into account the known bending of the conduction band edge [5]. Therefore the experimental values could be expected to lie somewhere in between the results of the two estimations. A summary of the energies for the neutral sulphur (S^0) level in pure Si and Ge as well as the expected shifts according to these two models for the various samples are given in Table 1. The variation in the threshold values derived from data in Fig. 1 is much smaller, however. We conclude thus that the S centres seen are surrounded by a significantly lower Ge content than suggested by the alloy concentration.

Considering all of the above and comparing it with our results, we conclude that the S centres seen are surrounded by a significantly lower Ge content than suggested by the alloy concentration. The fact, that we are not able to resolve single lines shows the existence of strain fluctuations. Using Eq. (1) and the result for α , we can estimate a lower limit for the fluctuation amplitude which is necessary to cause broadening bigger than the typical separation of the sharp intra-centre transitions. As a result, we estimate a fluctuation

amplitude Δx comparable to the mean value of the Ge concentration x .

The results obtained here indicate that the overwhelming majority of S donors are hardly affected by the presence of Ge. At 10% Ge content, the statistical probability for S to have one or two Ge neighbours is 30% and 5%, respectively. In other words, there is already a substantial probability for sulphur atoms to have Ge neighbours. We expect a strong effect of the nearest neighbours mostly for the deep, highly localised ground state. The strong shift of the ground state energy between Si and Ge ambience should manifest itself here. Since we do not observe it, we may conclude thus that S in our samples is surrounded almost exclusively by Si atoms and it feels the presence of Ge only via potential fluctuations caused by far distant Ge. A natural explanation for this observation is the existence of Ge clusters of high Ge content which, however, do not contain S donors at sizeable numbers. All our findings thus point to strong, non-statistical fluctuations in the alloy distribution.

The new assignment of hyperfine parameters for deep defects in diamond

U. Gerstmann*, H. Overhof

AG Theoretical Physics, Physics Department, University of Paderborn, D-33095 Paderborn, Germany

Abstract

Hyperfine (hf) parameters calculated for the vacancy in diamond show deviations from the experimental data, that have been ascribed to the neglect of lattice relaxations. Extending the formalism to include lattice relaxations we have removed the discrepancies for the interactions with the nearest neighbor ligand nuclei. However, the disagreement for the interactions with the next neighbor shell apparently increased thereby. Extending our calculations to include all ligands up to the fifth shell we show that the hf interaction assigned to the next nearest neighbor shell at (2 2 0) must be reassigned to the (3 3 1) ligand shell instead. The same reassignment holds for substitutional Ni defects in diamond and for several deep donors in silicon, but apparently not for the silicon vacancy in SiC. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: LSDA; Hyperfine interactions; Diamond; SiC

1. Introduction

The local spin density approximation of the density-functional theory (LSDA-DFT), most successful in determining the ground state properties of deep defects in semiconductors, can be applied to excited states as well, if these differ in symmetry from the ground state [1]. Total energies and hyperfine (hf) interactions for the 5A_2 excited state of the neutral vacancy in diamond show a similar accuracy as results for the 4A_2 ground state of the negatively charged vacancy [2]. The significant deviations of calculated hyperfine parameters assigned to interactions with the nearest and next nearest ^{13}C neighbor nuclei from the experimental data [3,4] have been ascribed to the neglect of lattice relaxations, as hf interactions probe the magnetization density at the nuclei, which certainly will be affected by lattice relaxations.

Several calculations show that for the neutral vacancy in diamond, there are only small deviations from a breathing mode relaxation, but the direction of this breathing relaxation is still controversial: Li and Low-

ther [5] report a 10% inward relaxation, Breuer and Briddon [6] obtain a 13% outward relaxation, whereas according to Zywietz et al. [7] and Messmer et al. [8] the outward relaxation is only about 7%.

To reinvestigate the influence of the lattice relaxation, we have included lattice relaxations into the calculation of hf interactions. We obtain an outward relaxation of 7% for the nearest neighbors. While this relaxation removes the discrepancies of the hf interactions with the nearest neighbor ligands, it even increases the disagreement observed for the interactions with the next shell of ligands observed experimentally. Extending our calculations to the fifth shell of ligands, we show that the hf interaction commonly assigned to the next nearest neighbors at (2 2 0) must be reassigned to the (3 3 1) ligand shell instead. A similar reassignment is necessary for substitutional Ni defects in diamond and for several deep donors in silicon, but certainly not for the silicon vacancy in SiC.

2. Computational

Reliable magnetization densities near the ligand nuclei are obtained by the linear muffin-tin orbitals method in

the atomic-spheres approximation (LMTO-ASA) [9]. In a Green's function approach, the problem of an isolated impurity in an otherwise perfect crystal separates into two parts. The Green's function $g^0(E)$ of the perfect crystal is constructed first. The Green's function $g(E)$ of the impurity problem is obtained from g^0 solving the Dyson equation

$$[1 + g^0(E)(\Delta P(E) - \Delta S)]g(E) = g^0(E). \quad (1)$$

Here $\Delta P = P - P^0$ is the perturbation of the potential function by the impurity while the matrix $\Delta S = S - S^0$ is the relaxation-induced change of the LMTO-ASA structure constants. Assuming $\Delta S = 0$ minimizes the size of the matrices and optimizes the performance of the numerical calculations, but is equivalent to a neglect of lattice relaxations.

In this work, we take into account the relaxation-induced changes of the structure constants ΔS in a next nearest neighbor approximation. We demonstrate the accuracy of the relaxation obtained from Eq. (1), taking the silicon vacancy in 3C-SiC as an example.

In all charge states the silicon vacancy in SiC is known to have T_d symmetry with a slight outward relaxation of the nearest neighbors. This is due to the small overlap of the strongly localized carbon dangling bonds [7]. Thus, pairing effects which could lead to Jahn-Teller distortions are rather small. Therefore, this defect is a perfect

example to compare the results of the extended Green's function method with results from supercell approaches (FHI96-MD [10,11], SCC-DFTB [12,13]). The relaxations of the nearest neighbor atoms calculated within our approach (Fig. 1) are slightly smaller than those predicted from first-principle supercell calculations [7,10]. Note that the different methods predict a similar dependence of the relaxation on the charge state of the defect.

For the negative silicon vacancy, experimental EPR data give similar ligand hf interactions for different SiC polytypes [14]. As shown in Table 1, the 6.1% outward relaxation of the nearest ^{13}C neighbor atoms obtained from our calculation removes the discrepancies between theory and experiment, reducing the isotropic hf parameter from 63.47 to 48.71 MHz — nearly the experimental value of 46.90 MHz (see Table 1). This gives us confidence to use the Green's function LMTO-ASA approach to calculate nearest neighbor relaxations for similar defects as well.

3. The vacancy in diamond

According to previous calculations [7,15], the relaxation of the next nearest neighbors of the vacancy in diamond is very small (<1% inward). We, therefore, shall discuss nearest neighbor breathing displacements exclusively. Furthermore, the states for which EPR spectra are reported are not subject to Jahn-Teller distortions.

Applying the LMTO-ASA Green's function method to all charge states of the vacancy in diamond we obtain the relaxations shown in Fig. 2. The breathing relaxation decreases from 11.5% outward relaxation for V^{2-} to 4.5% inward for V^{4-} . This is not compatible with results from supercell calculations: these predict quite different (8% [10,11] and about 4% [12,13]) outward relaxations that virtually do not depend on the charge state of the vacancy (see Fig. 2). Experimental EPR data with resolved ligand hf interactions are available for two different charge states, the neutral and the negative state. Fortunately both states, the 4A_2 ground state of V^- and the 5A_2 excited state of V^0 , are neither affected by Jahn-

The result of a cluster calculation with a model potential [5] is denoted by an asterisk (*). Note that local density theory yields the ground state configurations for the charge states +2, −1, and −4 only.

Teller distortions nor by configuration interactions, since there are no further $a_1^0 t_2^2$ configurations that could be admixed to the orbital singlet states (see also Ref. [2,6]). This offers the possibility to check the LSDA spin densities for different atomic configurations against experimental ligand hf interaction data, and thereby to compare the consequences of the lattice relaxations predicted by different methods.

To this aim, we have calculated the hf parameters for the relaxed geometries predicted by our total energy calculations and by different supercell calculations. For

the 4A_2 state of the negative vacancy, the FHI-code leads to a relaxation of 7.8% [7,10]. This corresponds to an isotropic hf interaction of about 70 MHz, significantly less than the experimental value (101.7 MHz) with a deviation that is comparable in magnitude to the error found for the unrelaxed structure. In contrast, in this case the SCC-DFTB calculation [12] gives a geometry that leads to hf interactions (100.7 MHz) that are close to the experimental values. However, the SCC-DFTB calculations predict for the 5A_2 excited state a 3.8% outward relaxation, for which we obtain the isotropic hf value of 73.5 MHz, appreciably larger than the experimental value of 53.7 MHz.

The results of our present Green's function approach simultaneously explain the hf splittings due to the nearest neighbor ^{13}C ligands for both charge states as shown in Table 2. Predicted outward relaxations of 6.7% and 3.6% for the excited neutral and for the negative charge state of the vacancy, respectively, remove most of the discrepancies with the experimental data (see also Table 2).

This result can also be understood following a simple method for estimating the geometric structure of atoms from the hybridization ratio [18], as already used by van Wyk et al. [4]. From the hf parameters of the two defect states which differ by a factor of two, these authors estimate that for the neutral vacancy the displacement of the nearest neighbors must be 50% stronger than for the 4A_2 ground state of the negatively charged vacancy.

In contrast to the results for the nearest neighbors, the disagreement observed for the experimental data commonly assigned to the next nearest neighbor (2 2 0) shell increases if we include the lattice relaxations. Since, as mentioned above, the displacements of these atoms are

negligible, these discrepancies cannot be explained by our limitation of the lattice relaxation to the nearest neighbors. Comparing the experimental hf interactions with calculated results for shells which belong to the class of the (220) shell, we find satisfactory agreement for both the isotropic and the anisotropic interactions for the 5A_2 state as well as for the 4A_2 state, if we assign the experimental data to the (331) shell in both cases.

A closer look at Table 2 shows the same reassignment to hold for substitutional Ni defects in diamond as well. Here, the main argument against the (220) assignment comes from the fact that the experimental anisotropic hf interaction is nearly axial. We note in passing that with similar arguments, it can be shown that a comparable reassignment of the ligand hf interactions should be made for deep substitutional donors in silicon, but certainly not for the silicon vacancy in SiC, as can be seen in Table 1.

Acknowledgements

We are grateful to Eva Rauls and Balint Aradi for helpful discussions and for providing us with their unpublished results from numerous supercell calculations. Additionally, it is a pleasure to acknowledge financial support from the Deutsche Forschungsgemeinschaft (DFG) for this work.

Transition metals in diamond: Do chemical trends arise from ab initio calculations?

Karl Johnston*, Alison Mainwood

Department of Physics, King's College, London, Strand, London, WC2R 2LS, UK

Abstract

The stability of transition metals as point defects in diamond is examined. Several impurities that have not been seen in diamond are modelled to understand whether they could be present, but are as yet, undetected. We model their solubility characteristics such as solvation enthalpies and entropies. The results indicate that the most likely transition metal impurities in diamond will be from metals with the greatest d-character. The most stable impurity is predicted to be nickel, in agreement with experimental work on these defects. The calculations also give credence to some of the models that have been proposed for these defects, in particular, that semi-divacancy defects relieve the strain imposed by these large impurity atoms. © 2001 Elsevier Science B.V. Keywords: Transition metals; Diamond; Stability

1. Introduction

The most common defects in diamond are either intrinsic or are those elements close to carbon in the periodic table such as N and B. Transition metals are an exception to this. The main reason for interest in them comes from synthetic samples where transition metals are used as solvent catalysts for the controlled production of industrial diamond. Synthetic stones now make up over 90% of the industrial diamond market [1]. One of the side effects of using metals in this way is that they become incorporated in the grown diamond as point defects; however, interestingly only two—Co and Ni—of the many used appear to form defects [2]. They have been identified unambiguously using optical and paramagnetic methods; the hyperfine information from EPR proving to be invaluable in the identification of the chemical species of the impurity [3,4]. There are three dominant lattice sites which are associated with these defects: interstitial, substitutional and “semi-divacancy” [4,5]. In a bid to answer some of the questions about which metals could form defects, we model the solvation enthalpy and entropy of transition metals impurities in

diamond. This helps us to gain an insight into the likelihood of more defects being identified.

In this study, we examine the metals that are most commonly used for the synthesis of diamond—iron, nickel and cobalt—and several on the first transition series, which are rarer—vanadium, manganese and copper. Because of the lack of a reliable pseudopotential for chromium, the full series cannot be modelled, but there will still be enough data to observe trends.

2. Method

The computer program AIMPRO [6] has been used to model many defect systems in a wide variety of materials. The typical clusters employed in this study were of 150 atoms, of which 70–90 were host/impurity atoms. Norm-conserving pseudopotentials for the carbon and metal atoms were used as derived by Bachelet et al. [7]. The metal atom was inserted in the centre of a cluster based around the site in question: substitutional, interstitial or semi-divacancy. The electronic wave functions were expanded in s- and p-Gaussian orbitals, centred on the nuclei, with the electron charge density fitted in the same way. These structures were then

*Corresponding author. Fax: +44-20-7848-2420.

E-mail address: karl.johnston@kcl.ac.uk (K. Johnston).

relaxed by first finding a self-consistent energy, then calculating the forces, and relaxing the system using a conjugate gradient function until an equilibrium point is reached. The runs have been repeated for clusters of varying sizes to see if the results obtained are size-independent; the typical variation is only of 1–2%. Vibrational properties of a defect centre can be obtained by diagonalising a dynamical matrix generated from the double derivatives of the total energy as described in Ref. [6]. These have an accuracy of about 10% although results are more unreliable close to the Raman frequency.

3. Stability of transition metals in diamond

The method that we use is primarily based on that of Mainwood and Stoneham [8]. Estimating the stability of the metal in the diamond requires dealing with several quantities: solvation enthalpies and entropies and long-range strain. The solvation enthalpy of a metal–carbon solution is estimated by using a similar Born–Haber relation to the one that appears in Ref. [8]:

$$E_{\text{Tot}}(MC_{n-x}) - E_{\text{Tot}}(C_n) - E_{\text{coh}}(M), \quad (1)$$

where $E_{\text{Tot}}(MC_{n-x})$ is the total energy of the cluster containing the metal; $E_{\text{Tot}}(C_n)$ is the total energy of the “pure” diamond and $E_{\text{coh}}(M)$ is the cohesive energy of the metal which is taken from the values given by Kittel [9]. This assumes that the transition metal is dissolved from the metal. The transition metal impurity will introduce strain into the lattice. This strain will effectively extend beyond the range of the cluster. Continuum elastic theory [10] predicts that this strain will fall off as the cube of the distance from the impurity. To estimate the strain, we use the technique of Safonov et al. [11]. This relates the strain components e_{ij} at a point (x_1, x_2, x_3) a distance, r , away as

$$e_{ij} = Ar^{-3}(\delta_{ij} - 3x_i x_j / r^2), \quad (2)$$

where δ_{ij} is the Kronecker delta. A is an elastic mismatch parameter. The total strain energy per unit volume is then given by Nye [12] as

$$\delta_{ij} = \frac{1}{2} \sum_{ij} c_{ij} e_i e_j, \quad (3)$$

where c_{ij} are the elastic moduli of diamond [13]. The long-range strain energy is shown for the various types of defects in Fig. 1. We see that, for the majority of metals, the strain is similar. However, there are some points to note. Generally, the semi-divacancy exhibits the lowest strain, supporting an intuitive feeling that moving a large substitutional atom to a semi-divacancy site should relieve strain in the lattice. This is most obvious for the copper impurity, where the substitutional impurity has very high strain whereas the

Fig. 1. The elastic strain energies for the various impurities under consideration in this paper. The divacancy impurity has generally the lowest long-range strain, in agreement with theoretical approaches describing the formation of this defect.

Cu	3.49

^a Values taken from Ref. [3] (Kittel).

transition to the divacancy results in considerably less strain.

The next component that describes the solubility is the solvation entropy. The main contribution to this is the vibrations of the atoms. In the case of a cluster, this means calculating the local vibrational modes due to the impurity have to be calculated, as described in Born and Huang [14], from which the solvation entropy is given by [8]

$$S_v = -k \ln \left\{ \frac{\prod_{i=1}^n v_{li}}{\prod_{i=1}^n v_{0i}} \right\}, \quad (4)$$

where v_{li} are the vibrations with the impurity present and v_{0i} when it is absent. The values of the contributions to the vibrational entropy are shown in Tables 1 and 2. When we take these in addition to the enthalpies, we arrive at an estimate for the Gibbs' free energy:

$$\Delta G = \Delta H - T \Delta S, \quad (5)$$

where ΔH is the change in enthalpy, and ΔS , that of entropy.

The results are shown in Figs. 2–4. It is clear from these figures that the impurities most likely to be found

in the diamond are those of increasing d-character. Nickel is predicted to be the most stable metal impurity in diamond, in agreement with experimental observation, where the vast majority of the work has been on identifying this metal in the various lattice sites mentioned in the introduction. The second most likely impurity is cobalt, which is also found experimentally. From the graphs, it would also appear that copper—admittedly a rarely used catalyst—would be a likely defect; in silicon, it is widely known as fast diffuser [15]. However, when we refer back to Fig. 1, the considerable

Fig. 4. The stability of the substitutional metal in diamond.

Fig. 5. The atomic radii of the metals under consideration. There is a definite similarity to the trend observed in the interstitial atoms.

long-range strain that is introduced, reduces this likelihood for the substitutional and interstitial impurities, although not for the divacancy case. This supports a recent paper by Baker [7], which re-evaluates the EPR W36 centre in terms of its origin from a semi-divacancy copper defect. Intriguingly, iron does not appear to be very stable in diamond. Iron is an efficient solvent for graphite. As a result, almost all the solvent catalysts used to grow in diamond are iron alloys. Its non-stability as a point defect in diamond is therefore, surprising, although it is worth noting that no point defects containing iron have been unambiguously

identified in synthetic diamonds grown with iron or iron-alloy solvent catalysts. The interstitial metal results bear a strong resemblance to the atomic radii of the metals, as shown in Fig. 5. As this impurity does not bond to the lattice, it is the most similar to the unaffected metal in the diamond lattice, a fact borne out by the stability results.

Annealing of monovacancies in electron and γ -irradiated diamonds

S. Dannefaer*, A. Pu, V. Avalos, D. Kerr

Department of Physics, University of Winnipeg, 515 Portage Avenue, Winnipeg, MB, Manitoba, Canada, R3B 2E9

Abstract

Diamonds were irradiated by either 2.3 MeV electrons or by ^{60}Co γ -rays. In the case of electron irradiation, positron annihilation and optical absorption showed that 30–35% of the monovacancies (positron lifetime of 145 ps) were removed by interstitials between 700 and 1020 K. Above 1020 K, divacancies were formed giving rise to TH5 optical absorption and a positron lifetime of 185 ps. Above 1120 K, TH5 absorption was replaced by absorption at 507/517 nm, but no change in the positron lifetime was observed. Annealing of the γ -irradiated type Ib diamonds differed substantially from that for the electron irradiated samples; 60% of the monovacancies were removed between 350 and 525 K. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Diamond; Vacancies; Annealing; Positron annihilation

1. Introduction

The purpose of this work is to investigate the mechanisms by which irradiation-produced monovacancies anneal out upon heat-treatment. Monovacancies were introduced either by 2.3 MeV electron irradiation or by ^{60}Co irradiation, where the latter type of irradiation causes damage due to Compton scattered electrons with a maximum energy of only 1.1 MeV. It will be shown that the annealing behaviour of monovacancies differs significantly between these two irradiation conditions.

2. Experimental

In Section 2.1 details of the samples and irradiations are given and in Section 2.2, a brief introduction to positron annihilation.

2.1. Experimental details

Two type IIa natural diamonds were electron irradiated by 2.3 MeV electrons to a dose of

$1.4 \times 10^{18} \text{ cm}^{-2}$ over a time period of 14 h at 281 K after which the positron source was sandwiched between the samples. The two ^{60}Co γ -irradiated samples were type Ib synthetic diamonds with a substitutional nitrogen concentration of 90 ppm. They were irradiated to an absorbed dose of 6 MGy (H_2O) accumulated during 7 days of irradiation at 300–350 K. Isochronal annealing (1/2 h) was done in air up to 700 K, while above this temperature a protective atmosphere of Ar was used.

Positron experiments were done with a lifetime spectrometer with a full-width at half-maximum of 170–175 ps and Doppler spectra were measured with an energy resolution of 1.2 keV. Data analysis was based on spectra containing $(6\text{--}10) \times 10^6$ counts. Optical measurements were done at 80 K in the wavelength range of 220–1100 nm.

2.2. Positron annihilation

In this work two positron techniques were used, lifetime spectroscopy and Doppler broadening. In the first technique vacancies are detected because positron trapped by vacancies have a longer lifetime than in the untrapped state (bulk) due to the smaller electron density in vacancies. In Doppler broadening experiments the electron momentum distribution is measured, and trapping by vacancies causes the positron to

annihilate with electrons with a narrower momentum distribution than in the bulk: The so-called *S* parameter is designed to give a quantitative measure for this narrowing.

The rate by which positrons are trapped by vacancies (the so-called trapping rate) is linearly dependent on their concentration. In lifetime spectra this causes an increase in the intensity of the lifetime arising from the trapping, and for the *S* parameter in an increase in its value; a more detailed account of positron annihilation can be found in Ref. [1].

3. Results and discussion

The results for the electron irradiated samples are presented in Section 3.1 and those obtained for the γ -irradiated samples in Section 3.2.

3.1. Electron irradiation

Optical absorption of six zero-phonon lines were measured as a function of annealing temperature. The six lines were: 741 (GR1, arising from neutral monovacancies), 488 (TH5), 507 (M1), 517 (M2), 595, and 610 nm. The two latter lines were weak compared to the other lines and will not be considered further; the identifiers given in the parentheses originate from optical works. The four main optical absorption lines were quantified by integration over a 10 nm wide range centered at each line after a linear background subtraction for each of the lines. Fig. 1 shows the integrated absorption normalized to the maximum value for each of the four lines; the integrated absorptions of the 507/517 nm lines were identical.

Absorption due to neutral monovacancies (GR1) decreases by 30% up to 1020 K, with a hint of a 'stage' close to 820 K. The main annealing stage above 1020 K is accompanied by an increase in the 488 nm line (TH5) and during its subsequent decrease above 1110 K the 507/517 lines grow in, although faintly present already above 1000 K. It is noteworthy that the maximum value of the absorption of the 488 nm line equals, to within 10%, the sum of the maximum values for the 507/517 nm lines. This indicates that these three lines are closely related.

Positron lifetime results are presented in Fig. 2. Panel (a) shows that the irradiation-produced lifetime of 145 ± 3 for positrons trapped by monovacancies [1] is constant up to 1020 K. Above 1020 K the lifetime increases and levels off at 185 ± 3 ps, which shows that vacancy agglomeration occurs during the decrease in GR1 absorption.

In Fig. 2b is shown the fraction remaining of the trapping rate, i.e. its value at any of the annealing temperatures divided by its value before annealing.

Fig. 1. Normalized optical absorption as a function of isochronal annealing temperature for electron irradiated samples. Panel (a) depicts that for GR1 and panel (b) for 488 (TH5) and 507 nm (M1); absorption at 517 nm (M2) is identical to that for 507 nm. Curves in panel (b) are merely guides to the eye.

Fig. 2. Positron lifetime results obtained at 293 K as a function of isochronal annealing temperature for electron irradiated samples. Panel (a) shows the irradiation-produced lifetime and panel (b) the normalized trapping rate.

The fraction remaining of the trapping rate and the fraction remaining of GR1 decreased by the same amount up to 1020 K (30–35%), and since there was no evidence for vacancy agglomeration according to the

lifetime results (Fig. 2a), we conclude that monovacancies are removed due to migration of interstitials. Hunt et al. [2] have recently ascribed a 10% decrease in monovacancy concentration due to recombination with single (split) interstitials. This took place upon annealing to 750 K and is consistent with the decrease in GR1 absorption at 820 K observed in this work. However, interstitials with higher thermal stability are required for the further 20–25% reduction in monovacancy concentration up to 1020 K: This leaves 65–70% of the interstitials unaccounted for.

Above the annealing temperature of 1020 K, vacancy agglomeration is most likely due to creation of divacancies in view of theoretical calculations of the positron lifetime for divacancies [3] and of the emergence of the 488 nm line (TH5) and by the EPR signal (R4/W6) for divacancies [4].

The positron experiments show that the 507/517 nm lines are also associated with divacancies, since the positron lifetime did not vary during the changes in the absorption at 488/507/517 nm. Furthermore, the observation that the positron trapping rate (Fig. 2b) is constant throughout the changes in these lines (Fig. 1b) shows that divacancies are not lost during these processes.

Importantly, this implies that interstitials do not remove vacancies above 1020 K, and thus raises the question of where the remaining 65–70% of the interstitials went? An explanation could be that these interstitials were removed during irradiation by dislocations as well as by the large vacancy clusters commonly observed by positrons [1].

In summary, divacancies are confirmed to be created by monovacancy migration above 1020 K and we suggest that the 507/517 nm lines are associated with 'high' temperature forms of the divacancy.

3.2. γ irradiation

To further investigate the fate of interstitials, type Ib synthetic diamonds were irradiated with ^{60}Co γ -rays (1.13 and 1.3 MeV) to create monovacancies due to Compton scattered electrons of a maximum energy of 1.1 MeV. The idea is that such irradiation would create close vacancy–interstitial pairs (Frenkel pairs) which would curtail removal of interstitials by other defects, and consequently exhibit a different annealing behaviour than that arising from 2.3 MeV electron irradiation.

It should be pointed out that the γ -irradiated diamonds were of type Ib so monovacancies would be negatively charged and no absorption due to neutral monovacancies (GR1) was observed. Absorption from the negatively charged monovacancies, however, could not be observed due to the strong absorption from substitutional nitrogen.

Positron results are shown in Fig. 3 and display notable differences compared to the 2.3 MeV electron irradiated samples. According to panel (a) the radiation-produced vacancies give rise to a positron lifetime of 130 ± 3 ps, some 15 ps shorter than for the previous samples. The normalized trapping rate is shown in panel (b) of Fig. 3. It is remarkable that annealing of vacancies takes place at much lower temperatures than for the 2.3 MeV electron irradiated samples (cf. Fig. 2b). Another remarkable observation comes from the low temperature Doppler S parameter measurements between 8 and 300 K shown in Fig. 4. Negatively charged monovacancies should normally result in a strong decrease in the S parameter with increasing temperature, but here S is seen to increase slightly with temperature.

The defect inventory created by γ irradiation is quite different from that for 2.3 MeV electrons, and we

Fig. 3. Irradiation produced lifetime (panel (a)) and normalized trapping rate (panel (b)) for the γ -irradiated samples, as a function of annealing temperature. Measurements were made at 293 K.

Fig. 4. S parameter as a function of measurement temperature for the γ -irradiated samples.

suggest that close vacancy–interstitial pairs $V I^+$ (Frenkel pairs) are created by γ radiation. This suggestion explains the low temperature annealing of the vacancies and the overall neutral charge of the Frenkel pair would account for the behaviour of the S parameter, while at the same time explain why no GR1 absorption is observed. Further experiments on γ -irradiated synthetic type IIa and type IIb diamonds are in progress.

4. Conclusion

Positron experiments confirm the association of the optical absorption line TH5 with the divacancy, and suggest that the absorption lines at 507 and 517 nm (M1 and M2, respectively) are also due to divacancies.

Damage arising from ^{60}Co γ irradiation, i.e. by electrons of maximum energy of 1.1 MeV, is suggested to be in the form of close vacancy–interstitial pairs with an overall neutral charge and stable only up to ~ 400 K.

Acknowledgements

We are indebted to Mr. C. Hunter, MDS Nordion Canada, for graciously providing the γ irradiations, to Dr. Uedono, Tsukuba, Japan for the type Ib diamonds, and to GIA, USA for the type IIa diamonds. This research was financially supported by the Natural Sciences and Engineering Council of Canada.

Abstract

Optical absorption, interference and microscopy studies of diamond samples implanted with light ions (H^+ , D^+ and He^+) and annealed at various regimes revealed new features of irradiation induced graphitisation of diamond: the “low temperature” graphitisation directly related to vacancies, the specific mechanism of graphitisation accompanied by blistering in H^+ implanted samples and high temperature graphitisation stimulated by residual radiation damage. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Diamond; Ion implantation; Graphitisation

1. Introduction

Due to metastability of diamond (under ambient conditions the stable phase of crystalline carbon is graphite) it tends to transform to graphite under heat treatment and/or irradiation [1,2]. This puts a severe limitation on ion implantation doping. On the other hand ion-beam induced graphitisation opens new prospects of defect engineering [3].

In this paper we present the results of studies of formation of graphitised layers in diamond under various conditions of implantation with H^+ , D^+ and He^+ ions and annealing. The use of the light ions offers some advantage over heavier ions since the former produce buried graphitised layers at a considerable (~ 1000 nm) depth, which is essential for applications. It is shown that the phenomenon of radiation-induced graphitisation is more complicated than it was previously anticipated. Of particular interest are the data referring to implantation with hydrogen, which reveal a specific role of hydrogen in “conservation” of radiation damage.

2. Experimental

Polished (110) samples of IIa or intermediate (IIa–Ia) natural diamond were bombarded at room temperature by 350 keV H^+ , D^+ and He^+ ions with doses in the range $2\text{--}12 \times 10^{16} \text{ cm}^{-2}$. Implanted areas 0.75×1.75 mm in size were specified by masks. Annealing was performed at temperatures up to 1700°C in a graphite furnace. The formation of the graphitised layers was monitored by optical absorption, interference and microscopy.

3. Results

3.1. Radiation damage and graphitisation

In the case of implantation of light ions it can be thought that the radiation damage consists mainly of vacancies and interstitials. The latter are annealed at temperatures well below those characteristic of the process of graphitisation, which is thus determined by the amount and spatial distribution of vacancies.

In Fig. 1 the spatial distributions of implanted species and radiation damage (vacancies) calculated by Monte Carlo simulation are shown for the dose $3 \times 10^{16} \text{ cm}^{-2}$ of 350 keV H^+ , D^+ and He^+ ions. It is seen that the

Fig. 1. Spatial distribution in diamond of the implanted species and radiation damage calculated by Monte Carlo simulation.

amount of radiation damage decreases with the decrease of ion mass (at the energy of 350 keV, the number of vacancies produced per implanted ion is 56, 12 and 5 for He^+ , D^+ and H^+ , respectively). According to the simple model there must be direct correlation between these numbers and corresponding critical doses for graphitisation. However, our studies have shown that this simple suggestion does not work, partly due to the interaction of radiation defects with each other and with implanted or background impurities neglected by Monte Carlo simulation.

3.2. D^+ and He^+ implantation

We have found much similarity between the data referring to D^+ and He^+ implantation, with proper dose scaling factor. That is why we concentrate on the results for D^+ implantation all the more because they are of particular interest in comparison with those for H^+ .

In Fig. 2 optical density spectra of diamond are shown for various conditions of implantation and annealing. It is seen that absorption of implanted samples (before annealing) is dominated by two broad bands at 600 and 290 nm. These bands (at room temperature) refer, respectively, to the GR1 and GR2-8 optical systems produced by neutral isolated vacancies [4]. In all D^+ and He^+ implanted samples the vacancy absorption bands practically disappear after annealing at 780°C.

In the samples implanted with $6\text{--}12 \times 10^{16} \text{ cm}^{-2}$ of D^+ ions, the disappearance of the vacancy absorption after annealing at 780°C and higher temperatures is accompanied by emergence of interference. This indicates that in the depth of the crystal a layer is formed (with is quite smooth judging from the great number of periods of the interference) with optical parameters different from those of the bulk material. Absorption spectra (after subtraction of the interference) are very

Fig. 2. Optical density spectra of diamond samples for various conditions of D^+ implantation and annealing.

similar to those of highly oriented pyrolytic graphite [5,6]. Basing upon these data combined with the sharp increase of conductivity of the buried layer at these conditions we can state that the graphitised layer is formed in the depth of implanted diamond and vacancies play the dominant role in its formation.

The depth of the layer determined from the analysis of the interference data does not change up to the annealing temperature 1460°C and decreases slightly with the increase of the dose: $1774 \pm 4 \text{ nm}$ for $6 \times 10^{16} \text{ cm}^{-2}$ and $1665 \pm 4 \text{ nm}$ for $12 \times 10^{16} \text{ cm}^{-2}$. These values are in satisfactory agreement with the data inferred from Fig. 1 though the discrepancy between the experiment and the theory is conspicuously worse than in the case of heavier ions.

In the annealing temperatures range 1460–1600°C, the layer increases in thickness but remains quite smooth. At 1660°C its optical density increases sharply and the interference disappears. In the microphoto of the sample it is seen that the graphitised layer is no longer smooth due to the growth in the “vertical” direction. At 1700°C the expanding graphitised layer reaches the surface of the sample. The graphitisation spreads also laterally from the boundary of the implanted areas into the undamaged part of the crystal. There are some points within this part where graphitisation starts without any stimulation by external agents.

Our results on D^+ implantation with doses $6\text{--}12 \times 10^{16} \text{ cm}^{-2}$ (as well as those for heavier ions with properly scaled doses) suggest that we deal with two different mechanisms of graphitisation: “low temperature” graphitisation starting at $\sim 800^\circ\text{C}$ and stimulated by vacancies and “high temperature” graphitisation in the range 1460–1700°C which is the combination of the process stimulated by the already (at lower temperatures) formed graphite phase and/or some residual defects and the spontaneous process dominating at 1660–1700°C without any evident external agents.

3.3. H^+ implantation

The results for H^+ implantation are quite different from those presented in 3.2 for D^+ . First of all, for the whole range of doses $2\text{--}12 \times 10^{16} \text{ cm}^{-2}$ no graphitization is observed after the annealing at 780°C , while vacancy related absorption disappears, just like in the case of D^+ implantation. Optical absorption due to residual radiation damage decreases with the increase of annealing temperature.

In samples implanted with H^+ doses 12, 10 and $8 \times 10^{16} \text{ cm}^{-2}$, starting from annealing temperatures 780°C , 1120°C and 1350°C , respectively, weak interference is observed. At the annealing temperatures above 1460°C the amplitude of the interference increases sharply indicating the formation of a graphitised layer. In this case we observe quite a peculiar kind of graphitisation accompanied by blistering, i. e. formation of bubbles filled with a gas (hydrogen). In Fig. 3 it is seen that the dark graphitised layer is broken into islands with dimensions $10\text{--}50 \mu\text{m}$ separated by light colored ungraphitised areas. The bubbles $\sim 100 \mu\text{m}$ in size are clearly seen. One of them (in the low right corner of the figure) is broken, its upper part has gone forming a pit with boundaries oriented along crystallographic axes. The phenomenon of blistering in diamond is similar to the one well known for silicon [7]. The implanted hydrogen atoms form relatively stable associations with radiation defects (passivation) immediately after implantation or at early stages of annealing. At the annealing temperatures higher than 1460°C these associations are broken providing both the lattice defects and free hydrogen atoms. The former stimulate the process of graphitisation while the latter can at these temperatures diffuse and form in the disordered layer (and only in this layer) the hydrogen filled bubbles of a

peculiar shape with lateral dimensions two order of magnitude larger than the thickness. Nonuniformity of the graphitised layer and the presence of the bubbles do not allow quantitative measurements of optical absorption. However the interference is quite strong and well resolved, this means that the graphite islands are all at the same depth, which can be accurately determined. This depth for H^+ implanted samples (1870 nm) is predictably higher than that for D^+ implantation (1770 nm) with the same ($\sim 15\%$) relative deviation from the data of theory.

4. Discussion

Among the results of the present work which need to be discussed is the difference in characteristics between the graphitisation processes induced by implantation of D^+ and H^+ . In the first case we observed the “low temperature” ($\sim 800^\circ\text{C}$) mode of graphitization which can be directly related to vacancies. On the other hand, in H^+ implanted samples this stage is absent, the graphitization is observed starting from the annealing temperature 1460°C and is accompanied by blistering.

Bearing in mind chemical identity of H and D (and consequently their ability to passivate lattice defects) it looks strange at first sight that there is no blistering in the case of D^+ implantation and no low temperature stage for H^+ implantation. The explanation might be in different amount of radiation damage produced by H^+ and D^+ (5 and 12 vacancies per ion, respectively, according to the Monte Carlo simulation data). With all the limitations of these estimates, with the lack of data referring to initial ($T < 800^\circ\text{C}$) stages of annealing (in particular, to the proportion of vacancies annihilated with interstitials) we might cautionary suggest that the passivation effect is more pronounced for H^+ implantation. In this case considerable fraction of radiation damage which survives the initial stage of annealing is passivated by hydrogen, so the amount of “unpassivated” damage is not enough to stimulate the “low temperature” graphitisation. The passivated component of radiation damage is “stored” up to the annealing temperature needed to break the associations of hydrogen atoms with defects (and to start both graphitisation and blistering). On the other hand, in D^+ implanted samples the passivated fraction of radiation damage is considerably lower, so the unpassivated damage (vacancies) can stimulate the “low temperature” graphitisation which represents a drastic change of the structure of the material, so it is now hardly pertinent to speak in terms of disruption (at higher temperatures) of what used to be associations of deuterium atoms with defects in diamond lattice. The absence of deuterium blistering in this case can be attributed both to its lower (compared to

Fig. 3. Microphoto of island graphitization and blistering in the diamond sample implanted with $8 \times 10^{16} \text{ cm}^{-2}$ of H^+ and annealed at 1460°C .

hydrogen) diffusion coefficient in diamond and to its high solubility in graphite.

5. Conclusions

Our studies of graphitisation of diamond under various conditions of implantation and annealing have demonstrated that the process of graphitisation is more complicated than it was previously anticipated. Of particular interest are the “low temperature” graphitisation directly related to vacancies, the specific mechanism of graphitisation accompanied by blistering in H^+ implanted samples and high temperature graphitisation stimulated by residual radiation damage.

Abstract

Electron energy-loss spectroscopy (EELS) performed near dislocation cores is one of the few experimental techniques that can yield valuable information about the electronic levels associated with dislocations. In this study, using *ab initio* calculations, we model and predict low-loss and core-excitation EELS spectra acquired on various dislocation cores in silicon and diamond, and compare the results with bulk spectra. In diamond, we consider in particular 90° partial glide, undissociated 60° shuffle, and 30° partial dislocations. We find evidence of empty states localized on diamond shuffle dislocation cores and positioned below the bulk band edge, which modify the EELS spectrum. In silicon, we find changes—analogueous to those seen experimentally—in core-excitation EELS near stacking faults and partial glide dislocations. © 2001 Elsevier Science B.V. All rights reserved.

The presence of dislocations in semiconductor crystals can strongly influence the electrical and optical properties of the material. The growth of polycrystalline CVD diamond, in particular, generates high densities of dislocations (up to 10^{12} cm^{-2}), which originate in the substrate-interface region and can propagate throughout the thin film [1]. The influence of these structural defects on the electrical and optical properties of the material is determined essentially by the nature of the atom bonding at the dislocation core. The atomic structure of dislocations, and their dissociation into partials, has been widely studied experimentally in silicon and diamond by transmission electron microscopy [2,3]. However, this technique does not yield any information about the electronic structure of the dislocation core. Spatially resolved electron energy-loss

spectroscopy (EELS) performed near dislocation cores can in principle yield valuable information about electronic levels associated with dislocations, both within and above the band gap. Recent EELS experiments performed near dislocations in Si [2] and diamond [4] have shown differences from bulk regions, but there are still issues regarding their interpretation. Such information could prove crucial to help resolve whether any electrical or optical activity is associated with undecorated dislocations. In this study, we perform first-principles simulations of a variety of dislocation cores, and, by means of a simple model, we identify extended defect structures that lead to changes in EELS spectra compared with the bulk regions.

We perform self-consistent *ab initio* simulations of dislocations in Si and diamond crystals within the local density approximation (LDA) to density functional theory, using the recently enhanced AIMPRO code [5]. The wave functions are expanded in a set of *s*, *p*, and *d* atom-centered Gaussian orbitals. We use

pseudopotentials to describe the ion cores [6]. A single dislocation is placed within a hydrogen-terminated nano-crystal in a supercell, thus imposing perfect periodicity along the [110] dislocation core. The supercells contain between 60 and 160 atoms, and are fully relaxed to their equilibrium positions. Initial relaxations of the dislocation cores are performed using the self-consistent charge density functional tight-binding method [7], with clusters of up to 500 atoms. The dislocation cores are then further optimized with AIMPRO to obtain accurate band structures.

Low-loss EELS results from electronic transitions between the valence bands (VB) and the conduction bands (CB). The signal obtained experimentally is usually interpreted as being representative of $-\text{Im } \epsilon(E)^{-1}$, where $\epsilon = \epsilon_1 + i\epsilon_2$ is the dielectric function and E is the energy loss. We calculate the imaginary part of the dielectric function in the dipole approximation [8,9]:

$$\epsilon_2(E) = \frac{4\pi e^2}{\Omega} \sum_{c,k} |\langle \Psi_k^c | r | \Psi_k^v \rangle|^2 \delta(E_k^c - E_k^v - E), \quad (1)$$

where Ω is the unit cell volume, and $|\Psi_k^{v,c}\rangle$ are VB and CB states, with energies $E_k^{v,c}$, respectively. The real part of the dielectric function is obtained through a Kramers–Kronig (KK) transformation.

Core-excitation EELS results from electronic transitions between deep core states and the CB. In view of the localization of the initial state on an atom, core EELS spectra are related to an angular momentum projected local density of states on the atom. If the initial core state $|\Psi_k^i\rangle$ is s-like (as for the diamond K-edge), the core EELS spectrum from an atom at \mathbf{R} is proportional to a p -projected local density of states at \mathbf{R} , written symbolically as

$$I_R(E) = \sum_{c,k} |\langle \Psi_k^c | p_R | \Psi_k^i \rangle|^2 \delta(E_k^c - E_i - E), \quad (2)$$

where $E_i = E_a + \Delta V(\mathbf{R})$. E_i (E_a) is the core level for the solid (for the atom, respectively). To first-order perturbation, $\Delta V(\mathbf{R})$ is the difference in potential at the atomic core between the bulk and the atom. In Si, we find $\Delta V(\mathbf{R})$ varies by ± 0.15 eV near the dislocation, and, as a first approximation, we neglect it in the following. This level of theory makes no account of final state effects, which should in principle include interactions between the excited electron and the hole. However, as we show below, it allows a qualitative understanding of EELS spectra, and permits comparisons between bulk and defect regions to be made. The scissor operator is used to adjust calculated LDA band gaps to experimental ones. The Brillouin zone (BZ) integrations are performed using 1000–5300 k -points for bulk, and 50–150 k -points for supercells. Core EELS spectra are displayed with a Gaussian broadening of 0.4 eV for Si, and 0.8 eV for diamond. Low-loss EELS spectra are broadened

using a Lorentzian function, which conveniently allows an analytical KK transformation.

We start by considering the core-excitation EELS spectrum of bulk diamond, shown in Fig. 1, where we compare it with two experimental observations. Qualitative agreement between the computed and measured values is obtained and the peak positions are well described. Oscillations in the theoretical spectrum at high energies are calculational artifacts that result from convergence difficulties with the BZ integrations. Absorption seen experimentally below the band gap may be attributed primarily to surface effects, particularly for the experimental data acquired on diamond nano-crystals [11].

In Si and diamond, 60° glide dislocations dissociate into 30° and 90° partial dislocations [10,3]. These partial dislocations are believed to have reconstructed cores consisting entirely of four-fold co-ordinated atoms. In diamond, we have studied the low-loss and core-excitation EELS spectra of the undissociated 60° glide, as well as the 30° and 90° partial glide dislocations. A typical result for glide dislocations is shown in Fig. 2A, where we consider the lowest-energy form of the 90° partial, which possesses a double-period reconstruction along its core [10]. We find no evidence of gap states associated with the undecorated glide dislocations, and only small changes in the corresponding EELS spectra compared with bulk.

In diamond-structured semiconductors, the (111) planes of atoms are alternately separated by long and

Fig. 1. Theoretical K-edge EELS spectrum of bulk diamond (solid line), compared with experimental data on type-IIb diamond from Bruley and Batson [4] (crosses) and on diamond nano-crystals from Gutiérrez-Sosa, et al. at UMIST [11] (squares). The results are given in arbitrary units, and the energy zero is set at the conduction band minimum (CBM), where the curves have been aligned.

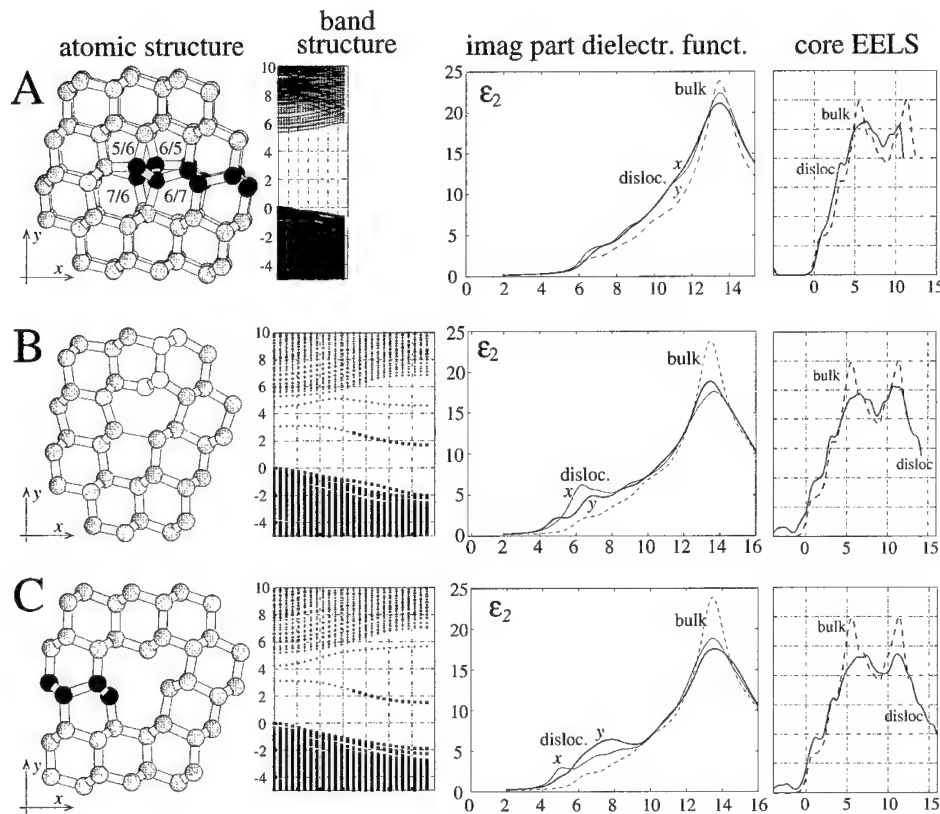

Fig. 2. Atomic structure, band structure along the dislocation core in the gap region, imaginary part of the dielectric function, and predicted K-edge EELS spectrum for a 90° glide partial dislocation with a double-period reconstruction (panel A), a 60° shuffle dislocation (panel B), and a 30° partial dislocation with an open core (panel C) in diamond. Lighter (darker) atoms indicate the stacking faults (inserted atoms, respectively). In view of the double-period reconstruction, the BZ of structure A is folded to half the thickness of those of structures B and C. In the band structures, squares indicate filled states and crosses indicate empty states of a neutral dislocation. The dielectric function is shown for incident beams polarized in the $[1\bar{1}\bar{2}]x$ (thin line) and $[1\bar{1}1]y$ (thick line) directions orthogonal to the dislocation axis. For core-excitation EELS spectra, the energy zero is set at the CBM. Energy scales are given in eV.

short distances. Shuffle dislocations differ from glide dislocations in that the removed half-plane of atoms terminates after a short, rather than a long, inter-plane separation. We have studied the undissociated 60° shuffle dislocation in diamond, shown in Fig. 2B, and its dissociation into 30° and 90° partials. Since shuffle dislocations can be obtained from glide dislocations by inserting (or equivalently removing) an extra row of atoms, several core structures of the dissociated shuffle dislocation are possible. One of these is shown in Fig. 2C, and corresponds to a 30° partial with an open core. This core structure could be obtained, for example, by the dissociation of Fig. 2B into Figs. 2A and C.

For diamond shuffle dislocations (Fig. 2B) and open-core partial dislocations (Fig. 2C), we find evidence of empty states localized on the dislocation cores below the conduction band edge. If core-excitation EELS is

performed on these dislocations, the empty gap states create supplementary absorption peaks below the conduction band minimum (CBM), which could account for the EELS experimental evidence [4]. Strong differences in the imaginary part of the dielectric function for the structures in Figs. 2B and C, compared with bulk regions, also lead to changes in the predicted low-loss EELS.

Turning to Si, we show in Fig. 3 the predicted EELS spectra acquired at an intrinsic stacking fault, at a 30° glide partial dislocation, and at a 90° glide partial dislocation with a double-period reconstruction. None of these defects possess deep gap levels. Experimental results of this kind have been obtained recently [2]. We note that there is a small predicted increase in the EELS spectrum around 0.5 eV above the CBM for the 90° partial, as also evidenced experimentally. The number

Fig. 3. Theoretical core-excitation EELS spectra for bulk, a 90° glide partial with a double-period (DP) reconstruction, a 30° glide partial, and an intrinsic stacking fault (ISF). These spectra are determined by averaging over core excitations calculated for several atoms bordering the defects. The energy zero is set at the CBM in each case.

and the positions of the first few peaks in the EELS spectra differ from one structure to the other, as also seen in the experiment. In view of the simple theoretical model used here, these results should be taken as a qualitative guide to the experimental observations.

In summary, we find that changes in the densities of empty states at shuffle dislocations create strong differences in both low-loss and core-excitation EELS of diamond. Reconstructed glide dislocations in dia-

mond, however, create only small differences in the EELS signal on and off the core. In silicon, similar small differences in core EELS are found near partial dislocations. Future developments of the theory, which are underway, will include accounting for the electron-hole interactions in core EELS.

The authors would like to thank A.Gutiérrez-Sosa, A.J. Harvey, and U. Bangert, for stimulating discussions and for providing experimental data on diamond.

The variation of optical absorption of CVD diamond as a function of temperature

Clara Piccirillo^{a,*}, Gordon Davies^a, Alison Mainwood^a, C.M. Penchina^{a,b}^a *Physics Department, King's College London, Strand, London WC2R 2LS, UK*^b *Department of Physics, University of Massachusetts, Amherst, MA 01003-4525, USA*

Abstract

The infrared absorption of CVD diamond films is reported as a function of temperature in both intrinsic and boron-doped samples. In pure diamond, because of the inversion symmetry of the lattice, there is no one-phonon IR absorption, but there are bands corresponding to the interaction of the photon with two or more phonons. We fit the measured temperature dependence of the absorption by including the Bose–Einstein factors for the two phonons involved at each energy.

The infrared absorption of boron was measured in the range 500–5000 cm⁻¹ between 14 and 630 K. We show that the temperature dependence of the absorption can be understood in terms of thermal ionisation and thermal transitions between electronic states. © 2001 Elsevier Science B.V. Keywords: Diamond; Boron; Infrared absorption; Phonons

1. Introduction

Pure diamond has negligible absorption for photons with energies below the band gap at 5.47 eV except for the region in the infrared between 1500 and 4000 cm⁻¹ (0.18–0.5 eV) at low temperatures. Absorption of a photon to produce a single phonon is forbidden by symmetry, but the creation of two or more phonons gives a weak absorption. This has been studied to try to determine the energies of the phonons at high symmetry points in the Brillouin zone [1–4]. In this paper we interpret the temperature dependence of the absorption in terms of the phonons which contribute.

If the symmetry of the lattice is broken by the addition of impurities or dopants, then some one-phonon absorption is allowed. This is well known for nitrogen, where the one-phonon absorption is used to determine the concentration of the nitrogen and its complexes [5]. For the only effective-mass-like acceptor, boron, an infrared spectrum in the range 500–5000 cm⁻¹ (0.06–0.62 eV) is observed. This spectrum consists not only of

a one-phonon peak, but also of absorption due to electronic excitations between bound states of the boron, ionisation of the boron and transitions of holes between valence band states [6–8], all of which vary strongly with temperature.

2. Experimental details

Absorption measurements were made using a Perkin Elmer 1720 Fourier transform spectrometer. The sample was mounted in an Oxford Instruments flow cryostat for measurements down to 14 K. Measurements up to 620 K were made in a custom made cell fitted with a resistive coil heater that was in contact with the copper sample holder. A heat shield reduced the emission from the hot sample stage that could be radiated to the detector. The samples were CVD diamond plates of at least 8 mm square, to decrease the effect of emission from the sample mount.

Surveys of the boron-containing samples were made at room temperature using a Nicolet FTIR coupled to a microscope stage. No inhomogeneities were detected in the spectra recorded through 25 μm square apertures, on

E-mail address: clara.piccirillo@kcl.ac.uk (C. Piccirillo).

a much smaller scale than the 3 mm diameter focus used for the temperature-dependent measurements. The samples were chosen so that the boron concentrations, determined by the calibration of Collins and Williams [9] from the absorption in the 2800 cm^{-1} absorption line, varied from $6.8 \pm 0.3 \times 10^{16}$ to $3.2 \pm 0.2 \times 10^{18}\text{ cm}^{-3}$. A pure sample of CVD diamond was used as a reference sample to remove the intrinsic absorption from the spectra.

3. Intrinsic absorption

Fig. 1 shows the intrinsic absorption at room temperature. The peaks identified in Ref. [4] are indicated. The two-phonon absorption in the range ~ 1400 – 2665 cm^{-1} sits on top of a very weak 3-phonon absorption, which has been removed in the analysis.

In order to conserve energy, the sum of the energies of the two phonons involved must equal the energy of the photon. To conserve momentum, the wave vectors of the two phonons must be equal and opposite, since the wave vector of a photon is negligible compared to that of the phonons. Two identical phonons cannot be created by a photon because that implies the creation of an electrical dipole, so two different branches of the phonon dispersion curves are required. The phonon dispersion curves for diamond (for example [10]) indicate that the energies at which one would expect high intensities are at the zone boundaries where there are large regions of k -space with phonons of near constant energy. In particular the zone boundaries at X, W, L and K show levelling out of at least some of the

phonon branches [10]. As examples of this, Vogelgesang et al. [4] have identified the prominent peaks labelled 9, 12 and 14 on Fig. 1 with transitions involving phonons at Σ along (110) branches, very close to K, and rather smaller features labelled 8 and 15 with the X and W points.

At higher temperatures the number of phonons created with energy E , varies as $(1 + n(E))$, where $n(E)$ is a Bose-Einstein factor. Hence, for any pair of phonons of energy E_1 and E_2 created by a photon of energy $(E_1 + E_2)$, the intensity of the absorption is proportional to [1]

$$(1 + n(E_1))(1 + n(E_2)). \quad (1)$$

Fig. 2 shows the absorption spectra at temperatures up to 598 K, showing a substantial increase in absorption at higher temperatures.

Using the identification of the phonons listed by Vogelgesang et al. [4], we have calculated the temperature dependence of the main features of the spectrum. Fig. 3 shows that several of the peaks, such as 3, 14 and 19, agree very well with experiment, but others, for example peaks 8, 9, and 12, do not. It is possible that the phonon branches involved in the absorption have been misidentified—for example reassigning the lower energy phonon involved in peaks 9 and 12 to $\Sigma^{(4)}(A)$ rather than $\Sigma^{(3)}(A)$ fits the temperature dependence satisfactorily.

4. Boron one-phonon absorption

The one-phonon absorption due to boron overlaps the intrinsic two and three phonon bands discussed above. Therefore, we have subtracted the intrinsic

Fig. 1. Intrinsic absorption of diamond at room temperature in the two-phonon region. The peaks are labelled as in Ref. [4] and with the high symmetry points with which the relevant phonons are associated, as described in the text.

Fig. 2. The infrared absorption at temperatures of 302, 351, 448, 515, 556 and 598 K, showing the monotonic increase in absorption as the temperature rises.

Fig. 3. The variation as a function of temperature of some of the peaks identified in Fig. 1. The lines show the theoretical fit (Eq. (1)) using the phonon energies listed in Ref. [4].

Fig. 4. The infrared absorption at 27 K (broken line) and 300 K (continuous line) in boron-doped diamond. The intrinsic absorption has been subtracted. The labelled features are explained in the text.

absorption spectrum recorded at the same temperature from each spectrum of the boron-containing samples. Spectra were acquired in the temperature range 14–620 K. Fig. 4 shows the infrared spectrum of one sample at room temperature compared with the spectrum at 27 K. The two peaks labelled I and II correspond to electronic transitions at the boron acceptor and the third peak (labelled III on Fig. 4) to the creation of a single phonon (allowed by the presence of the boron). Also noticeable is the increase of background absorption above about 3000 cm^{-1} due to ionisation of the boron and at lower energies due to the transitions of holes already in the valence band between valence band states. A Fano resonance at the Raman energy (1332.5 cm^{-1}) is marked in the inset in Fig. 4 by an asterisk.

In order to compare the data from the four samples, in Fig. 5a–c, the integrated areas under the three peaks I,

II and III, respectively, have been normalised by dividing by the integrated area extrapolated to zero temperature. Fig. 5a–c shows the variation with temperature for the three peaks. Each shows a decrease in absorption, A , at higher temperatures due, we can assume, to thermally induced effects, and can be fitted by the function:

$$A = \frac{1}{1 + b_1 \exp(-\Delta E_1/kT) + b_2 \exp(-\Delta E_2/kT)} \quad (2)$$

for peaks I and III, where k is Boltzmann's constant, and b_1 and b_2 are degeneracy parameters. The two activation energies are: $\Delta E_1 = 65 \pm 7\text{ meV}$ ($524 \pm 56\text{ cm}^{-1}$), $\Delta E_2 = 384 \pm 80\text{ meV}$ ($3100 \pm 40\text{ cm}^{-1}$) for peak I (Fig. 5a). For the one-phonon transition—peak III (Fig. 5c) the energy values were: $\Delta E_1 = 69 \pm 10\text{ meV}$ ($556 \pm 80\text{ cm}^{-1}$), $\Delta E_2 = 218 \pm 45\text{ meV}$ ($1760 \pm 360\text{ cm}^{-1}$).

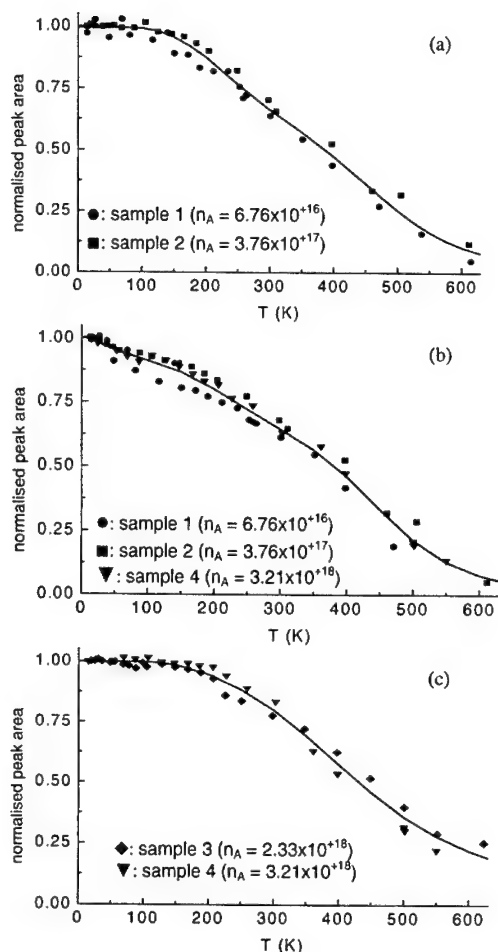

Fig. 5. The temperature dependence of the normalised integrated areas under the three peaks labelled (a) I, (b) II and (c) III in Fig. 4. The lines show the fit using Eqs. (2), (3) and (2), respectively.

For peak II (Fig. 5b), an additional transition at very low temperatures was evident and a third exponential was necessary to fit the data

$$A = \frac{1}{1 + b_1 \exp(-\Delta E_1/kT) + b_2 \exp(-\Delta E_2/kT) + b_3 \exp(-\Delta E_3/kT)} \quad (3)$$

The energies of the three processes were: $\Delta E_1 = 5 \pm 2$ meV (40 ± 16 cm⁻¹), $\Delta E_2 = 61 \pm 12$ meV (490 ± 100 cm⁻¹), $\Delta E_3 = 370 \pm 78$ meV (2980 ± 320 cm⁻¹).

The activation energies near 380 meV (3100 cm⁻¹) correspond to the ionisation of the acceptor, and the low energy one at ~ 5 meV (40 cm⁻¹) is probably the spin orbit splitting observed by Kim et al. [11]. The energies near 65 meV (520 cm⁻¹) have not been reported previously.

Phonon-assisted processes have been observed in B-doped diamond [12]. Strong infrared absorption peaks

at 506 ($347 + 159$) and 464 ($305 + 159$) meV, indicated the internal transition of the hole to excited states with the emission of one phonon of a typical optic phonon energy of 159 meV (1282 cm⁻¹)—they are marked with A and B, respectively, in Fig. 4. In the case of peak (III), the ionisation of the boron takes place with the absorption of one phonon—it can be seen that

$$\Delta E_{\text{ionis}} - \Delta E_{\text{phon}} = 380 - 159 = 221 \text{ meV} (1782 \text{ cm}^{-1})$$

This result is in agreement with the energy ΔE_2 for peak III.

5. Conclusions

The temperature dependence of the infrared absorption in intrinsic and boron-doped diamond has been studied in order to investigate the detailed processes involved. For pure diamond, the temperature dependence of the peaks in the two phonon band can be understood in terms of the phonons at high symmetry points in the Brillouin zone. In boron-doped diamond, the absorption peaks are due to internal electronic transitions and one-phonon excitations.

Photoelectrical properties of the 1.682-eV and 3 H centres in diamond

Konstantin Iakoubovskii*, André Stesmans

Laboratorium Voor Halfgeleiderfysica, Semiconductor Physics Laboratory, Katholieke Universiteit Leuven, Celestijnenlaan 200 D, 3001 Heverlee-Leuven, Belgium

Abstract

A narrow (few meV halfwidth) dip was observed at 1.682 eV in the photocurrent (PC) spectra from diamond films grown by chemical vapour deposition (CVD). The shape of the dip matched that of the absorption line from the well-known 1.682 eV Si-related centre. However, optical absorption measurements show that it cannot be explained by straight absorption of light at the 1.682 eV centre. A similar appearance of narrow peaks was observed in PC and absorption spectra for the interstitial-related 3 H centre in this work and for the vacancy-related GR1-8 and ND1 lines previously. The phenomenon can be explained by suggesting involvement of electron transfer process: e.g., electrons from the excited states of a given centre are captured by the defects responsible for the background PC, thus PC-(in)activating the latter. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: CVD diamond; Absorption; Photoconductivity; Vacancies

1. Introduction

Most diamond films grown by chemical vapour deposition (CVD) show an optical signal at 1.682 eV. It has been thoroughly characterised by optical absorption and luminescence techniques [1,2]. The results suggest it to correspond to a defect centre that has a C_2 symmetry axis and contains a Si atom and a vacancy. In samples grown on Si substrates, most of the 1.682 eV centres are concentrated within a 1- μ m-thick surface layer at the substrate side of the CVD film. The intensity of the 1.682 eV optical absorption peak can be enhanced up to 10 times by UV illumination, and the photo-induced changes decay on a time-scale of hours. Some photocurrent (PC) spectra from CVD diamond show a dip at 1.682 eV too, whose shape resembles the 1.682 eV absorption line. This observation was interpreted as self-absorption of incident light by the 1.682 eV centres [1,3].

In this report we demonstrate that self-absorption cannot explain the strength of the 1.682 eV PC dip. Alternatively, a simple model is proposed, which considers an electron transfer from the excited states of the 1.682 eV centres to the defects responsible for the background PC. It is suggested that this model can provide a natural explanation of the narrow lines observed in PC spectra of irradiated diamonds.

2. Experimental details

Polycrystalline diamond films with random orientation of the grains have been grown by microwave-assisted CVD on Si substrates [1]. The substrates were removed by acid etching. Thermally evaporated gold was used for electrical contacts. Preliminary experiments showed that this resulted in a low-resistive Ohmic contact at the rough growth side of the films and a highly resistive contact at the smooth substrate side. Therefore, two contacts were evaporated on the rough side of a 50- μ m-thick film, forming a gap-cell

E-mail address: kostya.iak@fys.kuleuven.ac.be (K. Iakoubovskii).

configuration with contact spacing of 1 mm and contact width of 2 mm, being equal to the sample width. Wires were attached to the contacts using silver paint, which also masked all the film area, except for the $1 \times 2 \text{ mm}^2$ gap between the contacts. The sample was mounted on top of a $2 \times 2 \text{ mm}^2$ flat Si diode and illuminated by light from a 50 W halogen lamp passed through a monochromator. No narrow spectral features were found in the spectrum of the illumination source. In this arrangement, transmittance and PC spectra were simultaneously measured from the same sample area. For UV illumination, light from a pulsed N_2 laser, providing 100- μJ 3-ns pulses at 3.678 eV with a frequency of 35 Hz, was directed at the sample for 10 min. A DC voltage of 140 V was applied to the contacts. Applied voltage had no effect on the absorption spectra.

Some of the studied CVD samples have been irradiated by a dose of $10^{18} \text{ MeV neutrons/cm}^2$ at the Research reactor of the Moscow Engineering Physics Institute.

3. Results

Fig. 1 presents the room-temperature transmittance and PC spectra observed in the 1.62–1.74 eV range from an as-grown CVD film before and right after UV illumination. More extended spectra have been presented and analysed previously [1]. The background PC is a quasi-plateau, following a broadened threshold at $\sim 0.8 \text{ eV}$. The threshold is probably due to electron transitions from the valence band to a distribution of levels centred around $E_v + 0.8 \text{ eV}$, attributed to dangling bond related defects. The 1.682 eV dip is present both in transmittance and PC spectra, being less intense in the former. UV illumination induced the following

Fig. 1. Transmittance and photocurrent spectra (300 K) from as-grown CVD diamond film before and after UV irradiation.

changes: The amplitude of the transmittance dip increased 1.7 times. The background PC increased about 5 times, with an apparent change in slope. However, the relative intensity of the 1.682 eV dip in the PC spectrum remained constant within 20%.

Fig. 2 shows room-temperature transmittance and PC spectra in the 2.35–2.55 eV range from a neutron-irradiated CVD film. A dip at 2.463 eV, attributed to an interstitial-related 3H centre, is present in both spectra, being more pronounced in PC as was the case for the 1.682 eV dip in Fig. 1. The background PC originates from a threshold at $\sim 1 \text{ eV}$. Previous PC and photo-Hall studies of irradiated diamonds [4–6] reported detection of the narrow vacancy-related features ND1 and GR1, GR2... GR8 both in absorption and PC spectra, measured at 8 or 80 K. In the PC spectra the GR1 line with associated vibronic sideband was observed as dips, but the ND1 and GR2-8 systems were present as peaks. Attempts to reproduce those PC results in this work failed because of a strong decrease in PC signals when cooling the sample. Meanwhile, those peaks could not be resolved at room temperature.

No changes could be induced by UV illumination in the spectra of Fig. 2, however, the following observation has been made: The sample used for the Fig. 2 was subjected to isochronal (1 h) annealing at different temperatures in the range 200–1100°C. Annealing in the range 500–1000°C resulted in the apparent removal of the 3H absorption. However, it could be restored by the mentioned UV illumination. After annealing at $T = 1100^\circ\text{C}$ the 3H centre could not be seen either with or without UV illumination. This observation along with our previous results [7] shows that the interstitial-related 3H centre is stable up to the temperature of 1000°C, but not 400°C, as widely believed.

Fig. 2. Transmittance and photocurrent spectra (300 K) from neutron-irradiated CVD diamond film.

4. Discussion

The differences in the intensity of the 1.682 eV dip in the transmittance and PC spectra of Fig. 1 exclude self-absorption of light as the reason of the PC dip. The 1.682 eV transmittance line corresponds to *internal* resonant excitation of a Si-related centre. In order to explain the effect of such process on PC the following charge-transfer model is proposed. It assumes that electrons from the excited states of the 1.682 eV centres can be transferred to defects, termed X, responsible for the broadband background PC. Transfer of excitation between different defects is rather common for diamond [2,8]. The $E_V + 0.8$ eV levels of the X defects become populated and do not contribute anymore to PC, at least at energies below 4 eV. As a result, PC is selectively quenched at the energy of the 1.682 eV absorption line. By changing the relative concentrations and occupancies of the 1.682-eV and X centres it is possible to alter the relative intensities of the 1.682 eV dips in transmittance and PC spectra in a wide amplitude range. UV illumination could induce all those processes, but at non-equal rates, thus affecting differently the transmittance and PC spectra of Fig. 1.

The charge-transfer model can be directly transferred from the 1.682-eV to the 3H centre: Previous photo-Hall measurements reveal that the background PC from irradiated diamond in the 1–3 eV range corresponds to electron transitions from the valence band to a $E_V + 1$ eV level [5,6]. As in the case of the 1.682 eV centre, electron transfer from the excited state of the 3H centre to the $E_V + 1$ eV level can naturally explain resonant PC decrease at 2.463 eV (Fig. 2).

It is possible that the defects, responsible for the $E_V + 1$ eV level in irradiated diamond and for the $E_V + 0.8$ eV level in as-grown CVD films, have a common dangling bond related origin.

The charge-transfer model can also be applied to narrow peaks in PC from irradiated diamonds, attributed to the ND1 and GR1-8 absorption lines. The GR1-8 absorption peaks were unambiguously identified as due to the transitions from a common ground state to a series of excited states at neutral vacancy (V^0) in diamond, while the ND1 line is assigned to the internal excitation of V^- [9]. Photo-Hall measurements reveal that the GR2-8 and ND1 PC peaks correspond to p-type and n-type conductivity, respectively [5,9]. The sharpness of the features suggests that none of the corresponding defect levels situate within the valence or conduction band of diamond. Meanwhile, low temperature of those measurements (8–80 K) should have suppressed photothermal ionisation processes.

Currently tolerated explanations for the ND1 and GR2-8 PC peaks imply the following: The GR2-8 lines are attributed to a complex multi-electron excitation at V^0 (see [10,11] for details), which, along with the internal

excitation of V^0 , produces a hole in the valence band of diamond. For ND1 it is proposed that the excited state of V^- ($[V^-]^*$) is situated at the bottom of the conduction band, and the electronic states of the conduction band and of $[V^-]^*$ are orthogonal and thus are not mixed. Consequently, the ND1 line is sharp and electron transfer from $[V^-]^*$ to the conduction band is possible [12].

Both models are rather complex and require many assumptions about the microscopic properties of the vacancy in diamond. Here we would like to point to simpler alternatives:

PC dips at 1.673 eV (GR1) and 1.682 eV are both superimposed on a threshold originating from $E_V \rightarrow E_V + (\sim 1 \text{ eV})$ transitions, and consequently may be explained by the same charge-transfer mechanism, described in the first paragraph of the Discussion. Alternatively, the 1.673 eV PC dip can be caused by straight light absorption at the GR1 centre. The charge-transfer model can also apply to the n-type ND1 PC peak: Let us assume that there is an efficient electron transfer between the excited state of V^- and a defect Y, responsible for background n-type PC in the spectral range of ND1 absorption. Internal excitation of V^- will then produce more occupied Y centres, thus increasing the (n-type) PC in the spectral range of the ND1 absorption.

Apparently, the charge-transfer model does not apply to the GR2-8 lines, where PC *peaks* are observed for p-type conductivity. However, it is worth noting that PC is a function not only of carrier generation, but also of recombination rate. The latter can be strongly reduced by shallow traps that should be considered when interpreting the PC spectra. For example, it is easy to picture a mechanism, increasing the concentration of effective hole traps via electron transfer from the excited states of V^0 to some other defect. Such process would lead to increase in PC at energies of the GR2-8 absorption. A positive vacancy, produced upon electron removal from V^0 may even be considered as a candidate for such shallow trap. In our opinion, such mechanism can explain the GR2-8 PC peaks in a much easier way than the multi-electron excitation model [10,11].

5. Conclusion

A narrow-line structure, attributed to internal excitation of a deep centre, can be observed in photocurrent (PC) spectra and this is not a rare phenomenon in diamond. Straight absorption of incident light cannot account for the strength of the photocurrent features in many cases, in particular, for the 1.682 eV and 3H centres in diamond, considered in the present work. However, those features can be naturally explained by a model based on electron transfer from an excited state of

a deep centre to a defect responsible for the broad background PC band. This model can be applied to the unusual PC features associated with electron excitation of the negative and neutral vacancies in diamond. However, we would like to stress that the goal of the present paper is not to claim an unambiguous explanation of the vacancy-related narrow-line PC structure in diamond, but to draw attention to simple electron transfer mechanisms which may provide alternative to the existing quantum mechanical models.

Abstract

We present electron paramagnetic resonance (EPR) and photo-EPR investigations on the AB3 and AB4 centers found in synthetic diamond crystals. We observed a strong increase of the AB4 EPR signal intensity when diamond samples were illuminated with monochromatic light for photon energies $h\nu > 2.06 \pm 0.02$ eV. Additionally, a quenching of the AB3 signal intensity was observed for photoexcitations at $h\nu > 2.26 \pm 0.02$ eV. The nature of the physical processes responsible for the observed photoinduced changes in both centers is discussed. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: HPHT diamond; Nickel; EPR; Deep levels

1. Introduction

The identification and characterization of point defects continues to be a primary focus of research in diamond. Much of the current interest arises because of the influence of such defects on the performance of diamond in several applications. In diamond synthesized at high pressure and high temperature (HPHT), transition metals, especially Ni and Ni alloys, are used as solvent/catalysts. In such crystals Ni is incorporated as a dispersed impurity and several Ni-related defects are formed during the growth process. Nitrogen is the most abundant impurity both in natural and synthetic HPHT diamond, and is incorporated in different forms, predominantly as isolated substitutional N_s (N^0 : P1 EPR center [1]) and substitutional pairs (N_s-N_s). Electron paramagnetic resonance (EPR) studies on diamond grown from nickel solvent enriched with ^{61}Ni ($I = \frac{3}{2}$, natural abundance 1.2%) have directly proven the incorporation of nickel as a paramagnetic impurity with a spin $S = \frac{3}{2}$ (the W8 EPR center) [2,3]. In the recent years several paramagnetic defects with strong evidence of nickel participation were found by magnetic

resonance techniques [4–9]. Contrary to the available amount of information concerning the formation conditions and structure of these nickel-related centers, there is little knowledge about their energy levels in the diamond gap. For paramagnetic centers these energy levels can be determined by photoelectron paramagnetic resonance (photo-EPR). Photo-EPR studies involving the W8, P1, and AB5 ($S = 1$ [5]) centers have shown that the W8 photoquenching [10] is caused by the promotion of electrons to the conduction band, and that the energy level of the AB5 center is located at $E = E_c - 1.88$ eV [11]. The main advantage of the photo-EPR as a tool for the determination of defect level energies, as compared to other methods, is based upon the fact that it allows a direct correlation between the spectroscopically identified defects and their energy levels. This technique may provide also additional information about the optical behavior of paramagnetic centers, like their optical cross sections and their aptitude for capturing and recombining charge carriers.

Among the nickel-related defects in diamond, the AB3 and AB4 centers were found for the first time in samples that experienced a heat treatment after growth. Both centers have a spin $S = \frac{1}{2}$ and orthorhombic-I symmetry [6]. In this article we present new EPR and photo-EPR results on these nickel-related centers.

2. Experimental details

In this study we used diamond single crystals synthesized by H. Kanda at the National Institute for Research in Inorganic Materials (NIRIM), Japan. The samples were grown by the temperature gradient method at high pressure and high temperature using Ni as solvent/catalyst. Two of the diamond samples were annealed during 4 h at 1600°C under a stabilizing pressure of ~6 GPa. The samples were oriented either by growth facets or by faces polished along the main crystallographic planes.

EPR and photo-EPR measurements were carried out using a Bruker ESP 300E spectrometer operating both in X-band (9.5 GHz) and Q-band (34 GHz). Oxford Instruments helium gas flow and bath cryostat systems in the X- and Q-band, respectively, maintained the samples temperature at selected values between 4.2–100 K. The samples were always cooled down in the dark to guarantee a thermal equilibrium state prior to the illumination procedure in the photo-EPR experiments. A Xe lamp associated with a grating monochromator provided the monochromatic light source for sample illumination. This was done in the X-band through a hole at the used TE₁₀₂ cavity, while in the Q-band the samples were irradiated via a 0.4 mm optical fiber inserted into the helium cryostat. The light from the monochromator was coupled into another 0.4 mm optical fiber at whose end we measured the spectral dependence of the photon flux. When illuminating the samples, the two fibers were connected.

3. Experimental results and discussion

3.1. AB4 center

The EPR spectrum of the AB4 center was for the first time detected in diamonds that were heat-treated after growth [6]. In the present study we only detect this center in the samples that were annealed at 1600°C. The AB4 EPR signal was observed both at room temperature and at temperatures between 4.2 and 100 K. For these samples a strong increase of the AB4 signal intensity was observed upon sample illumination.

In order to monitor the kinetics and the wavelength dependence of this photoinduced effect, we fixed the external magnetic field **B** at the position of maximum intensity of the first derivative of one of the AB4 EPR lines and monitored the time dependence of the EPR signal intensity (I_{EPR}) upon monochromatic illumination. In order to avoid an erroneous evaluation of the photoinduced changes by monitoring overlapping EPR lines from different centers, we chose the well isolated lower magnetic field AB4 line for **B** || <011>. The photoinduced changes in the AB4 signal intensity for

excitation photon energies $h\nu = 2.01, 2.05, 2.09$, and 2.14 eV are shown in Fig. 1. For a sequence of increasing photoexcitation energies $h\nu$, the difference ΔI_{EPR} between the photoinduced EPR signal intensity and the I_{EPR} measured prior to illumination was estimated through fitting the I_{EPR} vs. time data with exponential decay functions, see Fig. 1. The spectral dependence of ΔI_{EPR} determined from this fitting is presented in Fig. 2(a). The observed enhancement of the AB4 EPR signal intensity is interpreted as a result of a photo-

Fig. 1. Time dependence of the EPR signal intensity I_{EPR} of the AB4 center at $T = 100$ K for different excitation energies $h\nu$. Full curves represent experimental data and dashed curves are exponential fits.

Fig. 2. (a) Spectral dependence of the EPR signal change ΔI_{EPR} (as defined in Fig. 1) for the AB4 center (enhancement) and (b) for the AB3 center (quenching). The measurement temperature is 100 K. The circles represent experimental data and the solid curves are fits to the data by Eq. (1).

ionization process occurring on a defect with localized states in diamond. Generally, the ionization energy E_i of a defect involved in such a photoionization transition (PT) can be determined from the spectral dependence of the corresponding optical cross section σ . The requirements for a correct determination of this dependence from the photo-EPR data were extensively discussed by Godlewski [12]. In the present work we used the saturation value method, which is based on the determination of the optical cross section of the photoionization transition through the spectral dependence of the ΔI_{EPR} values. This allowed us to consider different starting populations of the center under study for each photon energy, and overcomes the difficulty of ensuring the same starting signal intensity prior to each subsequent photoexcitation in the temperature range of our measurements. The calculation of the dependence of ΔI_{EPR} on the optical cross section for a given PT requires the solution of a complex system of kinetic equations that would consider all the excitation, recombination, and capture processes occurring in the sample. Our approach to this problem is based on the general principle that the ΔI_{EPR} values depend in the same way on the light intensity I and on the optical cross section σ , as these two quantities appear always together in the form of $\alpha = I \times \sigma$ in the kinetic equations that describe the photoionization process. In the photo-EPR study of the W8 and AB5 centers [11] we described in detail how the relation between the ΔI_{EPR} values and the optical cross section can be obtained. In the case of the AB4 photoexcitation we assume that the enhancement of the AB4 EPR signal intensity results from one dominant photoionization process. Considering besides that the data shown in Fig. 2(a) were obtained under experimental conditions of a linear dependence between ΔI_{EPR} and α , the optical cross section of the involved PT is linearly related to ΔI_{EPR} . Fitting the spectral dependence $\sigma(h\nu)$ of the AB4 photoexcitation by the Lucovsky formula for a purely electronic cross section [13]

$$\sigma(E_i, h\nu) \propto \frac{(h\nu - E_i)^{3/2}}{(h\nu)^3} \quad (1)$$

we found the ionization energy $E_i = 2.06 \pm 0.02$ eV, see Fig. 2(a).

The observed enhancement of the AB4 signal intensity can be caused by two type of processes: (i) a direct electron (hole) excitation from the AB4 centers to the conduction (valence) band, or (ii) an indirect process if electrons (holes) excited to the conduction (valence) band from another defect are then captured by the AB4 centers. The unambiguous determination of the process that governs the photoinduced increase of the AB4 EPR signal intensity is hindered by the fact that this spectrum could only be detected in one type of the available set of samples. The W8 and AB5 signals decrease in the same

samples for excitation energies $h\nu$ higher than 2.5 and 1.9 eV, respectively. However, the appearance of a strong photoinduced effect with a threshold at 2.06 eV only for the AB4 lines, together with the observation of different spectral dependencies for the photoinduced changes of other centers present in the same samples, indicate that a direct photoionization is the most probable process to explain the observed behavior of the AB4 center under illumination. Whether the increase of the AB4 signal is resulting from a direct (i) or an indirect (ii), it can occur either by electron or by hole ionization. The observation of the nitrogen donor signal (P1) prior to any illumination of the samples indicates that the Fermi level is located at or above the $N^{0/+}$ level. The position of this defect level in the diamond gap have been taken as $E = E_c - 1.7$ eV [14]. Therefore, the observed transition with the threshold at 2.06 eV is interpreted as promotion of electrons to the conduction band.

3.2. AB3 center

The EPR measurements at temperatures between 4.2 and 100 K reveal in all samples the presence of the AB3 EPR spectrum. This spectrum is not detectable at room temperature.

The intensity of the AB3 EPR lines in annealed diamonds decreases upon sample illumination with visible light. The time dependence of this process was recorded for different excitation wavelengths and the ΔI_{EPR} values were determined as described above for the AB4 center. The obtained spectral dependence of ΔI_{EPR} normalized to a constant photon flux is presented in Fig. 2(b). A photon energy threshold of about 2.3 eV was determined for the observed decrease of the signal intensity. Provided only one photoionization process is responsible for the decrease of the AB3 EPR signal intensity and taking into account that the experimental data shown in Fig. 2(b) were obtained under the condition of a linear dependence between ΔI_{EPR} and α , the optical cross section of the PT is linearly related to ΔI_{EPR} . The best fit of Eq. (1) to the curve shown in Fig. 2(b) is obtained for $E_i = 2.26 \pm 0.02$ eV.

This photoinduced effect on the AB3 center was only observed in annealed samples whereas in as-grown diamonds that exhibit the AB3 spectrum a sensitive change of the AB3 EPR signal intensity upon illumination was not detected. We see two possible explanations for this behavior of the AB3 center: (a) the decrease of the signal intensity results from the capture, from the conduction (valence) band, of electrons (holes) that were excited from another defect produced during the annealing process and located at 2.26 eV in the diamond gap; or (b) the direct photoionization of AB3 centers is observed and the photoexcitation effect in the as-grown samples is undetectable due to the small amount of

acceptor (donor) levels available to capture the photo-excited electrons (holes). The time dependence of I_{EPR} of the AB5 center measured at different photoexcitation energies for the same annealed samples have shown that by changing the photoexcitation energy from 2.23 to 2.32 eV a second process which overlaps with the photoquenching of the AB5 EPR signal sets in [11]. This process and that leading to the decrease of the AB3 signal intensity have possibly the same origin. As in the AB4 photoexcitation mechanism, the photoionization transition that leads to the changes in the AB3 signal intensity should involve the promotion of electrons to the conduction band, independently of process (a) or (b) occurs.

4. Conclusions

Photoionization processes involving the AB3 and AB4 paramagnetic centers were studied in as-grown and annealed diamond samples grown from a nickel solvent/catalyst. The strong increase of the AB4 EPR signal intensity observed by optical excitation with photon energies $h\nu \geq 2.06$ eV is interpreted as resulting from photoionization of AB4 defects located at 2.06 eV below the conduction band. The photoinduced decrease of the AB3 signal intensity evidences the presence of an acceptor state at $E = E_c - 2.26$ eV in HPHT diamond.

Acknowledgements

The authors would like to thank H. Kanda (NIRIM, Japan) for supplying the samples. The work was supported in part by “Acções Integradas Luso-

Alemãs”, Project No A-13/99. RNP thanks the Institute for Solid State Physics, TU-Berlin, for its hospitality and acknowledges the financial support from FCT under contract PRAXIS XXI/BD/18405/98, which made a longer stay in the Federal Republic of Germany possible.

Electrically detected magnetic resonance studies of phosphorus doped diamond

T. Graf^{a,*}, M.S. Brandt^a, C.E. Nebel^a, M. Stutzmann^a, S. Koizumi^b

Abstract

Phosphorus doped n-type epitaxial diamond films have been studied by electron spin resonance (ESR) and electrically detected magnetic resonance (EDMR). At low electric field, the dominant defects influencing the electronic transport are carbon dangling bonds, while at higher fields the anisotropic spin resonance signal of a new phosphorus-related center with $g_{\perp} = 2.0026$, $g_{\parallel} = 2.0042$, $A_{\text{iso}} = 17.6$ G, and $A_{\text{aniso}} = 1.8$ G is observed. These results indicate that room temperature conductivity in this film is dominated by hopping via phosphorus-related defect centers rather than via hydrogenic donor states of phosphorus atoms on substitutional sites. © 2001 Elsevier Science B.V. 1. Introduction

As a potential semiconducting material, diamond has several outstanding properties. The major obstacle for the realisation of bipolar diamond-based electronic devices still is the lack of shallow n-type dopants. One possible candidate for a shallow donor state is substitutional phosphorus, which unfortunately is much harder to incorporate into diamond than into silicon because of the mismatch in atomic radii. Nevertheless, several groups have reported phosphorus incorporation into diamond. In epitaxial samples grown using phosphine as a dopant source, n-type conductivity was found with activation energies of the Hall carrier concentration of 0.4–0.6 eV [1]. For the same samples, infrared absorption peaks were observed at 0.52 and 0.56 eV and related to a photoionization onset in photoconductivity measurements [2]. The aim of the present paper is to investigate the microscopic structure of the phosphorus-related electronic states in these samples by electron spin

resonance (ESR) to obtain information on their ground state wavefunction.

ESR of phosphorus-related states in diamond has been observed in polycrystalline powders [3], in crystals grown from phosphorus catalyst [4], and in CVD films implanted during growth [5] or after growth with subsequential annealing [6]. In the crystalline films, isotropic hyperfine lines with a characteristic splitting of 27–28 G were observed and attributed to the $I = 1/2$ nuclear magnetic moment of substitutional ^{31}P . Unfortunately, these samples have a large number of implantation defects besides the phosphorus states so that n-type conductivity has not been confirmed yet. Only recently, 28 G split hyperfine lines were observed in these samples together with the characteristic infrared absorption at 0.52 and 0.56 eV also found in the samples of Ref. [1,2], suggesting that shallow states give rise to the ESR signal [6].

Conventional ESR of epitaxial diamond layers usually is dominated by the large density of well-known nitrogen P1 centers in the substrate [7]. We therefore have used electrically detected magnetic resonance (EDMR) experiments, which are sensitive to paramagnetic states in the path of conductivity only. Therefore,

*Corresponding author. Tel.: +49-89-289-12768; fax: +49-89-289-12737.

E-mail address: tobias.graf@wsi.tum.de (T. Graf).

background signals from the insulating substrate do not interfere with signals of the conductive film, allowing the selective investigation of paramagnetic states in the P-doped epilayer.

2. Experimental details

The diamond film under investigation has been prepared by plasma-assisted chemical vapor deposition. By addition of phosphine to the gas phase with relative concentrations of $(\text{PH}_3/\text{CH}_4)=1000\text{ ppm}$ and $(\text{CH}_4/\text{H}_2)=0.075\%$, a doped epitaxial film with $1.5\text{ }\mu\text{m}$ thickness was deposited on the polished $[111]$ surface of a $2 \times 2 \times 0.5\text{ mm}^3$ type Ib synthetic diamond, as described in Ref. [1]. The nominal phosphorus concentration of this film was $5 \times 10^{18}\text{ cm}^{-3}$, which is just below the concentration expected for the metal-insulator transition, at which the hyperfine satellites of the nuclear spin $I = 1/2$ of ^{31}P would collapse [5]. A detailed description of the growth as well as measurements of photoconductivity and infrared absorption can be found in Ref. [2] and references therein, where the present sample is labeled as #4. For the electrical measurements performed in this paper, coplanar interdigital Au contacts with $50\text{ }\mu\text{m}$ spacing were deposited on top of the epitaxial film.

As noted above, the nitrogen P1 center in the substrate dominates the conventional ESR of the sample. Its anisotropic ESR signal has been used to orient the sample with respect to the external magnetic field and for g -factor calibration. EDMR measurements were taken in a conventional X-band ESR spectrometer (Bruker ESP-300, TE₁₀₂ cavity) in combination with a Keithley 237 Source Measure Unit and a Stanford Research SR570 Low-Noise Current Preamplifier. The spectra shown have been recorded at room temperature, but have been observed similarly at 100 K as well. Above room temperature, the dark conductivity of the sample is thermally activated with the characteristic ionization energy of about 0.5 eV attributed to the substitutional phosphorus level [1]. In contrast, at room temperature and below, the dominant transport process is hopping at the Fermi level, which is expected to be a spin-dependent transport path similar to existing results in other materials [8]. Therefore, room temperature EDMR measurements seem to be a suitable tool to resolve the hyperfine interaction of electronic spins with the nuclear spins of ^{31}P and to extract from this hyperfine splitting microscopic parameters of the electron wavefunction at the donor sites.

3. Transport regimes and EDMR at low electric field

Fig. 1 shows the IV -characteristic of the film at room temperature in the dark. Above $\pm 20\text{ V}$, the behavior is

Fig. 1. Room temperature IV -characteristic of the phosphorus doped diamond film with $50\text{ }\mu\text{m}$ interdigit finger contacts. The dashed line indicates the IV characteristics of an ohmic resistor, which is offset from zero voltage due to barriers at the non-ideal contacts. Open and closed circles show the intensities of the two signal components in EDMR.

Fig. 2. EDMR spectra at 10 V bias and at 30 V bias corresponding to 2 and 6 kV/cm in the case of a homogeneous field distribution. In the regime of low electric field, carbon dangling bonds dominate spin-dependent transport, while at higher electric fields the signal shows a complex structure of several resonances.

almost ohmic as indicated by the dashed line that corresponds to a differential resistance of $10\text{ M}\Omega$ and a conductivity of $10^{-6}\text{ }\Omega^{-1}\text{ cm}^{-1}$, consistent with the reported data for n and μ [2]. In contrast, the IV -curve at lower bias voltages is nonlinear, indicating that the current is limited by some kind of barrier, such as the space charge region of a Schottky contact below breakthrough in reverse-bias. Obviously, any electrical measurement such as EDMR should be analyzed with regard to the bias voltage that determines the dominant resistance. In the regime of high voltages, the applied electric field is able to overcome the barriers so that the measured current is limited by the epilayer of interest, whereas in the low-field regime the space charge layers limit the overall current.

The different EDMR signatures observed at high and low bias voltages shown in Fig. 2 support this qualitative explanation. While in the high-field regime at 30 V bias, a complex anisotropic signal is observed that will be discussed in more detail below, the low-field signal at 10 V bias can be identified directly by its isotropic g -factor $g = 2.0028$ and the peak-to-peak linewidth $\Delta H_{pp} \sim 7$ G. These parameters are commonly associated with carbon dangling bonds in amorphous hydrogenated carbon [9] as well as in polycrystalline diamond [10], and in crystalline thin CVD diamond films after implantation [5,6]. EDMR of carbon dangling bonds has been demonstrated in polycrystalline CVD diamond films with high defect density [11]. In the present homoepitaxial film, EDMR sensitivity is enhanced as these defects limit conductivity through the space charge regions of the interdigital contacts. The sign of the EDMR signal at low electric fields indicates a resonant quenching of the current due to a spin-dependent capture process of conduction band electrons. In contrast, the signal at high electric field corresponds to resonant enhancement of the current, which is typical for hopping transport at the Fermi level.

At intermediate bias voltages, the two different components to conductivity give rise to a superposition of the two types of EDMR spectra. In Fig. 1, the maximum resonant current change ΔI_{pp} of both spectral contributions is shown separately, the full symbols indicating the resonant current change for the contribution attributed to the epilayer outside the space charge region and the open symbols indicating the change due to dangling bonds. According to the picture given above, the crossover between both regimes takes place at the interchange between ohmic and barrier-dominated transport. The normalized EDMR intensity is $\Delta\sigma/\sigma = \Delta I_{pp}/I_{DC} \sim 10^{-6}$ for these maximum components of the signals. As for the smaller features, $\Delta\sigma/\sigma < 10^{-7}$, massive signal averaging is required to completely resolve each spectrum.

4. Interpretation of the EDMR at high electric fields

In Fig. 3, EDMR spectra for the three fundamental crystal orientations with respect to the magnetic field H_0 perpendicular to the $[\bar{1}10]$ axis of rotation are shown. They have been recorded at a bias voltage of 30 V, which is appropriate to suppress the contribution from the contacts and to select paramagnetic states from the phosphorus doped film. Within the complex pattern of overlapping resonances, the outer pairs of hyperfine satellites are clearly identified as P1 hyperfine triplets. They are identical to the ESR signal of the substrate besides some broadening due to the experimental conditions of EDMR. Although the substrate has a higher thickness than the epilayer, its room temperature

Fig. 3. EDMR at 30 V bias for three fundamental crystal orientations. The crystal rotation is performed around a $[\bar{1}10]$ axis, so that 0° rotation angle corresponds to $H_0 \parallel [111]$, $+35^\circ$ to $H_0 \parallel [110]$, and -55° to $H_0 \parallel [001]$. The outer transitions belong to P1 triplets that dominate the ESR signal of the Ib substrate. The inner set of lines is attributed to hyperfine satellites of a new phosphorus-related center. Also drawn are the positions of the 27 G hyperfine satellites reported for other P-doped diamond samples [5], but which are not found in this sample.

dark conductivity is too low for a contribution to the EDMR signal, suggesting the presence of deep P1 centers in the epitaxial film. Alternatively, microwave absorption of P1 centers in the substrate could lead to thermal crosstalk and to a resonant increase in conductivity.

In contrast, no significant absorption is detectable in ESR under identical conditions for the remaining resonance lines, so that these lines have to originate from spin-dependent transport at the Fermi level of the epilayer. Also indicated in Fig. 3 are the resonance positions for $\Delta H = 27$ G and $g = 2.0023$ which have been reported for ^{31}P -related centers in diamond earlier [5,6]. This hyperfine doublet is not observed in the present sample. Instead, we observe an isotropic line at 3329 G and an anisotropic set of lines at about 3347 G, more similar to the ESR signals reported in Refs. [3,4]. The interpretation of these lines as two independent resonances would result in g -factors of $g = 2.009$ and $g \sim 1.998$, which are well out of the narrow range of g -factors typical for diamond [12]. Therefore, the two resonances will be interpreted in the following as a set of hyperfine lines, although their anisotropy is not resolved completely on both sides. As indicated in Fig. 3, the difference can be simulated by g -factor anisotropy in addition to anisotropy of the hyperfine interaction. Both contributions have opposite

orientation at 3329 G, leading to a small total anisotropy and to overlapping lines for the satellites at lower magnetic field. In contrast, the anisotropy adds up for the 3347 G line. It is incompatible with the axial symmetry expected of surface states, which also might influence the conductivity [13]. Identical spectra have been observed for H_0 oriented parallel to $[1\ 1\ 1]$ and $[1\ 1\ \bar{1}]$. This is consistent with the C_{3v} symmetry of sp^3 orbitals in diamond. Spectra at intermediate angles also support the calculated line pattern included in Fig. 3, which simulates a C_{3v} -center with $g_{\perp} = 2.0026$, $g = 2.0042$, $A_{iso} = 17.6$ G, and $A_{aniso} = 1.8$ G. The pattern contains four symmetry related sites with $I = 1/2$, two of which coincide for the investigated axis of rotation. A more detailed analysis of the ESR parameters is hindered by the linewidth of $\Delta H_{pp} \sim 5$ G that leads to severe overlapping of the expected resonances. Nevertheless, the observed parameters are significantly different from those of the analysis of the powder pattern in polycrystalline samples $g = 2.0025$, $A_{iso} = 20.8$ G, and $A_{aniso} = 1.2$ G [3].

Up to now, all isotropic hyperfine constants reported for phosphorus in diamond are below 30 G, which can be converted into a probability density of the 3s orbital at the phosphorus atom of $<0.6\%$ [4]. Small ^{31}P hyperfine splittings have been discussed for several centers, for example a phosphorus-vacancy complex with low spin density on the central nucleus [14] or a complex similar to the NI center with phosphorus in a positive charge state at the next-nearest neighbor site of an unpaired electron [4]. For substitutional donors, the spin density at the donor atom can be estimated by the effective mass theory. The effective electron masses in diamond are uncertain up to now, but seem to have the same anisotropy as the effective electron mass of silicon, with a ratio of $m_c^*/m_{Si}^* \approx 1.5$ [15]. At the same time, the ratio of dielectric constants is $\epsilon_c/\epsilon_{Si} = 5.7/11.7 \approx 0.5$. Both ratios cause a higher degree of localization at donor atoms in diamond compared to silicon, as the ionization energy scales like $E \propto m^*/\epsilon^2$, and the localization radius like $a \propto \epsilon/m^*$. Considering only changes of the hydrogen-like envelope of the donor electron wave function without detailed calculation of Bloch functions and central cell corrections, the hyperfine splitting scales roughly like $A \propto |\psi(0)|^2 \approx (m^*/\epsilon)^3$ [16]. The extrapolation from phosphorus donors in silicon to diamond predicts $A_c > 1000$ G, in contrast to the arguments based on relative electronegativities, which suggest a smaller hyperfine interaction in diamond compared to silicon [5]. The experimental ionization energy of 0.6 eV is significantly higher than the value $E \sim 0.2$ eV predicted from effective mass theory, indicating an even higher degree of localization and larger hyperfine splitting [15]. At the signal-to-noise level of the present EDMR experiments, no additional hyperfine pairs were detected within a

magnetic field range of ± 2000 G. Nevertheless, one has to keep in mind that EDMR of dark conductivity is limited to spin-dependent processes in paramagnetic states close to the Fermi level. Therefore, in partially compensated samples, EDMR experiments cannot exclude the existence of shallow phosphorus levels in the presence of deeper compensating centers, for example dangling bonds, PI centers, or X_{P2} levels that were observed in similar samples by CPM at 0.81 eV [2].

5. Conclusions

ESR and EDMR experiments were performed on a P-doped diamond film exhibiting n-type conductivity. Two transport regimes have been studied separately: At low electric field, carbon dangling bonds limit dark current through barriers below the non-ideal contacts. At higher electric fields, a new ESR center with $g_{\perp} = 2.0026$, $g = 2.0042$, $A_{iso} = 17.6$ G, and $A_{aniso} = 1.8$ G was detected in the epilayer. It dominantly contributes to room temperature transport, but cannot be assigned to substitutional phosphorus donors. Most likely, the presence of compensating defects hinders the observation of substitutional phosphorus with EDMR of dark conductivity in these samples. Measurements of spin-dependent non-equilibrium processes like spin-dependent recombination could help to resolve this problem.

Abstract

Annealing of Ib and IIa diamonds at temperature of 1800 °C and pressure of 7.2 GPa was performed. It is shown that for experiments with comparable total duration, the nitrogen aggregation rate is significantly slower for a single-run than for multiple-run annealing. Consequently, many previously reported multiple annealing experiments could overestimate the rate of nitrogen diffusion in diamond. Small-angle X-ray scattering reveals that three-dimensional defect clusters were formed during annealing. The size of clusters (27–57 nm) is similar in annealed natural IaA, IaB, IIa and synthetic Ib diamonds. The presence of clusters is unrelated to ‘platelets’ and contain little, if any, nitrogen. Optical results reveal that annealing resulted in decay of the 4N–2V (H4) defects into 2N–V (H3) and that the B nitrogen defect is not responsible for the N9 optical center. © 2001 Elsevier Science B.V. 1. Introduction

Many physical and chemical properties of minerals depend on the concentration and type of point and extended defects present in their lattices. Diffusion of point defects can lead to creation of clusters and under favorable conditions even new phases can be formed. In this paper we report on a new type of extended defect formed in diamond during long continuous annealing at high pressure–high temperature (HPHT) conditions.

Oxygen, hydrogen and nitrogen are the principal impurities found in diamond. Nitrogen concentrations can be as high as 0.3 at%. Oxygen and hydrogen

concentrations can be comparable and, in some cases, higher than that of nitrogen. However, while most oxygen and hydrogen atoms reside in internal voids in the diamond lattice and within non-diamond inclusions, nitrogen predominantly forms integral lattice-bonded defects [1].

The common classification scheme for diamond is based on the principal nitrogen defect types as identifiable by infrared (IR) spectroscopy. In type Ib diamond nitrogen is dominantly present as single substitutional atoms, referred to as the C or P1 centers. Most synthetic diamonds belong to this type. HPHT annealing, performed either naturally or under laboratory conditions, leads to aggregation of single substitutional nitrogen atoms to the so-called A and B complexes in the order $C \rightarrow A \rightarrow B$ [2–4]. Diamonds with these defects are referred to as type IaA and IaB, respectively. Optical studies [5,6] combined with electron spin resonance

(ESR) show that the A center is comprised of a pair of nearest-neighbor substitutional nitrogen atoms. The microscopic structure of the B defect is not so firmly established. Results obtained by ESR [7] and optical methods [8] suggest a complex of four nitrogen atoms in tetrahedral coordination around a vacancy.

In addition to these simple point defects, most diamonds are rich in more complex and variable extended defects. Besides dislocations, twins and stacking faults, one of the best-known examples is termed 'platelets'—planar (in {100} plane) defects containing carbon and nitrogen atoms. It is suggested that platelets are formed from interstitial carbon atoms as a result of their migration at high temperature [9,10]. Another abundant group of extended defects in diamonds is termed 'voidites', which are typically octahedral formations with a large scatter in size (1–30 nm) and with lower electron density than diamond. Their composition is uncertain, but N–C–H compounds are considered as probable constituents [11].

X-ray diffuse scattering [12] and high-resolution electron microscopy [13] show that Ia diamonds also contain planar {111} defects. Existence of sphere-like (isometric) clusters with diameter ~ 8 –9 nm [14,15] or larger [16] has been reported. Values for hardness and low-temperature thermal conductivity appear to depend on the presence of such clusters [17]. Extended defects can be produced during laboratory or natural HPHT annealing [3,17].

Recently, large defect clusters have been identified by small-angle X-ray scattering (SAXS) in natural IaB and natural and synthetic IaA diamonds [17]. Measurements reveal the presence of spherical defect clusters about 9 nm in diameter in IaB crystals. In type IaA diamonds, the scattering contrast is much weaker and the cluster sizes are more variable (10–60 nm). The composition of those clusters was not clear, although it has been suggested that they may have a significant nitrogen component [17]. The purpose of this paper is to clarify the composition of large spherical defects (clusters) observed by SAXS by their reproduction under laboratory conditions. We present results of SAXS and optical

measurements on synthetic nitrogen-bearing diamonds and on a natural low-nitrogen stone, annealed at HPHT conditions for different periods, and demonstrate that nitrogen, if present at all, is not a significant part of those clusters.

In laboratory experiments on nitrogen aggregation, diamonds are usually annealed in a sequence of several short runs at high temperatures (up to 2800°C) in order to increase diffusion rate. Mechanical stresses as well as changes in pressure–temperature parameters during conventional annealing experiments unavoidably influence defect diffusion. The situation is very different for the majority of natural diamonds, which are annealed at relatively stable upper mantle conditions, at modest temperatures ($<1400^\circ\text{C}$ [18]), but for time-scales of $\sim 10^9$ years. Therefore, in the present work we performed experimental runs with durations up to 960 h hoping to make a closer approximation to the conditions of annealing of diamonds in the Earth's mantle.

2. Experimental

Two synthetic nitrogenous Ib diamonds and one low-nitrogen (IIa) natural stone from the Juina district of Brazil have been used in this work. Synthetic diamonds were grown with a Ni-based catalyst. Nitrogen contents in them, determined by Fourier-transform IR spectroscopy (FTIR), are presented in Table 1. Nickel content of synthetic stones was measured using synchrotron-based X-ray fluorescence (beamline L, HASYLAB). Total Ni concentration was of the order of tens of atomic ppm. Optical measurements, discussed below, revealed that the concentration of Ni-related point defects was on the ppb level, and thus most of Ni was likely present as metallic inclusions. FTIR measurements of the type IIa stone showed a presence of <20 ppm of nitrogen and no Ni could be detected in it by optical absorption or luminescence.

HPHT experiments were carried out using the Walker-style 1000-ton multi-anvil press of the Lunar

Table 1
Defect parameters in annealed diamond samples

Sample number	Nitrogen type	Duration (h)	Total N content (at. ppm)	Nitrogen aggregation ^a (%)	SAXS cluster size (nm)
1 ^b	Ib	10 h 40'	250	25	57
2	Ib	10	240	7	57
3	Ib	100	250	14	44
4	Ib	960	255	10	44
5	IIa	100	20	—	27

^a Nitrogen aggregation is a ratio of A center concentration to the total nitrogen content after annealing. It was below 1% before annealing.

^b Sample 1 was annealed incrementally in five separate experiments run for 462, 2, 74, 76 and 25 min.

and Planetary Laboratory, University of Arizona. Runs were conducted at 7.2 GPa and $\sim 1800^\circ\text{C}$ using 14/8 mm assemblies. Durations ranged from 10 h to 40 days and are provided in Table 1. Diamond fragments of approximately 2 mm in maximum dimension were loaded into Pt capsules and packed with dry graphite. Pressures of 7.2 GPa were obtained at a ram force of 294 tons (US) following calibration by Richter and Drake [19] and are believed to approximate well to hydrostatic conditions. Temperatures were held at 1595°C as measured directly using $\text{WRe}_{26}/\text{WRe}_5$ thermocouples located on the edge of the heater, 2.0 mm from the hot spot where the diamonds were located. Equivalent power, which was found to be a reliable estimation of temperature, was held constant for experiments where thermocouples failed. Measurements using a similar assembly with the thermocouple located at the hotspot confirm a temperature gradient of $\sim 100^\circ\text{C}/\text{mm}$, and thus samples are concluded to have been subjected to temperatures of $1795 \pm 50^\circ\text{C}$. Experiments were quenched by disconnecting the power supply.

SAXS measurements were performed in the angular region of 15° – 1.2° . A small-angle AMUR-K X-ray diffractometer [20] with Kratki-collimator and linear position-sensitive detector were used with a Ni-mono-chromated Cu-anode X-ray fine focus tube as the source of X-rays. The experimental curves were normalized to the primary beam intensity by applying corrections for sample absorption coefficients and holder scattering. Calculation of the size distribution of scattering objects was performed using GNOM software [21]. All mean defect diameters reported in this study are obtained from solutions, stable against variations of a maximum size of scattering centers. The best agreement with the experimental data was achieved by approximation of scattering centers as a polydisperse system of hard spheres.

FTIR spectra were acquired with a Philips PU9800 spectrometer in the range 400 – 3500 cm^{-1} at a 2 cm^{-1} resolution. Deconvolution of spectra was performed using software provided by David Fisher (D.T.C.). Most samples cracked during the annealing and thus the IR spectra of treated samples were taken from irregularly shaped pieces. Instead of conventional transmission geometry, a superposition of transmitted and diffuse components was measured using a DRIFT sample holder. This could affect the analysis of IR spectra. However, no significant changes in total nitrogen content with annealing were observed in IR spectrum from any sample.

Optical absorption was measured in the range 1.2 – 5.6 eV at 77 and 300 K using a home-built spectrometer. For given sample thickness a sensitivity of $\sim 10^{-2}\text{ cm}^{-1}$ was achieved. Photoluminescence (PL) measurements were performed at 77 and 300 K under 3.68 eV or 2.41 eV excitation provided by N_2 or Ar^+ lasers,

respectively. For 2.41 eV excitation the spectra could be measured at energies above (anti-Stokes mode) and below (normal, Stokes mode) the excitation laser line. This allowed interference-free detection of the H3 system with a zero-phonon line at 2.463 eV under 2.41 eV excitation. PL spectra were scaled to the integrated diamond Raman peak. After normalization, the concentration of the detected PL centers could be estimated by comparison of the spectra with the standards, in which the concentration of those centers was calibrated by optical absorption using the data of Davies [8].

3. Results

3.1. Optical studies

Optical spectra measured on the Ib HPHT samples before annealing were rather featureless: Absorption measurements revealed only a broad spectrum, associated with the C centers and only the 2.56 eV system, attributed to the Ni_i defect [8], has been observed in PL. Luminescence intensity was relatively weak, suggesting that the corresponding defect is present on the ppb level. The PL intensity was the same in samples 1 and 2 being about 3 times stronger than in the samples 3 and 4. Only C-defect spectra were detected in IR absorption, which were used to deduce the nitrogen content in the samples (see Table 1).

After annealing the intensity of the C center absorption decreased and a threshold at 4 eV , associated with the A center, emerged in all Ib samples. The signature of this center was also seen in IR absorption spectra. Moreover, weak absorption appeared from the 1.945 eV system, which was associated with the negatively charged nitrogen–vacancy ($[\text{N}-\text{V}]^-$) complex [8]. By integrating the corresponding vibronic band the $[\text{N}-\text{V}]^-$ concentrations were inferred as 80, 80, 120 and 170 ppb with the uncertainty of 40% for samples 1, 2, 3 and 4, respectively. PL from all these samples became much brighter after annealing. Spectra under 3.68 eV excitation from the Ib HPHT samples 1 and 2 were dominated by the S2 and S3 systems, associated with different complexes involving one Ni and two or more nitrogen atoms [22]. Intensity of PL was the strongest in sample 1, an order of magnitude weaker in sample 2 and even more faint in samples 3 and 4. In accordance with the absorption results, PL spectra under 2.41 eV excitation revealed the 1.945 eV system, having about the same intensity in samples 1 and 2 and about twice as strong in samples 3 and 4. However, sample 1 in addition showed the H3 system with intensity comparable to that of the $[\text{N}-\text{V}]^-$ band. Meanwhile, the H3 luminescence was much weaker in sample 2 and undetectable in samples 3 and 4.

Along with the UV-visible absorption and PL results, IR measurements on annealed samples show that the degree of nitrogen aggregation decreases from sample 1 to 4. Along with the absorption, related to the A defect, a weak E-component appeared. This component has been previously reported in some natural Ia/Ib diamonds [23].

In type IIa diamond (#5) optical absorption measurements reveal a presence of the N9 center on the level ≤ 1 ppm. PL detected minute amounts (ppb level) of N3 as well as H3, H4, 536 nm and 576 nm centers. Analysis of the vibronic structure revealed that the 576 nm system is irrelevant to the 575-nm $[N-V]^0$ related center. Annealing did not produce any changes in the intensity of N9, N3, 536 nm and 576 nm systems. Meanwhile, the intensity of the H4 lines decreased while that of the H3 signals increased. Comparison of absorption spectra from the different pieces of sample 5, before and after annealing, with absorption spectra from natural IaB diamonds revealed that no correlation exists between the intensity of N9 absorption and the concentration of nitrogen in the B form. For example, strong N9 peaks were recorded in the IIa sample 5 with almost no (≤ 20 ppm) B defects. Along with the previous work [24] this result disproves a widely tolerated idea that the N9 center is related to the B nitrogen.

No platelets were observed in IR spectra of our samples either before or after annealing.

Comparison of optical results of each run shows that, unexpectedly, the aggregation of nitrogen was the highest in sample 1, which was annealed for only 10 h but in several steps (see Table 1). All samples, but #5, still contain an appreciable fraction of nitrogen in the C form after annealing and only a small fraction ($\leq 25\%$) of nitrogen converted to pairs (A defect). This result is at odds with many other works, where almost complete transformation of nitrogen (C \rightarrow A) could be achieved after few hours of annealing at similar conditions [2–4].

3.2. Small angle X-ray studies

An introduction to the theory and details of the SAXS technique can be found in Ref. [25]. All diamonds investigated in this work were examined by SAXS and showed no scattering prior to the annealing. This indicates the absence of defect clusters.

After 100 h or 960 h annealing of synthetic stones (3 and 4) SAXS signals appeared. The deduced gyration radius of scattering defects was rather close for both samples and is equal to 17 nm. The best agreement with the experimental curves was achieved using the hard sphere approximation. The diameter of the spherical defects in samples 3 and 4 were estimated as 44 nm. Despite the similarity of defects size in samples 1–4 the scattering in sample 4 was much more intense than in samples 1–3. This indicates a higher contrast of

electronic density of the clusters with the diamond matrix and/or higher concentration of clusters per unit volume of diamond.

Rather unexpectedly, strong scattering, comparable to that from sample 4, was observed in the annealed type IIa diamond (sample 5). The diameter of defects in it is, however, significantly smaller and is close to 27 nm. The difference between SAXS curves prior and after annealing is shown in Fig. 1.

After 10 h annealing of synthetic diamonds (both incremental and continuous, samples 1 and 2) SAXS curves were close to the background. Because the approximation of defects by the hard spheres satisfactorily fitted experimental curves from samples 3, 4 and 5 this model was also applied to the small signals in samples 1 and 2 and yielded a diameter of the spherical defects of ~ 57 nm. However, referring to the weakness of the experimental signals, we would stress the approximate nature of this result.

The sizes of defects responsible for SAXS in samples studied in this work are similar to those observed previously for annealed synthetic and natural IaA diamonds [17]. Our SAXS data show that there is no well-defined boundary between the defect and surrounding matrix. Similar results were obtained earlier from X-ray diffuse scattering [26].

One of the most important results of this study is that the contrast between scattering clusters and the diamond matrix as well as their size can be similar in nitrogen-rich and nitrogen-poor samples. The contrast between the electronic density of the defects and the diamond matrix is significant. For nitrogen-containing samples this contrast increases with the duration of annealing and the defects size possibly decreases with the annealing time, though the latter fact needs larger statistics. Significant changes in the X-ray scattering became observable in the IIa (low-nitrogen) diamond after much shorter annealing (100 h), than that for the nitrogen-containing sample #4 (960 h). However, the reason for this phenomenon could be that the IIa

Fig. 1. Small-angle scattering from type IIa natural diamond.

diamond used in our study was natural and thus already significantly annealed. This explanation is supported by the fact that the small amount of nitrogen (<20 ppm) in this sample was present in the aggregated B form already before the experiment.

4. Discussion

Several factors can account for the observed small degrees of nitrogen aggregation and the differences between continuous and incremental runs. It is known that atoms of transition metals strongly increase nitrogen aggregation rate [27]. According to PL measurements, the concentration of Ni atoms was lowest in samples 3 and 4 which, combined with the longer durations of these experiments could explain the low aggregation rate observed for these samples compared to 1 and 2. However an additional mechanism is required to account for the differences in aggregation rate between samples 1 and 2 which contain the same quantities of nickel. During every HPHT annealing cycle some non-hydrostatic pressure component is present, especially when pressurizing and depressurizing the sample. This can result in production of vacancies, thus greatly facilitating nitrogen diffusion [28]. With annealing time, the majority of vacancies should disappear into a variety of sinks, and diffusion rates should subsequently decrease unless a new pressure load-release cycle occurs. We would conclude from these observations that many historical experiments on nitrogen aggregation could produce artificially high diffusion rates compared to natural settings which do not involve cyclical pressure changes.

One of the major results of this study is that continuous annealing leads to much lower nitrogen aggregation rate, than a series of short runs of comparable total duration. This should be taken into account when analyzing results of experiments on nitrogen aggregation.

Our experimental results also suggest that the observations by SAXS isometric clusters in diamond are not related [17] to previously reported extended defects in diamond, such as platelets or voidites. To the best of our knowledge, neither platelets nor voidites have ever been observed in IIa diamonds, whereas we have been able to produce the clusters in diamonds of that type. Additionally, the presence of defect clusters, differing from platelets, is indirectly supported by positron annihilation measurements [29,30]. The contrast of electronic density with the diamond matrix is much higher for platelets than for the clusters we observe, and additionally, the cluster contrast is sample dependent. It is reasonable to suggest that the variations of contrast could be related to different amounts of point defects inside the cluster. For example, pressure

increases the rate of interstitial-assisted diffusion [31]. If the clusters contain appreciable amount of interstitial atoms, then their contrast with the diamond matrix may depend on pressure during annealing. Pressure used in our experiments (7.2 GPa) is higher than average pressure experienced by most natural diamonds (4–5 GPa [18]). This could be an explanation why the SAXS contrast is higher for experimentally annealed samples than for natural IaB diamonds.

The similarity of SAXS patterns in annealed Ia and IIa diamonds does not obviate the possibility of nitrogen as a component of all clusters per se. For example, it was shown that 'man-made' voidites [32] and platelets [33] differ from 'natural' ones in terms of size, shape and probably, composition. Similarly there could be a large variety of ways to form observed extended defects. In several papers voidites formation was correlated with the platelet degradation [11,32], however, voidites have also been reported for diamonds without platelets or dislocation loops [34]. Despite the size differences, there is no evidence from SAXS measurements to suggest that the clusters in nitrogen-rich Ia and nitrogen-free IIa diamonds have different compositions. It is concluded therefore, that the clusters, observed in the present experiments, in addition to those observed previously for IaA and IaB stones [17], do not consist of nitrogen, but possibly contain carbon interstitials.

5. Conclusions

Annealing of Ib and IIa diamonds at temperature of ~1800°C and pressure of 7.2 GPa was performed. Long continuous runs (up to 40 days) were used in order to simulate the conditions of the upper mantle of the Earth and spectra obtained are similar to naturally annealed diamonds. It is shown that the nitrogen aggregation rate is significantly slower in single duration experiments than in those involving several runs, despite similar total time. It is therefore considered likely that many multiple-run annealing experiments described in literature over-estimate the rate of nitrogen diffusion in diamond. This conclusion has a significant bearing on the age/temperature relationships calculated for natural diamonds.

Three-dimensional clusters of defects were formed during our experiments, as detected by SAXS. Their size is similar to that of clusters previously observed in annealed natural and synthetic IaA and IaB diamonds. Nitrogen, if present at all, is not an important component of these clusters, but they may contain carbon interstitials. Generation of the observed clusters is independent of the formation of platelets.

Optical results reveal that HPHT annealing can lead to decay of the 4N–2V (H4) defects into 2N–V (H3) and that the N9 optical center is not the B nitrogen defect.

Volume expansion and stress tensors for self-interstitial aggregates in diamond

J.P. Goss^{a,*}, R. Jones^a, P.R. Briddon^b^a*School of Physics, University of Exeter, Exeter EX4 4QL, UK*^b*Department of Physics, University of Newcastle upon Tyne, Newcastle NE1 7RU, UK*

Abstract

We present the results of first principles local density functional calculations of the volume dilations and piezospectroscopic stress tensors for interstitial aggregates in diamond to facilitate correlation with the experimental centres. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Diamond; Dilation; Stress tensor; Self-interstitials

1. Introduction

In the absence of any imposed stress, isolated point defects are equally distributed over all possible orientations. Applying a compressive stress across a particular face results in an increase in energy of those defects exerting a compressive stress on this face, and a decrease in the energy of those which impose a tensile stress. The increase in energy is $\Delta E = (\text{Tr } B_i \cdot \epsilon)$ where ϵ is the imposed strain tensor and B_i is the traceless energy-stress tensor for defects with orientation i . The equilibrium populations of defects aligned along a direction at temperature T is then proportional to $\exp(-\Delta E_i/kT)$. If the defects can be aligned by stress, then the fraction with orientation i can be measured and the B -tensor found. The tensor does not depend on an energy barrier between different orientations, but the barrier must be low enough that the defects can reorient in the stress field and thermal equilibrium be established. The tensor B can be obtained by the total energy methods and previous calculations have produced agreement with the experimental stress tensors for an

aggregate of four self-interstitials [1] and oxygen defects [2] in Si.

In this paper we apply the same techniques to the known interstitial centres in diamond. The single, di- and tri-self-interstitial defects have been observed via electron paramagnetic resonance (EPR), labelled R2, R1 and O3, respectively (Figs. 1 and 2(a)). Stress alignment data [8] has only been reported for R2. This has been investigated previously by theory, with good agreement between the calculated and measured B -tensors [3]. Encouraged by this success, we report in this paper B -tensors for a number of other self-interstitial aggregates.

2. Method

We use a local spin-density functional method, AIMPRO, in large supercells containing the defect [2,4]. Each interstitial defect is modelled by placing the appropriate number of extra carbon atoms into the centre of a supercell containing up to 216 host atoms.

To calculate the stress tensor of a defect, one first relaxes the volume of the supercell containing it. This provides information about dilatation which can be measured. Strains are then imposed across the surfaces

of the relaxed supercell and the derivative of the energy with strain provides the components of the B -tensor.

The volume change caused by a defect can, in favourable cases, be measured and compared directly with calculations. We adopt the notation that the fractional change in volume is $\eta[X]/[C]$ for defect X , where $[C]$ is the number density of host sites. η has units of the volume per host atom, $V_{\text{ref}} = a_0^3/8$, and can be then be interpreted as the measured volume change caused by X . As an example A-centres (neighbouring substitutional nitrogen atoms) cause an increase in lattice parameter interpreted as $\eta = 0.11$ [5]. Calculations were carried out in a 64 atom cell containing an A-centre. Volume relaxation yields $\eta = 0.11$, in excellent agreement with the experimental data. This gives us the confidence in evaluating the volume changes associated with other defects.

3. Results

The structure of the single self-interstitial is a $[001]$ -oriented split-interstitial (Fig. 1(a)). For this centre we calculate $\eta = 1.9$, which is a factor of twenty times than that of the A-centre. Due to the high symmetry (D_{2d}), the B -tensor for a defect is given by a single term. For a z -oriented defect, the values of B_{xx} , B_{yy} and B_{zz} found from the 64 atom unit cell are 13.8, 13.8 and -27.6 eV, respectively. The B -tensor can be directly compared with experimental work on R2 [8], which implies $B_{xx} = B_{yy} = 12$ eV, $B_{zz} = -24$ eV.

The R1 EPR centre has been identified with one form of the di-interstitial (I_2) [6]. This consists of two parallel $[001]$ split-interstitial defects sited at nearest neighbour locations so that one pair of dangling bonds is reconstructed. This leaves the remaining pair parallel to a $[1\bar{1}0]$ direction as illustrated in Fig. 1(b). We have calculated the B -tensor and dilatation for I_2 . Since there are non-zero off-diagonal terms in the I_2 B -tensor, we diagonalise this matrix to find its principle values and

Table 1

Principal values and directions for the stress-energy tensors (eV per unit strain) of self-interstitial aggregates. The dilation constant per interstitial η/n is also given

Defect	η/n	B_1	B_2	B_3
I_1	1.9	-27.6	13.8	13.8
(R2)		$[001]$	$[100]$	$[010]$
I_2	1.7	-44.4	41.9	2.6
(R1)		23° to $[00\bar{1}]$	23° to $[110]$	$[1\bar{1}0]$
I_3	1.6	-89.7	45.9	43.8
(O3)		2° to $[001]$	2° to $[100]$	$[010]$
I_4	1.5	-120.5	60.3	60.3
		$[001]$	$[100]$	$[010]$

directions. The diagonal form of the B -tensor is given in Table 1, as well as the volume expansion in terms of η for this centre. Note that the volume dilation per interstitial is lower than that of I_1 , showing that as well as eliminating dangling bonds, aggregation of interstitials also reduces the local strain, and hence the formation energy.

One form of the tri-interstitial eliminates four of the dangling bonds leaving a pair of radicals. This is illustrated in Fig. 2(a), and can be understood as a next-nearest-neighbour di-interstitial in a (110) plane with an additional I_1 in the $(1\bar{1}0)$ plane also at the next-nearest-neighbour site. It possesses a C_2 axis along a cube direction. The D -tensor for the $S = 1$ defect is close to the O3 $S = 1$ EPR centre [7] which also has this symmetry. As before, the additional aggregation reduces the volume relaxation per interstitial (Table 1). The diagonalised B -tensor for I_3 is also given in Table 1.

The structure of the O3 EPR centre leads naturally to a stable form of I_4 shown in Fig. 2(b). This was originally suggested as a building block for $\{001\}$ platelets in diamond [9]. The bond angles only deviate by $\pm 9^\circ$ and bond lengths by $\pm 10\%$ from bulk values. The calculated η and B -tensor are listed in Table 1.

Fig. 2. Diagram showing the geometry of (a) I_3 (O3), and (b) I_4 . Three- and four-fold coordinated interstitial atoms are shown grey and black, respectively.

Note, the total volume relaxation for I_4 is close to that of only three isolated self-interstitials. The experimental value of B_3 for the corresponding defect in silicon is -28 eV [10]. Scaling this experimental value for I_4 in silicon by the ratio of the bulk moduli of diamond to silicon yields a value of $B_{zz} = -126.5$ eV, very close to the calculated value in this study.

Finally, it is useful to compare the volume changes of the interstitial defects with that of the vacancy in diamond. The level of theory employed cannot treat the individual multiplets of the vacancy, and in line with most previous work, we assume the defect is described by a single determinantal wave function. We used a 64 atom supercell from which we have removed a single atom. The atoms bordering the vacancy move outwards and form a cube of length 1.89 Å, but the net volume change of the entire supercell is practically zero, with $\eta < 0.01$. In fact, the only large deviations from bulk positions for the vacancy occur at the nearest neighbours. We conclude that the volume increase due to vacancies is very much less than that for interstitials, and in particular the effect on the lattice due to the single self-interstitial is at least one and probably several orders of magnitude larger than that due to the vacancy.

4. Discussion and conclusions

We have found volume increases and piezospectroscopic tensors B for several self-interstitial defects in diamond. The values of B found for the single interstitial agree very well with the measurements on the R2 EPR centre. To our knowledge, no other alignment studies have been carried out on other EPR centres linked with interstitials, although the R1 and O3 defects could potentially be directly measured. The volume displaced per interstitial diminishes as the aggregates get larger. This, along with the elimination of dangling bonds, contributes to the increased binding energy per interstitial with increasing aggregates size [3].

The very large magnitudes for the B -tensor elements of multi-interstitial defects imply that even for relatively small applied stresses a detectable polarisation of the defect orientation would be apparent, provided that any barrier to reorientation can be overcome.

Finally, it is clear that there is a vast disparity between the volume expansion arising from vacancy and interstitial related centres, of which I_1 is usually by far the dominant species. This means that any volume expansion measured for irradiated material by, for example, X-ray diffraction, arises from the single self-interstitial and not the vacancy. Such a volume effect should be discernible in X-ray experiments on heavily irradiated diamonds provided that the damage leaves the diamond essentially crystalline.

Modeling fluorescence of single nitrogen–vacancy defect centers in diamond

A.P. Nizovtsev^{a,*}, S.Ya. Kilin^a, C. Tietz^b, F. Jelezko^b, J. Wrachtrup^b^a *Institute of Physics, Belarus National Academy of Science, 220072 Minsk, Byelorussia*^b *Institute of Physics, University of Stuttgart, Stuttgart, Germany*

Abstract

Based on new spectroscopic information retrieved by experiments on individual Nitrogen–Vacancy (NV) defect centers in diamond, we introduced the five-level photophysical model of the center and demonstrate its applicability to describe consistently different experiments on single NV centers. The model takes into account the triplet–triplet character of the optical transition $^3A \rightarrow ^3E$ (637 nm) of the center and the presence of a metastable singlet state 1A . Supposing optical excitation rates B_T from spin substates $T = X, Y, Z$ of the ground 3A state as well as the fluorescence emission rates A_T to these substates to be different ($B_Z/B_X \approx 11$, $B_X = B_Y$ while $A_Z/A_X \approx 18$, $A_X = A_Y$), we were able to fit consistently the experimental data obtained for green-laser-excited single NV centers at room-temperature: (i) lineshapes of fluorescence-detected magnetic resonance at 2.88 GHz in the ground 3A state and their changes due to the strains in the diamond crystal, (ii) fluorescence saturation and (iii) photon antibunching/bunching in the fluorescence light emitted by a single NV center. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Single defect; Quantum optics; Optically detected magnetic resonance

1. Introduction

Recently the nitrogen–vacancy (NV) defect center in diamond has been observed [1] and studied in detail spectroscopically [2–5] as an individual quantum object using single molecule spectroscopy (SMS) (see, e.g. Ref. [6] for review). The centers consist of a nitrogen atom (N) and a vacancy (V) in adjacent lattice sites. At low NV concentration (≤ 1 center per μm^3) they are well separated spatially and can be detected individually [1] using scanning confocal microscopy. Therefore, exciting individual NV centers and counting emitted fluorescence photons with an appropriate photon detector, one can measure the average fluorescence intensity $\langle I_0 \rangle$ and the second order fluorescence intensity correlation function $g^{(2)}(\tau) = \langle I_0(t)I_0(t+\tau) \rangle / \langle I_0 \rangle^2$, study their variations from center to center and their changes under additional external influences. Experiments of such kind [1–5] have provided new insight into the photodynamics of the

center and contributed new information to the characterisation of the defect which has a long history based on conventional high-resolution spectroscopic techniques (see, e.g. Refs. [7–9] for review and references). In particular, it has been established [10] that under green/blue optical excitation the centers exhibit strong red fluorescence (yield $\phi = 0.96$) due to dipole-allowed E–A optical transitions with a zero-phonon line (ZPL) at 1.945 eV ($\lambda \approx 637$ nm) and a phonon-assisted band spaced ~ 300 meV apart. The essential feature of the NV center is that its electronic ground state is a spin triplet 3A [7–9,11]. At zero field the state 3A is split by crystal field into a doublet X, Y ($m_s = \pm 1$) and a singlet Z ($m_s = 0$) separated by 2.88 GHz. In turn, the excited electronic triplet state 3E of the center has a rather complicated fine structure [12] originating from spin–spin and spin–orbit interactions as well as from the strain in the crystal. Additionally, the center has a metastable singlet state 1A [13] to which it can escape from the fluorescent 3E state through intersystem crossing (ISC). Optical illumination generates the non-Boltzman distribution of populations of the ground 3A

E-mail address: apniz@dragon.bas-net.by (A.P. Nizovtsev).

state spin sublevels X, Y and Z due to transitions in the optical pumping circle that do not conserve spin projections. As a result, optically excited NV centers exhibit a strong ESR signal at 2.88 GHz. In turn, microwaves (MW) at ~ 2.88 GHz modify the populations of the spin sublevels which results in changes of the fluorescence intensity emitted by the optically excited center, thus providing the basis for a variety of fluorescence-detected magnetic resonance (FDMR) phenomena [7–9,11].

Experiments [1–5] with single NV centers which eliminate completely the effects of inhomogeneous broadening and ensemble averaging allowed (i) to measure the absolute value ($\sim 10\%$) of the FDMR effect [1], (ii) to study the fluorescence saturation [1–5] (saturation power of 1.3 mW has been determined at focused laser beam diameter $\sim 1.6 \mu\text{m}$), (iii) to observe antibunching of the fluorescence photons emitted by the center [3–5]. All the above experiments have been done at room-temperature and under green-laser optical excitation. In Refs. [3–5] the NV center photokinetics has been analysed in terms of the simplest three-level model that ignores the triplet character of the ground 3A state of the center. Here we introduce a more realistic five-level model which allows to describe consistently a wide range of optical and FDMR experiments dealing both with single NV centers and with their ensemble. The model is practically important for quantum optics

due to recent suggestions to use the single NV center as a single-photon emitter [3–5] as well as to a construct quantum computer using ^{13}C nuclear spins in vicinity of the center [14].

2. Five-level model of the NV center

The basic idea of the model for the green-laser-excited NV center is illustrated in Fig. 1 where the left part shows double-well potentials (DWP) for the ground 3A and excited 3E electronic states of the center calculated in Ref. [15] using a simple analytical expression for DWP to fit the experimental fluorescence spectra for few single NV centers [1]. Due to different positions of the DWPs minima, the most effective optical excitation of the center is provided by green/blue optical radiation. Internal conversion (IC) transfers the center to the fluorescing zero-phonon vibrational substate of the N atom in the upper DWP. Transitions to the vibrational states in the ground DWP form the fluorescence spectrum with the outer left transition in the Fig. 1 contributing to the ZPL, while the other ones contribute to the phonon sideband. Fast IC destroys completely the optical coherence, allowing to describe laser excitation of the center in terms of Einstein coefficients $B = bI_{\text{opt}}$. Moreover, it makes it possible not to consider the details of the fast

Fig. 1. Left: Double-well potentials for ground and excited electronic states of the center as well as respective vibrational energies of the N atom within the DWPs calculated in Ref. [15]. The figure takes into account a possible tunneling of the N atom into the vacancy. Right: Spin-triplet substructure of ground 3A and fluorescing excited 3E states and the presence of 'metastable' singlet 1A state S of the center. The five-level photophysical model of the center incorporates the states E, S, X, Y and Z.

movement of the center over intermediate vibrational states and consider only final zero-phonon states. In doing so we will neglect the complicated substructure of the excited state of the NV center [12] and consider it as a single fluorescing state E. On the other hand, to be able to describe the FDMR phenomena within the model we will consider the ground triplet electronic state of the center as consisting of three spin substates X, Y and Z. Additionally, our five-level model incorporates the singlet state 1A which is indicated on the right part of Fig. 1 as state S. According to Dräbenstedt et al. [2] the state S lies at 37 meV lower than the E state. Due to ISC transition the center can be shelved into this state with rate k . Opposite deshelling transitions SE will be taken into account by rate $d = d_T + d_{opt}$ consisted of the contribution d_T due to a phonon absorption as well as the contribution d_{opt} describing possible optical excitation of the center into higher singlet states followed there by ISC transition to the triplet manifold [2].

In general, optical excitation rates B_T from different spin substates $T = X, Y, Z$ as well as the spontaneous emission rates A_T to these substates are different for different substates T. The reasons are the spin-projection selection rules for excitation as well as the simplified description of the excited-state spin manifold as a single level. In particular, different spin sublevels of the excited electronic state are characterized by spin-selective rates for ISC transitions to and from the singlet state S resulting in their different populations. Effectively, these different populations, in combination with selection rules for emission, result in different rates of arrival of the center at the sublevels X, Y, Z by spontaneous emission. Clearly, the total fluorescence rate $A = 13.7$ MHz [16] is $A = A_X + A_Y + A_Z$. Due to symmetry considerations we will suppose spin subsubstates X and Y to be optically equivalent: $B_X = B_Y$ and $A_X = A_Y$.

The density matrix equations for the model can be written straightforwardly using respective rates B_T , A_T , k and d to describe optical and ISC transitions while considering the interaction of a triplet spin with MWs with all necessary details i.e. taking into account MW-induced coherences in terms of density matrix elements ρ_{XZ} , ρ_{YZ} and ρ_{XY} . In the representation rotating with the MW frequency ω , one gets a set of 11 by 11 linear differential equations with constant coefficients. In these equations essential parameters for MW-spin interaction are the Rabi frequency $W = W_{XZ} = W_{YZ} = -mB^\pm$ (m is magnetic dipole matrix element for transitions X(Y)-Z, and B^\pm are MW field amplitudes) and the detuning $\varepsilon = \omega_{XZ} - \omega$, $\varepsilon - \Delta = \omega_{YZ} - \omega$. Decay of coherence (e.g. of the element ρ_{XZ}) is described in these equations by the rate $\Gamma_{XZ} = K_{XZ} + (L_{XZ} + L_{XY} + L_{ZY} + L_{ZX})/2 + (B_X + B_Z)/2$ where K_{XZ} is the rate of pure spin dephasing due to fluctuating nuclear spins

around the NV center, $L_{TT'}$ takes into account spectral diffusion and spin-lattice relaxation and the final term, proportional to the optical intensity ($B_T = b_T I_{opt}$), results from finite lifetimes of spin substates due to optical excitation.

Under steady-state conditions the equations of the model can be solved analytically. The fluorescent state population ρ_{EE}^{st} is calculated to determine the average fluorescence intensity $\langle I_{fluor} \rangle = A\rho_{EE}^{st}$ and to describe the fluorescence saturation with optical power P_{opt} and the FDMR lineshape, i.e. the dependence of $\langle I_{fluor} \rangle$ on the MW frequency ω . The second order correlation function has been calculated according to $g^{(2)}(\tau) = [A_X\rho_{EE|XX}(\tau) + A_Y\rho_{EE|YY}(\tau) + A_Z\rho_{EE|ZZ}(\tau)] / A\rho_{EE}^{st}$, where $\rho_{EETT}(\tau)$ are the transient solutions for $\rho_{EE}(\tau)$ with the initial condition that at time $t = 0$ the center is in the state T. The weight coefficients A_T/A are the probabilities for the center to be in the state T after the emission of the first photon at the moment $t = 0$.

Analysis has shown that a consistent description of the experiments [1–5] can be done if one supposes that the induced absorption rates $B_X (= B_Y)$ and B_Z for the green-laser excited NV center differ by a factor of ~ 11 ($B_Z/B_X \sim 11$), while the fluorescence rates $A_X (= A_Y)$

Fig. 2. Experimental FDMR lineshapes for two individual NV centers [1] and those calculated using the five-level model of Fig. 1 with parameter values indicated in the text. Center 2 exhibits ideal C_{3v} symmetry (zero-field splitting $\Delta = \omega_{XZ} - \omega_{YZ} = 0$) while for center 1 this symmetry is broken due to influence of strain ($\Delta = 5.4$ MHz).

Fig. 3. Noise-corrected experimental $g^{(2)}(\tau)$ functions measured in Refs. [3–5] at different optical powers P_{opt} and those calculated using five-level model of Fig. 1 at parameter values indicated in the text.

and A_Z to these sublevels differ by a factor of 18 ($A_Z/A_X \sim 18$). At room temperature ISC shelving/deshelving rates are high enough: $k \sim A/3$; $d \sim A/10$ with optical deshelling d_{opt} to be negligible. The model with these parameters predicts optical alignment of the center (under low-intensity optical illumination) at which most of population is in Z substate: $\rho_{ZZ}^{\text{st}} \sim 0.4$, $\rho_{XX}^{\text{st}} = \rho_{YY}^{\text{st}} \sim 0.3$, $\rho_{SS}^{\text{st}} \sim 0.006$. The model gives the experimentally monitored value $\sim 10\%$ of the FDMR effect and fits well the FDMR lineshapes (Fig. 2). Using the laser beam diameter as an additional fitting parameter and taking the experimental value of $\sim 0.15\%$ for the fluorescent photon detection efficiency we were able to fit well the experimental data of Refs. [3–5] for the fluorescence saturation behavior, the saturation power $P_{\text{opt}} = 1.3 \text{ mW}$ and the saturated fluores-

cence intensity $\sim 5 \text{ kcounts/s}$. Finally, the correlation functions $g^{(2)}(\tau)$, calculated within the model, fit rather well the noise-corrected experimental ones [3–5], demonstrating strong photon antibunching at short times (Fig. 3). Preliminary analysis shows that additionally the model with the above parameters describes well experimental data on FDMR transients, obtained previously [11] for NV ensemble.

Irradiation effects in semiconducting diamonds

N. Kristianpoller*, D. Weiss, R. Chen

*School of Physics & Astronomy, Raymond and Beverly Sacker Faculty of Exact Sciences, Tel-Aviv University,
Ramat-Aviv, Tel-Aviv 69978, Israel*

Abstract

Effects of X-ray, β and UV irradiation on semiconducting diamonds (type IIb) were studied and compared with those induced at the same conditions in natural (type Ia) and in synthetic diamonds. Methods of optical absorption, of X-ray and light induced luminescence, of thermoluminescence (TL) as well as of optically stimulated luminescence and optically stimulated thermoluminescence (OSL and OSTL) were used for the investigations. The IIb diamonds showed in the UV a weak absorption band at 260 nm and a sharp increase of absorption below 230 nm, while in the Ia samples the absorption increased sharply below 300 nm and absorption bands appeared near 310, 385 and 415 nm. In the X-ray induced luminescence of all samples an emission band appeared near 440 nm; in the Ia samples, additional band was recorded near 500 nm and a very weak one at about 360 nm. In all samples TL could be excited by X-ray, β as well as by 360-nm UV radiation; and in the IIb diamond also by 225 and 470 nm. In the TL of IIb diamonds main emission bands appeared at 475 and 665 nm, and in the OSTL of the Ia samples at 650 nm. The thermal activation energies were evaluated and found to be of about 0.36, 0.52 and 0.67 eV at the 360, 420 and 520 K peaks, respectively. The main TL peaks appeared in all samples above RT at the same temperatures and with the same thermal activation energies. The results indicate that these TL peaks are due to the same radiation induced trapping levels in all investigated types of diamonds, while in the emission of the various samples different luminescence centers are involved. The TL reached in all investigated samples saturation for relatively low radiation doses. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Irradiation effects and formation of radiation induced defects in diamonds have been studied for several decades. Most of these studies concentrated on natural—type Ia diamonds; in some studies also semiconducting—type IIb diamonds were investigated (e.g.: [1–4]). More recently also synthetic diamonds [5] as well as diamond films grown by chemical vapor deposition technique (CVD) [6] were applied for these studies. Some of the CVD diamonds were also found to be highly suitable for application in radiation dosimetry [7].

In the present work, effects of X-ray, β and UV irradiation were studied in semiconducting diamonds (type IIb) and compared with those induced at the same conditions in natural (type Ia) and in synthetic-boron containing diamonds. Methods of optical absorption, of X-ray and light induced luminescence (XL and PL) of thermoluminescence (TL) as well as of optically stimulated luminescence and optically stimulated thermoluminescence (OSL and OSTL) were applied for the studies.

2. Experimental techniques

The X-ray irradiations were performed with a W-tube (40 kV, 15 mA) and the β irradiations with a ^{90}Sr source of a 1.5 Gy/min dose rate. The UV irradiations were

E-mail address: nahum@post.tau.ac.il (N. Kristianpoller).

carried out with a Xe lamp (150 W) and a grating monochromator. The β irradiations were carried out at room temperature (RT) and the X and UV irradiations at various temperatures between 80 and 300 K. The TL measurements above RT were carried out in a TL compartment, flushed by N_2 gas; the heating rate above RT was 5 K/s. For the low temperature absorption, luminescence and thermoluminescence measurements the samples were kept in liquid nitrogen vacuum cryostat and for the TL measurements they were heated at a rate of 20 K/min. The OSTL and OSL were stimulated at various temperatures between 80 and 400 K by monochromatic light in samples which had previously been exposed to X or β radiation. The optical absorption was measured with a Cary 17 spectrophotometer. The PL, OSL, TL and OSTL measurements were taken with Aminco-Bowman/2 luminescence-spectrometer.

3. Results and discussion

3.1. Optical absorption

The I Ib diamonds showed in the UV a weak absorption band near 260 nm and a sharp increase of absorption below 230 nm. In the Ia samples the absorption increased sharply below 300 nm and an additional absorption band appeared on the absorption tail at 310 nm and weaker bands at 385 and 415 nm.

3.2. XL, PL and OSL

During X-ray irradiation at RT, a luminescence band was recorded in the I Ib samples at 450 nm. At liquid nitrogen temperature (LNT) an XL emission band appeared in these samples at 435 nm and was narrower and by an order of magnitude stronger than at RT. In the Ia type diamonds a main XL band was recorded at RT at 445 nm with a shoulder at 500 nm and a weaker band at 360 nm. By cooling to LNT the main 445 nm band intensity increased by a factor of three. In Fig. 1, XL emission spectra of the various types of diamonds are given. No photoluminescence could be detected by UV excitation in the I Ib and in the synthetic diamonds neither before nor after prolonged exposure to ionizing radiation. In Ia samples, which had previously been exposed to ionizing radiation, a luminescence emission could be excited by UV light. This luminescence disappeared after heating to about 800 K and is therefore attributed to an OSL emission, where carriers are trapped by ionizing X-ray or β irradiation at certain defect levels and then optically stimulated by UV or even visible light. These results also indicate that the defects, induced by ionizing radiation, become unstable at about 800 K. The main OSL emission band was at

Fig. 1. X-ray induced emission spectra of various samples measured at LNT: (a) a synthetic diamond, (b) a semiconducting I Ib and (c) a natural Ia diamond.

340 nm and had a stimulation maximum at the absorption peak at 310 nm. An additional broad band was recorded in the Ia samples between 420 and 480 nm; this broad band is apparently composed of two spectral components at 435 and 475 nm. The 340 nm emission band could also be excited by longer wavelengths up to about 550 nm. This finding supports the conclusion that this emission is due to a process of optical stimulation. The intensity of all these OSL emission bands increased markedly by cooling from RT to LNT.

3.3. TL and OSTL

In all samples, TL could be excited by X, β as well as by UV radiation. TL peaks above RT appeared in the various samples at 360, 420 and 520 K. The relative intensities of the various peaks differed and in some samples additional peaks were recorded at about 480 and 550 K. The thermal activation energies at the main TL peaks were evaluated by the “initial rise” and “different heating rate” method (Booth formula) [8]. The values of the thermal energies were found to be in all samples about 0.36, 0.52 and 0.67 eV at the 360, 420 and 520 K peaks respectively.

After irradiation at LNT, different TL peaks appeared in the various samples. After X irradiation, the main peak appeared in the I Ib samples at 265 K, and a weaker one at 145 K. In the Ia samples TL peaks appeared after

LNT irradiation at 180, 225, 260 and 300 K. In the synthetic samples, TL peaks were recorded at 145, 240, 300 and 355 K. The 355 K peak is probably the same as the 360 K peak, which appears after RT irradiation. This 360 K peak decays very fast at RT (about 75% of its initial intensity in 1 min); this is apparently due to thermal fading.

In all examined diamonds, TL could also be excited by UV light and the dependence of the excitation efficiency on the wavelength of the exciting light was measured. TL excitation spectra of the main 360 K peak had in all samples a maximum at 365 nm. In the IIb samples the UV excitation spectrum had an additional main maximum at 225 nm and at LNT also at 470 nm. In the IIb diamonds, the main peak appeared by 225 nm excitation at 265 K and by 365 nm excitation at 285 K. TL excitation spectra are shown in Fig. 2. In Ia diamonds that had previously been X-ray or β irradiated at RT and subsequently illuminated at LNT with light of 310 nm glow peaks were recorded during heating from LNT to RT at 116 and 285 K. These glow peaks could not be excited by 310 nm UV light in un-irradiated Ia diamond samples and not in X or β irradiated samples that were heated to 800 K before exposure to the 310 nm illumination. These 116 and 285 K glow peaks excited by the 310 nm illumination are therefore attributed to a process of OSTL. In this process, carriers which were trapped by the ionizing radiation in deep traps at RT, are subsequently stimulated by the illuminating light and

transferred to shallower traps; the OSTL is emitted during their thermal release and radiative recombination. It may be noted that the wavelength of 310 nm was also optimal for the stimulation of OSL in pre-irradiated Ia samples. In the pre-irradiated synthetic diamonds, illumination with 500 nm caused the optical bleaching of the 520 K TL peak and the rise of the 420 K peak; this is also attributed to a photo-transfer from a deep trap to a shallower one. No OSTL was recorded in the IIb samples.

The spectral composition of the TL emission was measured at the main glow peaks. In the TL emission of type IIb diamonds, the main bands appeared at 475 and 665 nm. The emission of the main OSTL peak in the Ia diamonds was at 650 nm. Emission spectra measured at the main glow peaks are shown in Fig. 3. The fact that different emission bands appeared in the various examined diamonds indicate that different luminescence centers are involved in the emission of these samples. The finding that the main TL peaks appeared in the various samples at the same temperatures and with the same thermal activation energies indicate that these TL peaks are due to the same radiation induced trapping levels.

Fig. 3. TL Emission spectra of IIb diamond recorded after UV irradiation at LNT with: (a) 225 nm, (b) 360 nm UV light and (c) emission spectrum of Ia diamond, recorded at the 116 K OSTL peak after X irradiation at RT and 310 nm illumination at LNT.

Fig. 4. Dependence of the TL intensity on beta dose of: (a) Ia diamond (enlarged $\times 10$), (b) IIb diamond and (c) synthetic diamond.

The dependence of the TL intensity on the dose of the exciting radiation were also measured. The dependence

of the TL intensity on the dose of the exciting β radiation is shown in Fig. 4 for the various investigated types of diamonds. It can be seen that the TL intensity reaches in these samples saturation for relatively low doses. A similar behavior of dose dependence was also recorded for UV excited TL. This behavior is not favorable for application in TL dosimetry, but may be different for other types of synthetic diamonds.

Nickel related defects in diamond: the 2.51 eV band

M.H. Nazaré*, J.C. Lopes, A.J. Neves

Departamento de Física, Universidade de Aveiro, 3810 Aveiro, Portugal

Abstract

Optical and magnetic properties of nickel related defects in as-grown diamond are reviewed. Published and new data on the problem of negatively charged substitutional nickel are presented and discussed. We show that the 2.51 eV absorption band occurs at the Ni_i^- , the spin-orbit and the Jahn–Teller interactions playing important roles in the optical properties of the defect. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Diamond; Nickel; Spin-orbit; Optical properties

1. Introduction

Transition metals (TMs), namely nickel, cobalt, iron, manganese and most of the first TM series, are used as solvent catalysts during the growth of diamond; hence the metals can become incorporated in the diamond, at atomic level, as point defects. However, only nickel and cobalt are known to exist in this way [1–3], i.e. bonded to the diamond lattice; the other TMs appear to resist incorporation or avoid detection. Nickel is now known to form optical and paramagnetic centres, and to have complex interactions with nitrogen. The observed properties of Ni related centres strongly depend on the nitrogen concentration ($[\text{N}]$) in the diamond. In as-grown high-pressure high-temperature diamond, either interstitial or substitutional Ni is observed, depending on the concentration of neutral nitrogen, $[\text{N}^0]$, which controls the Fermi energy and hence the charge state of the active centres.

In as-grown diamonds with $[\text{N}] < 10$ ppm, two Ni interstitial EPR centres are observed. The NIRIM1 has an isotropic g -factor, and is assumed to be a tetrahedral Ni_i^+ atom; the NIRIM2 has $g_{\perp} \sim 0$ and $g_{\parallel} = 2.3285$, and is assumed to be Ni_i^+ in trigonal symmetry [4]. Also, nickel related absorption bands occur at 1.2, 1.4 and 3.1 eV. The 1.4 eV system, which can be detected in luminescence as well, consists of a zero-phonon doublet,

at 1.401 and 1.404 eV. The splitting of the ground state was accounted for in terms of spin-orbit (S–O) interaction. Fine structure in each of the doublet has shown to be due to isotopic splitting and is consistent with one nickel atom per optical centre [5]. Uniaxial stress and Zeeman measurements have led to the conclusion that the defect has trigonal symmetry and that both the ground doublet and the excited singlet have effective spins $S = \frac{1}{2}$; the g -values, determined from the Zeeman data for the ground state of the doublet, agree with the g -values of the EPR study of the NIRIM2 defect. Therefore, it was then concluded, and recently confirmed [6,7], that the centre concerned is an interstitial positive Ni ion, Ni_i^+ , in a trigonal environment.

In as-grown diamonds with $[\text{N}] > 50$ ppm, an isotropic EPR signal (W8) with $g = 2.0319$ has been identified with the negative charge state of isolated substitutional nickel, Ni_s^- [8]. Optical features typical of these diamonds are two centres with zero-phonon lines (ZPLs) at 1.885 and 2.51 eV. The 1.885 eV defect has rhombic-I symmetry and, given the circumstantial evidence, it was suggested to occur at a Ni–N complex [9]. Absorption at 1.885 and at 2.51 eV has been tentatively correlated with the strength of the W8 signal [10], however, no definite answer was produced.

In this paper, using high-resolution absorption data and uniaxial stress measurements, we show that the 2.51 eV ZPL is consistent with a transition from a $^4\text{A}_2$ ground state into a $^4\text{T}_2$ excited state at a tetrahedral

*Corresponding author. Fax: +351-2344-24965.

E-mail address: mhnazare@fis.ua.pt (M.H. Nazaré).

defect; such a transition is forbidden by symmetry, but becomes allowed through S–O induced mixing of the excited and fundamental states. Furthermore, we show that S–O interaction splits the excited state, giving rise to the fine structure observed in the ZPL. In view of the results we propose that in fact the 2.51 eV absorption band occurs at the negatively charged substitutional nickel (Ni_s^-) that is the same defect where the W8 EPR signal occurs.

2. Experimental details

The samples used in this work were synthetic diamond grown by the Japanese Institute for Research in Inorganic Materials. Absorption measurements were made using a 100 W quartz-halogen tungsten lamp. Light from the sample was analysed and detected by a SPEX monochromator fitted with a 1200 grooves/mm grating and an RCA photomultiplier. Uniaxial stresses were applied using oil driven push rods, the samples being cooled by liquid nitrogen or liquid helium.

3. The 2.51 eV zero-phonon line shape

The 2.51 eV absorption band is depicted in Fig. 1. The ZPL is a multiplet spanning about 1.5 meV. Previous work [11] showed that the fine structure must be due to a split excited state and cannot be accounted for in terms of isotopic splitting originated by the different abundances of the Ni isotopes. The same work reported uniaxial stress measurements carried out at 77 K (at this temperature no fine structure can be detected), suggesting that the 2.51 eV centre has tetrahedral symmetry, the ZPL occurring between T_2 states. However no obvious explanation was advanced for the lack of splitting under stress of the ground state, nor for the unfitting predictions regarding the relative intensities. These discrepancies can be clarified in a model that considers

the 2.51 eV band to occur between the ground and first excited states, predicted by crystal field theory, of the Ni_s^- , that is between a 4A_2 ground state and a 4T_2 excited state. Although such transition is symmetry forbidden, S–O interaction makes it possible through mixing the excited 4T_2 state with the 4A_2 ground state; such being the case, and loosely speaking, the splitting pattern under stress would look like that of a transition between two T_2 states, where the ground state is not split. We now show that the fine structure can also be consistently accounted for in terms of the above model.

The Hamiltonian for a TM ion of the d^n configuration, placed in a cubic crystal field, can be written as

$$H = H_{\text{cub}} + H_{\text{S-O}}, \quad (1)$$

the two terms representing the crystal field and the S–O interaction, respectively.

At a site of tetrahedral symmetry, the lowest free ion term, 4F , of Ni_s^- ($3d^7$) is split by the crystalline field into an orbital ground state 4A_2 (Γ_2) at $-720B_4$, a 4T_2 (Γ_5) state at $-120B_4$ and a 4T_1 (Γ_4) state at $360B_4$. First order S–O interaction splits the 4T_2 state into $J = 1/2$ (Γ_7) at $5\lambda/2$, $J = 3/2$ (Γ_8) at λ and $J = 5/2$ ($\Gamma_8 + \Gamma_6$) at $-3\lambda/2$; second orders effects further split the $J = 5/2$ states.

The S–O splitting of a cubic term can be described by the effective Hamiltonian of second order in L and S [12]:

$$H_{\text{S-O}} = \lambda(\mathbf{L} \cdot \mathbf{S}) + \kappa(\mathbf{L} \cdot \mathbf{S})^2 + \rho(L_X^2 S_X^2 + L_Y^2 S_Y^2 + L_Z^2 S_Z^2). \quad (2)$$

Here, S is the spin (3/2) and L is the effective orbital-momentum operator within the cubic term ($L = 1$ for a T_2 term). The 4T_2 excited state can be written as the product of a spatial ($|T_{2i}\rangle$, $i = x, y, z$) and a spin ($|x_j\rangle$, $j = -3/2, \dots, +3/2$) part transforming as the Γ_5 and Γ_8 representations of the T_d double group respectively. In this basis set, the secular matrix of the Hamiltonian in Eqs. (1) and (2) can be written as

$$\begin{bmatrix} 3\beta + \Delta & 0 & -\sqrt{3}\beta/2 & 0 & i\delta/4 & 0 & i\sqrt{3}\kappa/2 & 0 & 0 & \sqrt{3}\gamma/4 & 0 & 0 \\ 0 & 2\beta + \Delta & 0 & -\sqrt{3}\beta/2 & 0 & i\delta/4 & 0 & i\sqrt{3}\kappa/2 & -\sqrt{3}\eta/4 & 0 & \lambda - \kappa/2 & 0 \\ -\sqrt{3}\beta/2 & 0 & 2\beta + \Delta & 0 & -i\sqrt{3}\kappa/2 & 0 & -i\delta/4 & 0 & 0 & \delta/2 & 0 & \sqrt{3}\eta/2 \\ 0 & -\sqrt{3}\beta/2 & 0 & 3\beta + \Delta & 0 & -i\sqrt{3}\kappa/2 & 0 & -i\delta/4 & 0 & 0 & \sqrt{3}\gamma/4 & 0 \\ -i\delta/4 & 0 & i\sqrt{3}\kappa/2 & 0 & 3\beta + \Delta & 0 & \sqrt{3}\beta/2 & 0 & 0 & i\sqrt{3}\gamma/4 & 0 & 0 \\ 0 & -i\delta/4 & 0 & i\sqrt{3}\kappa/2 & 0 & 2\beta + \Delta & 0 & \sqrt{3}\beta/2 & -i\sqrt{3}\eta/4 & 0 & i\delta/2 & 0 \\ i\sqrt{3}\kappa/2 & 0 & i\delta/4 & 0 & \sqrt{3}\beta/2 & 0 & 2\beta + \Delta & 0 & 0 & i\delta/2 & 0 & i\sqrt{3}\eta/4 \\ 0 & i\sqrt{3}\kappa/2 & 0 & i\delta/4 & 0 & \sqrt{3}\beta/2 & 0 & 3\beta + \Delta & 0 & 0 & i\sqrt{3}\gamma/4 & 0 \\ 0 & -\sqrt{3}\eta/4 & 0 & 0 & 0 & i\sqrt{3}\eta/4 & 0 & 0 & 3\beta/2 + \Delta & 0 & 0 & 0 \\ -\sqrt{3}\gamma + 4 & 0 & \delta/2 & 0 & -i\sqrt{3}\gamma + 4 & 0 & i\delta/2 & 0 & 0 & 7\beta/2 + \Delta & 0 & 0 \\ 0 & \lambda - \kappa/2 & 0 & \sqrt{3}\gamma + 4 & 0 & i\delta/2 & 0 & i\sqrt{3}\gamma + 4 & 0 & 0 & 7\beta/2 + \Delta & 0 \\ 0 & 0 & \sqrt{3}\eta + 4 & 0 & 0 & 0 & i\sqrt{3}\eta + 4 & 0 & 0 & 0 & 0 & 3\beta/2 + \Delta \end{bmatrix}$$

Fig. 1. The 2.51 eV absorption band, recorded at 4 K. The zero-phonon line is a multiplet spanning about 1.5 meV.

Here, $\beta = \kappa + \rho$, $\delta = \kappa - 2\lambda$, $\gamma = 3\kappa - 2\lambda$, $\eta = \kappa + 2\lambda$ and $\Delta = 600B_4$ are the energy separation between the ground (4A_2) and the first excited state (4T_2) before S–O interaction. Fitting the eigenvalues of the above matrix to the measured energy values and the intensity ratio of the components in the ZPL, calculated using the eigenvectors, to the measured ones, yields the following set of values for the parameters (all but the first in meV):

$$\begin{aligned} \Delta &= 2.5105 \text{ eV}, \quad \lambda = -0.163, \\ \kappa &= -0.326, \quad \rho = 0.532. \end{aligned} \quad (3)$$

Fig. 2 shows a comparison between the experimental zero-phonon band shape and the calculated one,

Fig. 2. Comparison between the experimental (points) zero-phonon band shape (the same as in Fig. 1) and the calculated one (line). A bi-Lorentzian shape for each component has been assumed. The values of the parameters (see text) were: $\Delta = 2.5105$ eV and (in meV) $\lambda = -0.163$, $\kappa = -0.326$ and $\rho = 0.532$.

assuming a bi-Lorentzian shape for each component of the ZPL, $I(\nu) = a/[b + (\nu - \nu_0)^2]^2$, and using the values in Eq. (3) to calculate the intensity (a) and the energy (ν_0) of each component. The width (b) of each component was measured experimentally.

4. Uniaxial stress results

The effects on the energies of the ZPLs of uniaxial compressions of up to 2 GPa applied along the $\langle 001 \rangle$, $\langle 111 \rangle$ and $\langle 110 \rangle$ axes, with the crystal cooled to 4 K, are shown in Fig. 3. The data are consistent with the 2.51 eV ZPLs being transitions from a 4A_2 ground state into a 4T_2 excited state in the centre of tetrahedral symmetry. The excited state is split into a quartet by S–O interaction taken to second order.

Since the strains used in the experiments are small, the stress-induced change in the Hamiltonian is linear in the stress tensor components σ_{ij} , and can be written as:

$$\begin{aligned} \Delta H &= C_A(\sigma_{xx} + \sigma_{yy} + \sigma_{zz}) + C_{E0}(2\sigma_{zz} - \sigma_{xx} - \sigma_{yy}) \\ &\quad + C_{E0}\sqrt{3}(\sigma_{xx} - \sigma_{yy}) + C_{xz}\sigma_{xz} + C_{zx}\sigma_{zx} + C_{xy}\sigma_{xy}. \end{aligned} \quad (4)$$

Here the electronic operators C_A, \dots, C_{xy} transform as shown by the subscripts in the tetrahedral point group. In terms of the basis set we define matrix elements $B = 2\langle T_{2x} | C_{E0} | T_{2x} \rangle / \sqrt{3}$ and $C = \langle T_{2x} | C_{xy} | T_{2y} \rangle$.

In the experiments it is not possible to separate the effects of totally symmetric stresses σ_{ij} on the excited T_2 and ground A_2 states, hence we define the parameter $A = \langle T_{2x} | C_A | T_{2x} \rangle - \langle A_2 | C_A | A_2 \rangle$. The analysis is simplified by noting that there are no matrix elements of the stress perturbation between states of different spins.

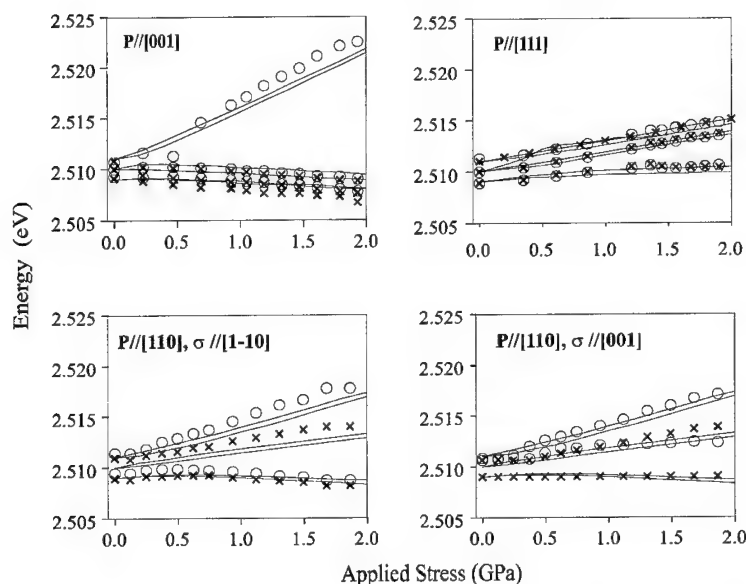

Fig. 3. Theoretical (lines) and experimental stress-induced splittings of the 2.52 eV zero-phonon line at 4 K (experimental points for $P//[110]$ were obtained at 77 K).

The lines in Fig. 3 have been calculated using this theory with the parameters: $A = 1.45$ meV/GPa, $B = 2.15$ meV/GPa, and $C = -1.93$ meV/GPa. The agreement between the predictions and the data establishes that the defect has tetrahedral symmetry, and that the 2.51 eV transition occurs between 4A_2 and 4T_2 states. Spin-orbit interaction admixes the ground and excited states, which makes the transition possible, and also produces the fine structure splitting.

5. Discussion

The work of Isoya et al. [8] shows that the $g = 2.0319$ EPR signal is from a Ni^{2+} ($3d^7$) located at a substitutional site in diamond, with an effective spin $S = 3/2$. We have shown that the fine structure and behaviour under applied stress of the 2.51 eV ZPL is consistent with a transition occurring between 4A_2 and 4T_2 states at a tetrahedral defect. These have the predicted symmetry and order of the crystal field split states originated from a 4F term of the d^7 electronic configuration expected for the Ni^{2+} ion in diamond, hence the conclusion that both the EPR signal and the 2.51 eV optical transition originate at the same defect.

The orbital degeneracy of the excited state implies that it is unstable against distortions, which lower its symmetry and lift the electronic degeneracy. This type of instability, first studied by Jahn and Teller, couples the electronic and vibrational motions lowering the energy of the symmetrical configuration by E_{JT} . If the Jahn–

Teller and the S–O interactions are comparable, it has been shown that the Jahn–Teller coupling partially quenches the first order S–O interaction within the T_2 state, reducing it by a factor $Q \cong \exp[-3/2(E_{JT}/\hbar\omega)]$, where $\hbar\omega$ is the average energy for the effective phonons, while it may either diminish or enhance the second order S–O interactions within this state [13,14]. The g -value for the ground state is related to $A = 2\lambda$ through $g = g_e - 8A/\Delta$; this gives for λ , within the ground state, a value of -4.7 meV, about 30 times larger than the S–O coupling parameter within the 4T_2 state. This indicates the importance of Jahn–Teller coupling to understand fully the optical properties of the Ni_s^{2+} .

Abstract

The low-temperature X-band EPR study of Ky1 and Ky2 centers assigned to positively charged carbon vacancy (V_C^+) in two quasicubic sites of 6H–SiC crystal is presented. The C_s symmetry, spin $S = 1/2$ and close coincidence of the g -tensor components have been revealed. The principal values of g -tensor are determined as $g_z = 2.0048$, $g_x = 2.0022$ and $g_y = 2.0037$ for Ky2 defect, where z - and x -directions reside in the $(1\ 1\ \bar{2}\ 0)$ plane and the z -axis makes up an angle 65° with the c -axis. The same residence of z - and x -axis and an angle 59° are found for Ky1 center with $g_z = 2.0058$, $g_x = 2.0025$ and $g_y = 2.0023$. For Ky2 center, the principal values and corresponding directional cosines of the hyperfine (HF) interaction tensor A are determined for four Si atoms in the nearest neighborhood of the defect. Ky3 center is tentatively proposed as V_C^+ defect in quasihexagonal site of 6H–SiC. The results of ab initio DFT calculations using cubic $C_{18}Si_{16}H_{36}$ and hexagonal $C_{18}Si_{20}H_{40}$ clusters corroborate the main features of proposed V_C^+ defect models including the point symmetry and values of HF parameters. © 2001 Elsevier Science B.V. Keywords: Intrinsic defect; Carbon vacancy; Silicon carbide; EPR

1. Introduction

Positively charged carbon vacancy V_C^+ was originally identified in p-type cubic SiC based on the intensity ratio of all hyperfine satellite lines to the main lines [1]. An EPR spectrum labeled T5 belongs to a paramagnetic defect with D_2 symmetry, spin $S = 1/2$ and axially symmetric HF tensor along $\langle 1\ 1\ 1 \rangle$ axis, $A_{||} = -18.9 \times 10^{-4} \text{ cm}^{-1}$ and $A_{\perp} = -13.8 \times 10^{-4} \text{ cm}^{-1}$. In the recent publications a variety of carbon vacancy-related defects have been found in electron irradiated p-type 4H- and 6H–SiC [2–6]. Some of them with the HF constants being about twice as large as for T5 center have also been attributed to V_C^+ center [4–6]. Subsequently, a revision of T5 nature as the $(V_C + 2H)$ complex has been proposed in Ref. [7].

As was found in our previous work [4], three carbon vacancy-related defects labeled Ky1, Ky2 and Ky3 are

detected in boron-doped 6H–SiC crystals after a high dose 2 MeV electron irradiation. The spin Hamiltonian parameters for $T \geq 77 \text{ K}$ were found for Ky1, Ky2 and Ky3 defects when some indications of motional averaging were observed [4]. However, the ultimate elucidation of defect nature requires the knowledge about its low-temperature symmetry. In this paper, we focus on the X-band EPR study of Ky1 and Ky2 centers at 4.2 K.

2. Experimental

The samples for electron irradiation were high quality Lely-grown 450 μm thick crystals of 6H–SiC with boron content of about $4 \times 10^{17} \text{ cm}^{-3}$. The electron irradiation was performed at 77 K with 2.0 MeV electron beam parallel to the crystal c -axis up to the dose of $1 \times 10^{18} \text{ cm}^{-2}$. The X-band EPR spectra of carbon vacancy-related defects were measured at 4.2 K at microwave power level of 40 nW. The angular variations were studied for a rotation of the magnetic field in three mutually perpendicular $(1\ 1\ \bar{2}\ 0)$, $(1\ \bar{1}\ 0\ 0)$ and $(0\ 0\ 0\ 1)$

crystal planes. The g -values were determined with a precision of $\Delta g = \pm 0.0001$ via a microwave frequency counter and a calibration of the magnetic field by a proton NMR probe.

3. Results and discussion

Six-line EPR spectra observed for Ky1 and Ky2 centers for rotation of the magnetic field in $(1\bar{1}\bar{2}0)$ crystal plane indicate C_s symmetry, spin $S = 1/2$ and a close coincidence of the g -tensor components. Distinctly oriented defects are magnetically equivalent in couples when magnetic field is rotated in $(1\bar{1}00)$ plane and three-line spectrum is detected for either center as shown in Fig. 1a. The spectrum Ky3 is only observed at a higher temperature, $T \geq 30$ K. Fig. 2 shows the angular variations of Ky1 and Ky2 central lines in three mutually perpendicular $(1\bar{1}\bar{2}0)$, $(1\bar{1}00)$ and (0001) crystals planes. From these dependences, the principal

values of g -tensor have been determined as $g_z = 2.0048$, $g_x = 2.0022$ and $g_y = 2.0037$, where z and x directions reside in the $(1\bar{1}\bar{2}0)$ plane and the z -axis makes up an angle 65° with the c -axis as shown in Fig. 3. The same residence of z - and x -axis and an angle 59° are found for Ky1 center, $g_z = 2.0058$, $g_x = 2.0025$ and $g_y = 2.0023$. Spin Hamiltonian parameters corresponding to HF

Table 1
Experimentally determined hyperfine parameters of Ky2 center in 6H-SiC

Ligand atom	Principal values of HF tensor (MHz)	Directional cosines corresponding to $A_{ }$
Si1	$A_{ } = 180.7 \pm 0.2$ $A_{\perp} = 119 \pm 1$	$l = (-0.13 \pm 0.01; 0.00; 0.991 \pm 0.001)$
Si2	$A_{ } = 129.5 \pm 0.6$ $A_{\perp} = 87 \pm 1$	$l = (0.85 \pm 0.01; 0.00; -0.53 \pm 0.01)$
Si3	$A_{ } = 153.7 \pm 0.3$ $A_{\perp} = 108 \pm 1$	$l = (0.60 \pm 0.02; 0.77 \pm 0.02; 0.22 \pm 0.01)$
Si4	$A_{ } = 153.7 \pm 0.3$ $A_{\perp} = 108 \pm 1$	$l = (0.60 \pm 0.02; -0.77 \pm 0.02; 0.22 \pm 0.01)$

interaction with nuclei of four Si atoms in the nearest neighborhood are determined just for the Ky2 defect and presented in Table 1. Each of these nuclei is characterized by quasiall HF tensor and an angle α between principal axis associated with $A_{||}$ and direction from the undistorted position of a Si atom to the center of the defect. The directional cosines listed in Table 1 correspond to α values in the range of 8–12°.

Due to longer then for Ky2 center spin-relaxation time, low intensity of the Ky1 spectrum precludes from the determination of its HF parameters at 4.2 K. The close values of HF parameters for Ky1 and Ky2 centers were found at 77 K, where their spectra have the same intensities [4]. Thus, from the identical spin and close values of the g -tensors and HF parameters, it is tempting to suggest that Ky1 and Ky2 spectra originated from the same carbon vacancy-related defect in two quasicubic sites of 6H-SiC crystal. In previous paper [4], this suggestion was supported by cluster calculations of the point symmetry and HF parameters with tetrahedral 52-atom clusters $\text{Si}_4\text{C}_{12}\text{H}_{36}$ and $\text{Si}_3\text{BC}_{12}\text{H}_{36}$ and geometry optimization at UHF/6-31G(d) level of theory [8] with fixed H atoms. In our new approach [9], the geometry optimization of larger 70-atom $\text{C}_{18}\text{Si}_{16}\text{H}_{36}$ cubic cluster has been performed with higher density functional level of theory and all electron split valence Gaussian basis set 6-311G(d) with polarization d-functions for both Si and C atoms. The D_{2d} point symmetry and the same $A_{||} \cong -166$ MHz, $A_{\perp} \cong -97$ MHz hyperfine parameters for all the four nearest Si atoms have been obtained. Relatively slight deviation of experimentally determined HF tensor from the D_{2d} point symmetry and close coincidence with theoretical values demonstrate a rather small perturbation of V_C^+ in quasicubic sites of 6H-SiC by axial crystal field.

The assignment of Ky1 and Ky2 centers to V_C^+ defect in two quasicubic sites of 6H-SiC lattice generates a question regarding the microscopic structure of V_C^+ in hexagonal site. As was pointed out earlier [4], the HF structure of Ky3 spectrum involves three doublets with an intensity ratio 1:1:2 (Fig. 4) analogous to Ky1 and Ky2 spectra. Additional observation of similar hyperfine structure on low-field HF line of Ky3 spectrum (Fig. 4c)

Fig. 4. X-band EPR spectrum of electron-irradiated 6H-SiC $\langle B \rangle$ for orientation of the magnetic field B parallel to the $[1\bar{1}00]$ direction (a). The details of hyperfine structure of Ky3 defect central line (b) and low-field HF line (c) are also shown, $T = 77$ K, $\nu = 9.072$ GHz.

suggests that this defect can be a candidate for V_C^+ in hexagonal site. Preliminary calculations of V_C^+ hyperfine parameters with 78-atom hexagonal cluster [9] reveal the dramatic changes of spin density distribution over four nearest Si atoms as compared to the cubic cluster. The major part of spin density is localized on Si1 and Si2 atoms located in a symmetry plane, see Fig. 3. Curiously, it has been found that the largest HF parameters take place for Si1 atom lying along the c -axis and equal to $A_{||} \cong -164 \times 10^{-4} \text{ cm}^{-1}$ and $A_{\perp} \cong -99 \times 10^{-4} \text{ cm}^{-1}$ in close agreement with the experimental values [4].

Notice that EI6 defect having the similar parameters as Ky3 center has been tentatively attributed to carbon antisite Si_C^+ [5]. However, five HF doublets should be observed in this case in accordance with the number of silicon atoms for such a defect.

In conclusion, the C_s point symmetry and parameters of spin Hamiltonian have been found from a low-temperature study of positively charged carbon vacancy in two quasicubic sites of 6H-SiC crystal. Ky3 center is

tentatively proposed as V_C^+ defect in quasihexagonal site of 6H-SiC. The results of ab initio DFT calculations using cubic $C_{18}Si_{16}H_{36}$ and hexagonal $C_{18}Si_{20}H_{40}$ clusters corroborate the main features of proposed V_C^+ defect models including the point symmetry and values of HF parameters.

Abstract

Radiation-induced defects in 6H-silicon carbide were investigated with electron paramagnetic resonance (EPR), the magnetic circular dichroism of the absorption (MCDA) and MCDA-detected EPR (MCDA-EPR). In irradiated samples, annealed beyond the annealing temperature of the isolated silicon vacancy (V_{Si}), we observed photo-EPR spectra of spin $S = 1$ centers, having the symmetry of nearest neighbor pair defects. By MCDA-EPR, they were associated to optical transitions with photon energies between 999 and 1075 meV. The hyperfine structure of the EPR spectra shows the presence of one single carbon and several silicon ligands. The experimental results are interpreted with the help of total energy and spin density data obtained from the standard local-density approximation of the density-functional theory, using relaxed defect geometries obtained from the self-consistent charge density-functional theory based tight binding scheme. The only model that explains all experimental findings is the photo-excited spin triplet state of the carbon antisite–carbon vacancy pair ($C_{Si}-V_C$) in the doubly positive charge state. We conclude that the $C_{Si}-V_C$ defect is formed from V_{Si} as an annealing product by the movement of a carbon neighbor into the vacancy. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon carbide; Vacancies; Antisite; Electron paramagnetic resonance

1. Introduction

The silicon vacancy (V_{Si}) is a basic defect in silicon carbide (SiC) which can be introduced during crystal growth or by irradiation with high-energy particles, e.g. during ion implantation. The negatively charged V_{Si}^- has been identified by electron paramagnetic resonance (EPR). It anneals out at 750°C with an activation energy of 2.2 ± 0.3 eV [1]. In elemental semiconductors, a lattice vacancy can anneal out by moving through the lattice. In a compound semiconductor like SiC, the situation is more complicated, because chains of antisite defects must be created if the vacancy moves by nearest neighbor hops. It has recently been proposed that the first step in such an annealing process, the transforma-

tion of V_{Si} into the $C_{Si}-V_C$ antisite-vacancy pair, is a quite probable process [2]. Here, we provide experimental evidence for the presence of the pair after annealing.

2. Experimental

The nitrogen-doped (10^{18} cm^{-3}) 6H–SiC samples were grown by the sublimation sandwich method. They were irradiated with reactor neutrons at a dose of $2 \times 10^{18} \text{ cm}^{-2}$ and then annealed for 2 min at 600°C, 1000°C and 1200°C, respectively. One sample of the same batch was left unirradiated, and another sample was irradiated but not annealed. EPR was measured with X-band (9.8 GHz) at 7 K. The samples were illuminated in situ with the light of a halogen lamp. The paramagnetic part of the magnetic circular dichroism (MCDA) is proportional to the spin polarization of the ground state of the optical transition. Saturating

E-mail address: lingner@physik.uni-paderborn.de (T. Lingner).

EPR transitions change the spin polarization which is observed as a decrease of the MCDA signal intensity (MCDA-EPR).

3. Computational

We used the self-consistent linear muffin-tin orbitals method in the atomic spheres approximation (LMTO-ASA), treating exchange and correlation effects within the framework of the local spin density approximation of the density-functional theory (LSDA-DFT) [3]. The atomic positions of the relaxed structure were obtained from additional calculations within the self-consistent charge density-functional theory based tight-binding (SCC-DFTB) scheme [4]. In a $(5 \times 6 \times 1)$ supercell model of the 6H polytype containing 300 atoms, the defect and its nearest and next nearest neighbors were relaxed. The relaxation energies were added to the LMTO total energies. Starting from the relaxed structures obtained from SCC-DFTB, the hyperfine (HF) interactions were calculated within an extended version of the LMTO-ASA Green's function method. For further details of this combined approach, see also Ref. [5].

4. Results and discussion

The EPR signal of neutron-irradiated and annealed 6H-SiC consists of six spin-triplet spectra. The angular dependence (Fig. 1) was analyzed using the usual spin Hamiltonian for $S = 1$ including fine structure (Table 1). For three of the centers (P6a, b and c), the principal axis z of the fine structure tensor is parallel to the c -axis of

Table 1

EPR parameters, angle θ between the principal axis of the fine structure tensor and the c -axis, and optical transition energies of the P6/P7 centers^a

Center	g	D (10^{-4} cm^{-1})	E (10^{-4} cm^{-1})	θ (deg)	$h\nu$ (meV)

P6c	2.003	430	0	0	1011
P7a	2.003	449	-4	71.2	1049
P7b	2.003	441	46	70.0	1030
P7c	2.003	416	-1	70.5	999

^a The notations P6 and P7 for the axial ($\theta = 0^\circ$) and the basal ($\theta \approx 71^\circ$) orientations is adopted from Ref. [6]. D is axially symmetric, E the anisotropic fine structure constant [9].

the crystal (axial orientations). The z -axis of the other three centers (P7a, b and c) is oriented in the six $\{11\bar{2}0\}$ planes at an angle θ to the c -axis (basal orientations). The angle θ is close to the ideal tetrahedral angle (70.529°). The letters a, b and c denote three different spectra of each orientation, which are thought to arise from the defect at the three inequivalent lattice sites in 6H-SiC. Similar spectra have been measured by EPR [6] and PL-EPR [7], but only two lattice sites have been identified so far [7].

The P6/P7 spectra were present in the samples annealed at 600°C , 1000°C and 1200°C . Their highest intensity was observed after a 1000°C anneal. They were not found in the unannealed and in the unirradiated samples. All EPR spectra emerged only during illumination with photon energies above $1.1 \pm 0.1 \text{ eV}$ and hence, belong to a photo-excited state.

The MCDA and photoluminescence (PL) spectra of the unannealed and the 600°C -annealed sample showed optical transitions of the V_{Si} -related defect reported in Ref. [8]. This signal is absent after a 1000°C anneal. Instead, MCDA lines between 1 and 1.1 eV are observed (Fig. 2). In each of these MCDA lines, a single EPR spectrum from Table 1 was detectable with MCDA-EPR. The higher the value of D , the larger is the photon energy of the optical transition observed.

The HF splitting of the P6c EPR signal (Fig. 3) indicates the presence of one single ^{13}C nucleus ($A = 48 \text{ MHz}$, intensity of one HF line $0.7 \pm 0.2\%$ of the central line) and four to eight ^{29}Si neighbors ($A = 12 \text{ MHz}$, intensity $15 \pm 5\%$ of the central line). The ^{29}Si -related HF lines are broadened and may contain contributions from different Si neighbor shells with similar HF constants.

The symmetry characteristic for a nearest neighbor pair defect and the intrinsic nature of the defect, limit the possible models to the vacancy pair ($V_{\text{Si}}-V_{\text{C}}$), the antisite pair ($\text{C}_{\text{Si}}-\text{Si}_{\text{C}}$) and the vacancy-antisite pairs

Fig. 1. Angular dependence of the P6/P7 EPR-spectra in 6H-SiC, measured at $T = 7 \text{ K}$ in X-band (9.87 GHz). Dots indicate the experimental data. The solid lines are calculated curves using the parameters given in Table 1.

Fig. 2. MCDA spectrum of neutron-irradiated and at $T_{\text{ann}} = 1000^\circ\text{C}$ -annealed 6H-SiC, measured under additional excitation of the sample with an Ar-ion laser. In each of the P6/P7 MCDA lines, one of the EPR spectra from Table 1 was measured with MCDA-EPR.

Fig. 3. Hyperfine structure of the P6c low field line for $\mathbf{B} \parallel \mathbf{c}$. The line marked with an asterisk belongs to a different defect.

$\text{V}_{\text{Si}}\text{-Si}_\text{C}$ and $\text{C}_{\text{Si}}\text{-V}_\text{C}$. Only $\text{C}_{\text{Si}}\text{-Si}_\text{C}$ and $\text{C}_{\text{Si}}\text{-V}_\text{C}$ have one prominent C nucleus. The antisite pair $\text{C}_{\text{Si}}\text{-Si}_\text{C}$ has excitation energies $< 0.2\text{ eV}$ and can, therefore, by no means explain the optical transitions of the P6/P7 centers ($\sim 1\text{ eV}$).

The formation energy of $\text{C}_{\text{Si}}\text{-V}_\text{C}$ is lower than that of V_{Si} for most charge states (Fig. 4). The calculated energy barrier for the formation of $(\text{C}_{\text{Si}}\text{-V}_\text{C})^0$ from V_{Si}^0 (1.7 eV, [2]) is close to the experimentally observed activation energy for the annealing of V_{Si}^0 ($2.2 \pm 0.3\text{ eV}$, [1]). $\text{C}_{\text{Si}}\text{-V}_\text{C}$ is, therefore, expected to be formed from V_{Si} as an annealing product.

In C_{3v} symmetry, $\text{C}_{\text{Si}}\text{-V}_\text{C}$ has an $a_1(\text{s})$ level in the valence band, an $a_1(\text{p})$ and an $e(\text{p})$ level in the band gap (Fig. 5). The ground state of $(\text{C}_{\text{Si}}\text{-V}_\text{C})^{2+}$ is a singlet 1A_1 ($a_1(\text{s})\uparrow\downarrow$). Photon energies above 1.15 eV (exp.: 1.1 eV)

Fig. 4. Formation energies of the silicon vacancy (V_{Si}), the carbon-antisite carbon-vacancy pair ($\text{C}_{\text{Si}}\text{V}_\text{C}$), and sum of formation energies of the isolated carbon antisite and the isolated carbon vacancy ($\text{C}_{\text{Si}} + \text{V}_\text{C}$).

Fig. 5. Induced density of states for the diamagnetic ground state of the $\text{C}_{\text{Si}}\text{-V}_\text{C}$ pair in the charge state +2.

can excite one electron from the $a_1(\text{s})$ level into the $a_1(\text{p})$ level, forming the 1A_2 ($a_1(\text{s})\uparrow a_1(\text{p})\downarrow$) state. A non-radiative transition to the energetically lower metastable triplet state 3A_2 ($a_1(\text{s})\uparrow a_1(\text{p})\uparrow$) is possible with help of phonons. This 3A_2 state gives rise to the P6/P7 EPR spectra observed experimentally. The MCDA is explained by the excitation of the $a_1(\text{p})$ electron into the $e(\text{p})$ state ($a_1(\text{s})\uparrow e(\text{p})\uparrow$). The calculated photon energy (1.52 eV) is in reasonable agreement with the experimental values (1.0–1.1 eV).

The calculated HF interaction with the C_{Si} approaches the experimental value when C_{Si} relaxes 22% away from V_C . This is close to the relaxation predicted by SCC-DFTB (16%). The three Si neighbors of V_C and three next nearest neighbors of C_{Si} (in the direction of the defect axis) contribute to the silicon HF interaction with similar constants, explaining the observed HF lines (6 ± 2 inequivalent Si nuclei).

A similar excitation scheme as for $(C_{Si}-V_C)^{-2}$ is possible for $(C_{Si}-V_C)^0$, but, in this case, the $e(p)$ state is occupied in the metastable triplet state 3E ($a_1(s)\uparrow \downarrow a_1(p)\uparrow e(p)\uparrow$) and gives rise to a large HF interaction with the Si neighbors of V_C (> 150 MHz), which, by far, exceeds the experimentally observed value. Thus, this charge state must be ruled out. For a more detailed discussion, see Ref. [5].

In summary, we have identified the $C_{Si}-V_C$ pair in 6H-SiC in the doubly positive charge state on all inequivalent lattice sites and in all orientations. The $C_{Si}-V_C$ pair is the ideal candidate for the annealing product of V_{Si} . The bad news, though, is that the $C_{Si}-V_C$ defect is electrically and optically active. It has a charge transfer level just above midgap. Thus, at least a second anneal step is required to remove the electrical activity of silicon vacancy-related defects.

Illumination effects in irradiated 6H n-type SiC observed by positron annihilation spectroscopy

F. Redmann^{a,*}, A. Kawasuso^{a,b}, K. Petters^a, H. Itoh^b, R. Krause-Rehberg^a^a Martin-Luther-Universität Halle-Wittenberg, Fachbereich Physik, D-06099 Halle, Germany^b Japan Atomic Energy Research Institute, 1233, Watanuki, Takasaki, Gumma 370-1292, Japan

Abstract

In the present study, we used positron annihilation spectroscopy to investigate defects after electron irradiation in 6H n-type SiC. The density of vacancy-type defects strongly increased during this treatment. An isochronal annealing experiment was performed, and the main recovery stage was found to be between 1000°C and 1400°C. This corresponds to the annealing range of the E_1/E_2 defect, which was also found by a correlated positron and DLTS study in 6H-SiC epilayers after electron irradiation (J. Appl. Phys. 80 (1996) 5639). Optical excitation experiments during the positron experiment show that the observed defect has an ionization level at about $E_c - 0.47$ eV, which is similar to the level $E_c - 0.44$ eV obtained by DLTS for the E_1/E_2 defect (Appl. Phys. Lett. 74 (1999) 839). Doppler-coincidence experiments suggest that the observed vacancy is surrounded by C atoms, so that most probably the Si vacancy (isolated or bound to an impurity or another defect) is the dominating defect after electron irradiation. © 2001 Elsevier Science B.V. 1. Introduction

Electrical and optical properties of defects in semiconductors play an important role in SiC based wide band gap electronic devices. One way to introduce defined defects in SiC is electron irradiation. Irradiated SiC was studied by several experimental methods to characterize the introduced defects (DLTS, PL, ESR). In order to study open-volume defects, we performed positron lifetime experiments for n-type 6H SiC irradiated with 2 MeV electrons (dose: 1×10^{17} and $3 \times 10^{17} \text{ cm}^{-2}$). The positron lifetime was found to increase after irradiation indicating the presence of vacancy-type defects. Annealing experiments were performed to observe the disappearing or agglomeration of vacancies. The excitation of electrons to the conduction

band due to illumination shows different annealing behavior dependent on the irradiation dose. Additional Doppler broadening coincidence experiments were performed to get information about the chemical environment of the vacancies observed by positrons.

2. Experimental details

N-doped SiC bulk wafers ($[N] = 1 \times 10^{17} \text{ cm}^{-3}$) of a thickness of 0.3 mm were purchased by the Nippon Steel Company and irradiated in the Japan Atomic Energy Research Institute (JAERI) with 2 MeV electrons for two different doses (1×10^{17} and $3 \times 10^{17} \text{ cm}^{-2}$) at room temperature. The size of the samples is $5 \times 5 \text{ mm}^2$. A conventional positron emitter $^{22}\text{NaCl}$ (10–90 μCi) was used as positron source. It was encapsulated with 4 μm of aluminum foil. Due to the high kinetic energy of positrons ($E_{\text{max}} = 0.54 \text{ MeV}$), 2% of them get through the thin samples. To prevent the annihilation of positrons in the sample holder, an additional piece of SiC was arranged on both sides of the sandwich. The

positron lifetime measurements were performed with a conventional fast-fast positron lifetime spectrometer (FWHM = 260 ps) in the temperature range of 15–600 K. The illumination experiment using an optical cryostat was carried out in the same temperature range. The effect of illumination on positron lifetime was examined using white and monochromatic light ($h\nu = 0.3\text{--}3.2\text{ eV}$). In the range between 100°C and 1300°C, the samples were annealed in a furnace under vacuum and up to 1700°C under ambient argon atmosphere to avoid the sublimation of silicon from the surface. Doppler broadening coincidence experiments were performed using two Ge-detectors with a resulting resolution function of about 1 keV.

3. Results and discussion

Fig. 1 shows the difference of the average lifetime of low-dose electron irradiated 6H SiC (dose: $1 \times 10^{17}\text{ cm}^{-2}$) with monochromatic light and in darkness as a function of photon energy. The direct transition of electrons from the valence band to the conduction band causes the disappearance of the illumination effect above a photon energy of 3 eV. It is found that the average lifetime increases from 0.4 eV and tends to saturate above 1 eV. This could be explained as the internal transition of electrons from localized levels to the

conduction band (fundamental absorption). The lower threshold energy for the appearance of the illumination effect is associated with the position of the energy level of defects in the band gap acting as a trapping center for positrons. According to the Lucowsky model [7], the threshold energy is determined to be $E = 0.47\text{ eV}$ from the fitting as shown in Fig. 1. DLTS studies showed that the energy level of E_1/E_2 is located at 0.35–0.44 eV below the conduction band [2,6]. In the case of an indirect transition from the ground state to the conduction band [2], the small difference of these two energies allows us to conclude that the observed threshold energy (0.47 eV) might be related to the E_1/E_2 level.

Fig. 2 shows the isochronal annealing behavior of average positron lifetime in darkness measured at 20 K. From this figure, two annealing steps are seen: the first is from room temperature to 250°C and the second is above 1000°C. The first step can be explained as the recombination of Frenkel pairs and the annealing of carbon vacancies, which are mobile below 300°C. Considering that pure silicon vacancies are mobile at 600–800°C [5], the higher thermal stability of trapping centers can be explained as a creation of complexes involving Si vacancies. This could be inferred due to the nearly constant defect-related lifetime ($190 \pm 5\text{ ps}$) determined by decomposition of positron lifetime spectra in the range of annealing temperature from 400°C to

Fig. 1. Difference of average positron lifetime under illumination and in darkness as a function of photon energy.

Fig. 2. Average positron lifetime as a function of annealing temperature for electron irradiated 6H n-type SiC (dose: $1 \times 10^{17}\text{ cm}^{-2}$).

1200°C. Above 1300°C, all detectable vacancy-type defects disappear [1]. Based on theoretical calculations [3] and a positron lifetime experiment combined with electron spin resonance [4], the lifetime of positrons at silicon vacancies is 187–193 ps. Thus, it seems that the major positron trapping center is related to silicon vacancies. It is important to note that the E_1/E_2 defects observed in DLTS experiments also disappear in the same temperature region [6]. Thus, we conclude that the E_1/E_2 center is decorated with a silicon vacancy. The annealing behavior under illumination shows very similar characteristics [8], so that introduced vacancy-type defects due to electron irradiation are responsible for the illumination effect.

Fig. 3 presents the annealing characteristics of average positron lifetime for the electron irradiated 6H n-type SiC with a dose of $3 \times 10^{17} \text{ cm}^{-2}$ for two different measurement temperatures. For the low-temperature measurements, the annealing characteristics show a very similar behavior in case of illumination and darkness. The effect of illumination decreases slightly due to the annealing temperature. The annealing behavior can be divided into four steps. The first step is the recombination of Frenkel pairs, which drastically reduces the average lifetime below 200°C annealing temperature. Then, a bright shoulder follows up to 500°C where carbon vacancies will become mobile and anneal out [1]. The average lifetime increases near 800°C due to the

building of complexes with silicon vacancies, and after 1200°C most of the introduced vacancy-type defects annealed out. The high-temperature measurements show a completely different annealing behavior. No illumination effect is to be seen up to an annealing temperature of 600°C. Above this temperature, the average lifetime is higher under illumination, which was not observed for the low-temperature measurements. The last picture in Fig. 3(c) shows the difference of average lifetime under illumination and in darkness. It shows that a small increase of average lifetime appears in the mobility range of the two kinds of vacancies.

The decomposition of positron lifetime spectra for the annealing temperature 800°C is displayed in Fig. 4. It demonstrates that for a measurement temperature of 300 K, two different types of defects act as trapping centers for positrons. Under illumination, the defect-related lifetime τ_2 has a value of 190 ± 10 ps similar to the silicon vacancy [3]. In darkness, an additional defect (unknown defect with an ionization energy, $E > 100 \text{ meV}$) acts as a trap ($\tau_2 = 165 \pm 10$ ps) in competition with the silicon vacancy. The decomposed lifetime is a mixture of these two defects where the value of positron lifetime for the silicon vacancy approaches the high measurement temperature. The above mentioned deep center must change its charge state (negative to neutral) due to the excitation of electrons from the deep level to the conduction band.

Fig. 3. Average positron lifetime as a function of annealing temperature for electron irradiated 6H n-type SiC (dose: $3 \times 10^{17} \text{ cm}^{-2}$) under illumination and in darkness. The picture (c) shows the difference of average lifetime between darkness and illumination for the measurement temperature of 20 K.

Fig. 4. Positron lifetime as a function of measurement temperature for 6H n-type SiC annealed at 800°C (irradiation dose: $3 \times 10^{17} \text{ cm}^{-2}$).

Fig. 5. Doppler broadening line-shape parameters S and W of the 511 keV annihilation peak as a function of annealing temperature (irradiation dose: $3 \times 10^{17} \text{ cm}^{-2}$).

Fig. 5 shows the annealing behavior for the Doppler broadening spectroscopy. The W -parameter is sensitive for the chemical environment of the trapping center. The S -parameter represents the open-volume space and the concentration of open-volume defects. The straight line found during annealing allows us to conclude that only monovacancies anneal out and no additional vacancy type defect is involved [10]. After 1200°C annealing some defects remain which cannot be isolated monovacancies [4]. This indicates that silicon vacancies and complexes with silicon vacancies are the major trapping centers.

4. Conclusions

In summary, we performed positron lifetime measurements with n-type 6H SiC after 2 MeV electron

irradiation for two different doses in darkness and under illumination. After the 1300°C annealing, vacancy-type defects and the illumination effect disappear. The annealing behavior in darkness shows very similar behavior to the E_1/E_2 centers observed by DLTS measurements [9]. Thus, we conclude that the observed defect contains silicon vacancies. The determined threshold energy of 0.47 eV for the illumination effect further supports this assumption. In the case of high-dose irradiation more than one optical active trapping center was found for the measurement temperature of 300 K. To clarify the structure of possible complexes with silicon vacancies, further experiments are necessary.

Abstract

Intrinsic-related defect centers (IRDCs) in 4H-/6H-SiC are generated by implantation of helium ions, protons or by irradiation of high energy electrons. The formation and thermal stability of these centers are studied by deep level transient and positron annihilation spectroscopy subsequent to anneals at 600–1800°C. It turns out that the formation of IRDCs depends on the injected particle. Further we have identified defect centers which show identical temperature dependence of DLTS defect concentrations and positron capture rates. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Ion implantation, which is an important tool to dope silicon carbide (SiC) with donors and acceptors, not only causes lattice damage but is also accompanied by an unintentional local disturbance of the stoichiometry of SiC. Based on the different masses of silicon (Si) and carbon (C) atoms, the heavier Si atoms accumulate close to the surface while the lighter C atoms are knocked on deeper into the bulk. This effect may, in addition, enhance the formation of intrinsic-related defect centers (IRDCs). For a survey of IRDCs in ion-implanted or electron-irradiated SiC, see e.g. Refs. [1–3].

In this paper, we conduct a detailed study of the formation and annihilation of IRDCs in helium (He⁺), proton (H⁺) or 2 MeV electron (e[−]) damaged and

subsequently annealed n-type 4H-/6H-SiC. Deep level transient spectroscopy (DLTS) and positron annihilation spectroscopy (PAS) are applied to determine defect concentrations and positron capture rates, respectively. It is the aim to examine whether the formation of IRDCs differs for the different generation processes and whether part of the observed defects are vacancy-related.

2. Experimental

Nitrogen (N)-doped epitaxially grown SiC layers of 4H and 6H polytype, respectively, are used for these investigations (CREE, $[N_N - N_{Comp}] = 5 \times 10^{15} \text{ cm}^{-3}$). Square-shaped samples with an area of 5 mm × 5 mm are cut from the wafers. Intrinsic defect centers are generated by irradiation of 2 MeV electrons (e[−] current = 0.5 mA, fluence = 10^{15} cm^{-2}) or by implantation of 2 MeV protons (Gaussian H⁺-profile with $R_p = 25 \mu\text{m}$

*Corresponding author. Fax: +49-9131-852-8423.

E-mail address: michael.weidner@physik.uni-erlangen.de (M. Weidner).

(calculated by TRIM.C), H^+ current = 30 nA, fluence = 10^{13} cm^{-2}) or helium ions (box profile generated by multiple implantation of He^+ ions with energies ranging from 30 to 950 keV, He^+ -current = 50 nA, total He^+ fluence = $8 \times 10^{12} \text{ cm}^{-2}$). The e^- -irradiated and He^+ -implanted samples are sequentially exposed to anneals at temperatures, T_a , ranging from 600°C to 1700°C for 30 min. They are characterized by DLTS subsequent to each heat treatment (similar processed samples were investigated by PAS, see Ref. [4]). In contrast each H^+ -implanted sample is isochronally annealed for 30 min at one fixed temperature. Anneals up to 1000°C are performed under vacuum in a rapid isothermal annealing (RIA)-system. Above 1000°C the samples are put into a SiC container and annealed under 1 atm Ar pressure in a resistance-heated graphite furnace. Subsequent to heat treatments above 900°C, a surface layer of 100 nm is etched off by reactive ion etching (RIE). Schottky contacts are fabricated by evaporation of nickel (Ni) through a shadow mask (contact diameter varies between 0.35 and 1 mm); large area Ohmic contacts (Ni) are evaporated on the backside of the samples. Prior to each annealing step the contacts are removed. DLTS spectra are taken in a temperature range from 90 to 700 K. The filling pulse width is 20 ms and the rate window is chosen between 0.25 and 32 ms. Defect concentrations are determined from the height of the DLTS peaks.

3. Results and discussion

Although all the observed DLTS spectra show identical features (IRDC-related peaks), the abundance of defect centers and their formation strongly depend on the particular injected particles. Fig. 1 shows DLTS spectra taken on an e^- -irradiated and annealed ($T_a = 900^\circ\text{C}$, $t_a = 30 \text{ min}$) 4H- (solid curve) and 6H-SiC (dotted curve) epilayer, respectively. The dominant-

ing peaks in the spectrum of the 4H-SiC epilayer (related to the y-axis on the left) are attributed to electron traps like the ET1-, ET3- and $Z_1/Z_2(4H)$ -center [5]. The activation energies and generated concentrations of these IRDCs are summarized in Table 1. Their chemical composition and microscopic structure are not known. Similar electron traps are described in Ref. [2]. In addition, the titanium (Ti) acceptor is observed at about 90 K. Ti is an omnipresent contamination in SiC due to graphite parts. In the case of the 6H-SiC polytype (related to the y-axis on the right), the E_1/E_2 - and $Z_1/Z_2(6H)$ -center prevail (for activation energies and concentrations, see Table 1).

The formation of the observed IRDCs in 4H-/6H-SiC strongly depends on the injected particles. As an example the annealing behavior of $Z_1/Z_2(4H)$ -centers in n-type 4H-SiC generated by He^+ -ions, H^+ -ions and high energy electrons, respectively, is displayed in Fig. 2. The implantation/irradiation parameters are selected in such a way that (a) the He^+ implantation generates a vacancy profile to a depth of 2.2 μm with a mean

Fig. 1. DLTS spectra taken on an e^- -irradiated and annealed ($T_a = 900^\circ\text{C}$, $t_a = 30 \text{ min}$) 4H- (solid curve) and 6H-SiC (dotted curve) epilayer, respectively. The corresponding defect parameters are summarized in Table 1.

Fig. 2. Annealing behavior of Z_1/Z_2 -centers in n-type 4H-SiC generated by implantation of He^+ - and H^+ -ions or by irradiation of 2 MeV electrons. The annealing time t_a at fixed temperature is 30 min. High Z_1/Z_2 -concentrations are determined by temperature-dependent $C-V$ measurements.

concentration of $2 \times 10^{18} \text{ cm}^{-3}$ (calculated by TRIM-C), (b) the H^+ ions accumulate in a depth of approx. 25 μm and can, therefore, not directly affect the formation of IRDCs in the investigated zone and (c) the 2 MeV electrons generate an almost homogeneous intrinsic defect concentration through the whole bulk of the SiC wafer. The temperature during ion implantation/ e^- irradiation is in each case below 50°C; this low temperature avoids annealing of lattice damage during irradiation. In He^+ - and H^+ -implanted samples, the Z_1/Z_2 -center is not observable directly after the implantation; its formation requires an annealing step at temperatures above 600°C. The Z_1/Z_2 -concentration increases with increasing annealing temperature and reaches a maximum value in the temperature range between 1100°C and 1200°C. This observation is also true for heavier ion masses (see Ref. [3]). Irradiation with 2 MeV electrons generates the $Z_1/Z_2(4\text{H})$ -center without additional anneal. We suggest that the number of displacements per injected particle is much lower for electrons than for ions. Therefore, isolated intrinsic defects must be formed in ion-implanted layers by additional heat treatments. Annihilation of the $Z_1/Z_2(4\text{H})$ -center occurs at temperatures $T_a > 1200^\circ\text{C}$ in all three cases.

Our experimental results are in contrast with data published by Storasta et al. [6], who reported that the maximum concentration of $Z_1/Z_2(4\text{H})$ -centers generated by H^+ -ions (2.9 MeV) does not show any distinct change with the annealing temperature up to 1300°C.

The concentration of ET1, ET3 and $Z_1/Z_2(4\text{H})$ -centers as well as that of E_1/E_2 - and $Z_1/Z_2(6\text{H})$ -centers in electron-irradiated n-type 4H- and 6H-SiC samples, respectively, as a function of the annealing temperature is displayed in Figs. 3 and 4. The annealing steps (30 min each) have been sequentially conducted. Up to 1000°C

Fig. 3. Annealing behavior of ET1-, ET3- and Z_1/Z_2 -centers in n-type 4H-SiC generated by irradiation of 2 MeV electrons. The annealing steps ($t_a = 30$ min at each applied temperature) have been sequentially conducted.

Fig. 4. Annealing behavior of E_1/E_2 - and Z_1/Z_2 -centers in n-type 6H-SiC generated by irradiation of 2 MeV electrons. The annealing steps ($t_a = 30$ min at each applied temperature) have been sequentially conducted.

the defect concentrations are not affected by the heat treatments. For temperatures $T_a > 1000^\circ\text{C}$, the concentrations strongly decrease. For $T_a > 1300^\circ\text{C}$, ET1- and ET3-centers are no longer detectable with our DLTS system. $Z_1/Z_2(4\text{H})$ -centers in the 4H polytype and E_1/E_2 - and $Z_1/Z_2(6\text{H})$ -centers in the 6H polytype show qualitatively a similar annealing behavior. In the temperature range from 1300°C to 1600°C, the concentration of these centers is strongly reduced (the DLTS signal of E_1/E_2 -centers is below the detection limit). Subsequent to anneals at $T_a > 1400^\circ\text{C}$, these defect concentrations begin to increase again. They are still detectable at a few 10^{12} cm^{-3} subsequent to a heat treatment at 1700°C (for the temperature range of thermal stability of defects, see Table 1, last column). These results are reproducible and have been repeated with a series of samples. The formation and dissociation of intrinsic-related defects in this temperature range appear to be extremely complex. Most of the intrinsic-

related defect complexes are dissolved in this temperature range and serve as a source for Si and C interstitials and/or vacancies. This increase in intrinsic defects may lead to the observed slight recovery of $Z_1/Z_2(4H)$, E_1/E_2 - and $Z_1/Z_2(6H)$ -centers.

PAS investigations on identically processed 6H-SiC samples (not shown here, see Ref. [4]) also result in a decrease of the positron capture rate of the particular defect centers at annealing temperatures above 1000°C. The clear temperature correlation between DLTS concentrations and positron capture rates strongly indicates that the centers under discussion ($Z_1/Z_2(4H)$ -center in 4H-SiC, E_1/E_2 - and $Z_1/Z_2(6H)$ in 6H-SiC) are vacancy-related.

4. Summary

Intrinsic-related defect centers are generated in 4H-/6H-SiC by implantation of He^+ -ions or protons or by irradiation of high energy electrons. The formation and annihilation of IRDCs is studied as a function of annealing temperature in the range from 600°C to 1700°C. The formation process of IRDCs depends on the injected particle. Implantation of ions (e.g. H^+ , He^+) requires an annealing step above 600°C to form IRDCs. In the 4H- and 6H-SiC polytypes ET1, ET3, $Z_1/Z_2(4H)$ and E_1/E_2 , $Z_1/Z_2(6H)$, respectively, are the dominating centers; they partially resist heat treatments up to 1700°C. In electron-irradiated samples, these defects are already present at maximum concentration without additional anneal. Based on the comparison of

DLTS and PAS results taken on identically processed 4H-/6H-SiC samples, it is concluded that vacancies participate in the investigated defect complexes.

Abstract

Theoretical simulation of hyperfine parameters for the nearest and next-nearest neighbor atoms of V_C^+ in SiC has been performed for the cubic and hexagonal clusters. The gradient-corrected all-electron DFT calculations with Becke's three-parameter functional have been performed by the use of split valence basis of Gaussian functions with d-functions. High performance of such approximations for the calculation of the hyperfine parameters of the well-known vacancy-related centers in SiC and Si has been demonstrated. We have found the D_{2d} local symmetry for the V_C^+ in the SiC cubic cluster. In hexagonal-like cluster, the D_{2d} symmetry is lowered to the C_s one. The symmetry plane contains the c -axis and one of the transverse bonds. Four Si atoms of the first shell become essentially inequivalent and have different hyperfine parameters. Two in-plane Si atoms concentrate the major part of the spin density and out-of-plane Si atoms exhibit relatively small hyperfine parameters. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Vacancy-related defects in electron-irradiated SiC polytypes have been the subject of extensive experimental investigations during the last three decades. The microscopic models of such defects, as a rule, are deduced from hyperfine parameters (HFPs) and corresponding relative intensities of the EPR lines originated from the ^{13}C and ^{29}Si isotopes located in different shells. The vacancy-related centers exhibit a great variety of properties depending on the doping of the crystal, dose of irradiation, energy of a beam and type of the particles. However, the experimental data and simple considerations are not enough to advance the adequate and unique microscopic models. In particular, magnetic resonance experiments themselves do not permit the

determination of a charge state of the defect. As a consequence, only a negatively charged isolated silicon vacancy is reliably identified at the present time. This identification is based on the experimental ENDOR determined value of the spin, $S = \frac{3}{2}$, and HFPs for the atoms of the first and second shells together with the first-principles calculation of the HFPs [1]. Ab initio plane-wave pseudopotential calculation for the fully relaxed silicon and carbon vacancies was performed in Ref. [2] for various charge and spin states using the local-spin-density approximation. However, these calculations gave no information except the spin states and point symmetry suitable for the assignment of these defects. On the other hand, the calculated HFPs generally are very sensitive to the level of theory used for the computation and an agreement with experimental results will suggest the quality of calculations.

In the last decade, several EPR spectra [3–7] with sufficiently different HFPs were tentatively assigned to the positively charged carbon vacancy V_C^+ in the SiC polytypes. Thus, for an unambiguous assignment, one

must perform a high-accuracy simulation of the hyperfine interactions at least with four silicon atoms of the first shell. The present work deals with the cluster DFT calculation of the symmetry and tensor of hyperfine interaction with atoms of the first and second shells of the V_C^- in purely cubic and hexagonal lattice sites of the SiC.

2. Computational method

It is well known that accurate calculation of the HFPs requires high-level post-Hartree–Fock treatment. Due to the local nature of the hyperfine interaction, the calculated parameters are sensitive to the basis set size, electron correlation and optimized geometry. In recent years, the high performance of the DFT-based calculations of the spin densities with gradient-corrected functionals was shown for the molecular systems containing atoms of the second and third rows. The most extensively employed is the B3LYP functional, which is a combination of Becke's three-parameter hybrid exchange functional with the Lee–Yang–Parr nonlocal correlation functional [8,9]. To apply such a method of calculation we have used the $C_{18}Si_{16}H_{36}$ and $C_{18}Si_{20}H_{40}$ clusters as the model systems for a simulation of the carbon vacancy (see Fig. 1). The first one simulates the purely cubic site in 3C–SiC and the second one—hexagonal site (h-site). To check the validity of such an approach for the reproducing of observed HFPs of vacancy-related centers we have performed test calculations for well-known defects such as the V_{Si}^- in cubic SiC ($S = \frac{3}{2}$, T_d symmetry) and the V_{Si}^- in silicon ($S = \frac{1}{2}$, D_{2d} symmetry). For this purpose, the $Si_{18}C_{16}H_{36}$ and $Si_{34}H_{36}$ clusters have been used. For the calculations of all the above-mentioned defects in cubic clusters, the all-electron split valence Gaussian basis set 6-311G(d) with polarization d-functions has been applied for both Si and C atoms. To save the computational time we have used STO-3G basis for the capped bond hydrogen atoms which were fixed during the total energy minimization.

The pseudopotentials with corresponding basis sets (31G for C and 21G(d) for Si atoms beyond the first and second shells) have been used for calculations with hexagonal cluster [10,11]. For the first and second shells, the all-electron 6-311G(d) basis has been used for the correct description of the spin density distribution in the actual region.

The isotropic hyperfine coupling constant a_{iso} and components T_{ij} of the traceless tensor of anisotropic hyperfine interaction (AHFI) with nucleus N have been calculated according to the relations

$$a_{iso}^{(N)} = \frac{4\pi}{3} g\beta g_N \beta_N \langle S_z \rangle^{-1} \rho^S(R_N), \quad (1)$$

$$T_{ij}^{(N)} = \frac{1}{2} g\beta g_N \beta_N \langle S_z \rangle^{-1} \int \rho^S(r) \tau_{ij}(r - R_N) dr, \quad (2)$$

Fig. 1. Clusters used for a calculation of the HFPs of vacancy-related centers: a—cubic $C_{18}Si_{16}H_{36}$ cluster and b—hexagonal $C_{18}Si_{20}H_{40}$ cluster.

where $\tau_{ij}(r - R_N) = r_{kN}^{-5}(r_{kN}^2 \delta_{ij} - 3r_{kN,i}r_{kN,j})$ and $\rho^S(r)$ is the spin density.

3. Results of calculations and discussion

The results of our calculations of the HFPs for the first and second shells are presented in Table 1 for several vacancy-related defects. In this table, for example, the notation $Si_2(I)$ designates the second symmetry inequivalent silicon atom of the first shell and so on. T_{11} , T_{22} and T_{33} are the principal values of the AHFI tensor calculated according to Eq. (2).

The T_d point symmetry for the V_{Si}^- in the 3C–SiC and the D_{2d} point symmetry for the V_{Si}^- in the silicon were obtained in agreement with the experiment [1,12]. It is well known for the negatively charged vacancy in silicon [13] that a strong dependence of the calculated point

symmetry and the HFPs on the cluster size occurs. However, our calculations show that for the positively charged vacancy in silicon, this is not the case. One may point out the good agreement of calculated and experimental values of the HFPs for both defects, used for the test calculations.

For the V_{C}^+ in cubic SiC, cluster calculations give D_{2d} point symmetry in agreement with the local-spin-density pseudopotential calculations with supercell approach [2]. Our calculations show that in this case, hyperfine splittings are sufficiently greater as compared to those ones for the T5 center [3]. Thus, the tentative assignment of this center to the V_{C}^+ must be revised. It is interesting to note that calculations with smaller $\text{Si}_4\text{C}_{12}\text{H}_{36}$ cluster give the same point symmetry D_{2d} and show small deviation of the HFPs for the Si atoms of the first shell from those for the larger cluster. For the V_{Si}^- in 3C–SiC we have found the more sufficient dependence of the calculated HFPs on the cluster size. Nevertheless, it may be deduced that the used cluster size is a good compromise between the precision of calculations and the CPU time.

For the V_{C}^+ in hexagonal cluster, the calculated point symmetry is C_s . In this case, the distance between the $\text{Si}_1(\text{I})$ atom (longitudinal bond) and $\text{Si}_2(\text{I})$ (transverse bond) is elongated up to 3.32 Å as compared to 3.086 Å in a perfect lattice. At the same time, the distance between two other atoms of the first shell is 2.28 Å. As a consequence of such a reconstruction, dramatic changes

in the spatial distribution of the spin density occur as compared to the purely cubic sites. Specifically, the major part of the spin density is localized on the $\text{Si}_1(\text{I})$ and $\text{Si}_2(\text{I})$ atoms located in the symmetry plane (see Table 1). Two symmetry equivalent atoms labeled $\text{Si}_3(\text{I})$ and located out of the symmetry plane, contain sufficiently smaller part of the spin density. Moreover, a sign of the spin density on the $\text{Si}_3(\text{I})$ atoms is negative. Thus, for the V_{C}^+ in the h-sites, one can expect dramatic changes of the hyperfine splittings originated from atoms of the first shell as compared to the purely cubic sites.

For the V_{C}^+ located in the quasicubic lattice sites in the hexagonal SiC polytypes, an intermediate behavior of the spin density distribution is suggested. In this case, one may regard the quasicubic lattice sites as slightly perturbed ones in 3C–SiC. Fig. 2 represents the comparison of the calculated HFPs for the Si atoms of the first shell in cubic cluster with available experimental data assigned to the V_{C}^+ defect with the C_s point symmetry in quasicubic sites of 6H–SiC [14]. One may see that for the Si_1 atom (longitudinal bond), the isotropic hyperfine interaction increases, while for the Si_2 atom (a transverse bond in a symmetry plane) it decreases as compared to the one for the 3C–SiC. At the same time, the values of a_{iso} for the Si_3 and Si_4 out-of-plane symmetry equivalent atoms remain practically unchanged. It may be assumed that large relative (but not absolute) deviation of calculated principal values of the AHFI tensor from

Fig. 2. Comparison of the HFPs for the first shell of the V_C^+ defect in the purely cubic sites (calculated) and quasicubic site in the 6H-SiC (experiment).

experimental ones may be caused by the used approximations as well as by influence of the specific crystal environment in 6H-SiC.

Notice that for all the considered defects listed in Table 1, the sign of the spin density on the atoms of the first shell is positive, with one exception for the $Si_3(I)$ atoms in hexagonal cluster. The spin density on the atoms of the second shell is also negative in some cases. This clearly demonstrates the significance of the spin polarization effects which are responsible for the negative spin densities.

Abstract

Experiments on proton irradiation with energy of 150 KeV, 8 MeV and 1 GeV were made. Capacitance–voltage characteristics measured at 650 K showed that 8 MeV and 1 GeV proton irradiation of 6H-SiC leads to an increase of uncompensated donor concentration. However, donor concentration in 6H-SiC remains unaffected after 150 keV proton irradiation. Deep centers were investigated by deep levels transient spectroscopy (DLTS). Results of C – V measurements are interpreted using DLTS data. The results obtained show the possibility of using proton irradiation for producing local high-resistance regions in SiC devices not intended for high-temperature applications. © 2001 Elsevier Science B.V. Keywords: SiC; Proton irradiation; DLTS

1. Introduction

There is several reports on formation of SiC layers semi-insulating (SI) at room temperature (RT) by means of proton irradiation [1–3]. However, the parameters and concentrations of radiation defects (RD) formed during irradiation have not been studied. In other works [4,5] RD parameters were studied but the compensation appearing in the course of irradiation was not analyzed.

The aim of this work was to fabricate SI 6H- and 4H-SiC layers by proton irradiation with different energies, compare their electrical properties, and determine the parameters of RDs responsible for the compensation. The samples were studied with capacitance–voltage (C – V) characteristics and deep levels transient spectroscopy (DLTS) methods.

2. Experiment

Silicon carbide p^+-n structures and epitaxial layers commercially produced by CREE Research, Inc., or fabricated at the Ioffe Institute by sublimation epitaxy (SE) [6] were used. The n -type layer thickness was about 5 μm ; that of the p -type layer: about 1 μm ; and substrate thickness: about 400 μm . The diameter of Schottky barriers or mesa structures of the diodes was in the range 600–700 μm . The concentration of uncompensated donors in the n -type layer ($N_d - N_a$) was $(0.8 - 4) \times 10^{16} \text{ cm}^{-3}$, that in the substrate, $(3 - 5) \times 10^{18} \text{ cm}^{-3}$, and concentration of acceptors in the p -type layer: $\sim 5 \times 10^{18} \text{ cm}^{-3}$. Thus, the doping level in the substrate and p -type emitter exceeded by no less than two orders of magnitude that in the n -type base layer.

A set of 6H- and 4H-SiC samples (p – n structure and Schottky diodes) were step by step irradiated with 8 MeV protons. Total irradiation dose (D) was changed from $1 \times 10^{14} \text{ cm}^{-2}$ to $2 \times 10^{16} \text{ cm}^{-2}$. Two sequential 1 GeV proton irradiations with D of 3×10^{14} and $9 \times 10^{14} \text{ cm}^{-2}$ were made on one 6H-SiC SE sample

*Corresponding author. Tel.: +7-812-247-9930; fax: +7-812-247-6425.

E-mail address: dd@pop.ioffe.rssi.ru (D.V. Davydov).

with Schottky diodes. The epilayer was nonuniformly doped— $N_d - N_a$ varied from 5×10^{14} to $8 \times 10^{15} \text{ cm}^{-3}$ at the surface and at $7 \mu\text{m}$ depth, respectively. Furthermore, three 6H-SiC SE samples having initial $N_d - N_a$ value of $4 \times 10^{16} \text{ cm}^{-3}$ were irradiated with 150 keV protons with doses of 10^{11} , 10^{12} , and 10^{13} cm^{-2} . All irradiations were carried out at RT.

The C - V characteristics were measured on a bridge C - V setup on a frequency of 10 kHz. A study of 8 MeV irradiated samples demonstrated a decline in the $N_d - N_a$ value measured at RT, with $N_d - N_a$ markedly increasing on heating a structure to 650 K. For 6H-SiC the $N_d - N_a$ value measured at 650 K was even higher than that in the initial structures prior to irradiation. With increasing irradiation dose, this difference became more pronounced (Figs. 1 and 2). Irradiation of lightly doped samples with D of 10^{16} cm^{-2} led to formation of SI layers with specific resistivity of about $10^9 \Omega\text{cm}$ at RT.

Typical C - V characteristics measured after 150 keV proton irradiation are shown on Fig. 3. At high reverse bias the characteristic is similar to initial one; but irradiation resulted in appearance of flat region at low bias voltages where the capacitance does not depend on voltage, and its value corresponds to depleted region width of $\sim 1 \mu\text{m}$. We attribute this to formation of a SI layer due to the irradiation. The characteristics measured at 100 K shift right along the voltage axis. Increase of the temperature to about 500 K led to recovery of initial C - V characteristics of the diodes. The shape of the characteristics were the same for all the samples (all the irradiation dose values).

First 1 GeV irradiation did not noticeably influence on C - V characteristics. However, after the second irradiation ($D = 1.2 \times 10^{15} \text{ cm}^{-2}$) RT capacitance became independent on voltage (the epilayer became SI). C - V characteristic measured at temperature of 500 K after second irradiation was linear (Fig. 4); it revealed

Fig. 1. 6H-SiC: $N_d - N_a$ measured at $T = 300 \text{ K}$ (1) and $T = 650 \text{ K}$ (2), difference of them (3), and concentration of the center located at $E_c - 1.22 \text{ eV}$ (4) vs. the irradiation dose.

Fig. 2. 4H-SiC: $N_d - N_a$ measured at $T = 300 \text{ K}$ (1) and $T = 650 \text{ K}$ (2), difference of them (3), and total concentration of the centers RD_1 , RD_2 , RD_3 , and RD_4 (4) vs. the irradiation dose.

Fig. 3. C - V characteristics of n-6H-SiC epilayer before irradiation (1) and after 150 keV irradiation with dose of 10^{13} cm^{-2} measured at RT (2), 500 K (3), and 100 K (4).

Fig. 4. C - V characteristics of unirradiated n-6H-SiC epilayer (1) and one measured at temperature of 500 K after 1 GeV proton irradiation ($D = 1.2 \times 10^{15} \text{ cm}^{-2}$) (2).

uniform doping with $N_d - N_a$ of $7 \times 10^{15} \text{ cm}^{-3}$ which exceeds much the initial one.

Six electron traps were found in DLTS spectra of n-type 6H-SiC samples irradiated with 8 MeV protons. Most of them were observed in electron-irradiated samples [7] or had parameters close to intrinsic structural defects. Two of the observed centers (with position in the band gap $E_c - 0.16 - 0.2 \text{ eV}$ and $E_c - 0.5 \text{ eV}$) were completely annealed out at 500–650 K. Sample with p-n junction was annealed at 800 K what resulted in small increase of the center $E_c - 0.7 \text{ eV}$ concentration.

DLTS investigation of electron traps in n-type 4H-SiC revealed 5 deep centers. Most of these were found in samples implanted with He^+ ions [4] or had parameters close to those of intrinsic defects. One of the observed centers ($E_c - 0.18 \text{ eV}$) was completely eliminated by annealing at 500–650 K.

Tables 1 and 2 list ionization energies of the observed centers, their estimated electron capture cross-sections (σ_n) and concentrations after irradiation with a dose of $2 \times 10^{14} \text{ cm}^{-2}$. For both of the polytypes studied, no pronounced difference was observed between the spectrum of deep centers formed in CREE epitaxial layers (CVD) and those grown by SE. The introduced RDs were completely annealed out at $\leq 2100 \text{ K}$.

In 6H-SiC epilayer irradiated with 1 GeV protons with dose of $3 \times 10^{14} \text{ cm}^{-2}$ DLTS revealed only two deep

electron traps: $E_c - 0.35 - 0.4 \text{ eV}$ (E_1/E_2) and $E_c - 1.2 \text{ eV}$ (R-center) in concentrations of $1 \times 10^{13} \text{ cm}^{-3}$ and $5 \times 10^{13} \text{ cm}^{-3}$, respectively. The R-center introduction rate was equal to 70 cm^{-1} for 8 MeV, and 0.17 cm^{-1} for 1 GeV protons.

3. Discussion and conclusion

As shown by the DLTS study, both 8 MeV and 1 GeV proton irradiation creates in n-type 6H-SiC a defect with the highest introduction rate ($E_c - 1.22 \text{ eV}$) with parameters close to those of the known structural defect—R center [8]. As follows from the parameters of the center located at $E_c - 1.22 \text{ eV}$, the recharging time (τ) for this center is of about two weeks at 300 K. Thus, the charge state of this and deeper lying centers does not change during $C-V$ measurements at RT. At the same time, the τ value for the center which is the closest to this level, ($E_c - 0.8 \text{ eV}$), is 3.3 s. Hence, the center $E_c - 0.8 \text{ eV}$ (and all shallower centers) can be considered completely ionized in $C-V$ measurements at RT.

In n-type 4H-SiC, several deep centers with ionization energy in the range of 0.96–1.5 eV are formed. The time constant of charge exchange for the $\text{RD}_{1,2}$ center is $5 \times 10^3 \text{ s}$ at RT. Similarly to the case of 6H-SiC, the charge state of these and deeper centers remains unchanged in the course of RT $C-V$ measurements. At

$E_c - E_0$ (eV)	σ_n (cm^2)	N_g (cm^{-3})	T_{ann} (K)	Implantation of He^+ [4]	Intrinsic defects
0.18	6×10^{-15}	2×10^{14}	< 650	P_1/P_2	Z_1 [4]
0.63–0.7	5×10^{-15}	5×10^{15}		Z_1	
0.96	5×10^{-15}	6.3×10^{15}		$\text{RD}_{1,2}$	
1.0	1×10^{-16}	6.3×10^{15}		RD_3	1.1 eV [9]
1.5	2×10^{-13}	5×10^{15}		RD_4	

the same time, the time τ for the Z_1 center, the closest to the mentioned above levels, as low as 3.6×10^{-2} s at RT.

At temperature of 650 K all known electron traps become ionized. Thus, the difference between the $N_d - N_a$ values measured at 300 and 650 K must be equal to the concentration of the center located at $E_c - 1.22$ eV for 6H-SiC and sum of $RD_{1,2}$, RD_3 , and RD_4 concentrations for 4H-SiC, determined from DLTS spectra. As seen from Figs. 1 and 2, this equality agrees well with experiment.

Most pronounced feature of 150 keV proton irradiation is insensitivity of the $C-V$ characteristics to dose of irradiation. This fact together with identity of the $C-V$ characteristics measured at 500 K after irradiation and ones of unirradiated samples means that the introduction rate of acceptor-like hole traps is equal to the one of donor-like electron traps. That is, 150 keV irradiation does not lead to change of charge density in space charge region of Schottky diodes at RT and higher temperatures. At the same time, at 100 K relatively shallow RDs are characterized by high τ and remains filled with electrons and, hence, their negative charge causes the shift of $C-V$ characteristics. Using approach described above (8 MeV protons) we estimated the R-center concentration. We extrapolate RT $C-V$ characteristic as shown in Fig. 4 (dashed curve) and obtained R-center concentration of $7 \times 10^{15} \text{ cm}^{-3}$. Hence, the R-center introduction rate by 150 keV proton irradiation is of about 700 cm^{-1} .

In conclusion, SI layers of 6H and 4H-SiC were created by proton irradiation with energies of 1 GeV, 8 MeV, 150 keV and 8 MeV, respectively. At the same time, it is shown that 1 GeV and 8 MeV irradiation of n-6H-SiC leads to increase of uncompensated donor concentration. Irradiation with energy of 150 keV leads only to capturing of electrons by

RD levels, but not to change in $N_d - N_a$ value. The introduction rate of the deepest RD in n-6H-SiC—R center was found to be 0.17, 70, and 700 cm^{-1} for 1 GeV, 8 MeV, and 150 keV protons, respectively. In 4H-SiC we obtained decrease of $N_d - N_a$ value after 8 MeV proton irradiation.

The obtained results may be applicable for creating local high-resistance SiC regions in technology of devices not intended for operation at high temperature, e.g., radiation detectors.

Interstitial-based vacancy annealing in 4H–SiC

E. Rauls^{a,*}, T.E.M. Staab^b, Z. Hajnal^a, Th. Frauenheim^a

Abstract

The migration of carbon interstitials through the 4H–SiC lattice and their recombination with vacancies has been investigated theoretically within the self-consistent charge density functional based tight-binding (SCC-DFTB) method. For vacancy–interstitial pairs created by irradiation, the capture radius of silicon and carbon vacancies has been examined, showing that interstitial migration through the otherwise perfect lattice starts getting important for distances larger than four nearest-neighbor atomic distances. © 2001 Elsevier Science B.V. 1. Introduction

Many defects in SiC have a strong influence on the electrical properties of the material. A detailed understanding of their structure and behavior due to radiation or a change in temperature is crucial to the application of SiC as material for high-power devices [1]. In spite of the great amount of experimental as well as theoretical work in this field, many defects in SiC are still not very well understood—among these are the most simple defects, single silicon and carbon vacancies. It is still an open question as to what happens on the microscopic scale, when the EPR-signals of these vacancies vanish after annealing of the crystal at certain temperatures [2]. The assignment of the signal made in Ref. [2] to a single carbon vacancy in 3C–SiC is still controversially discussed and the signal might instead belong to a defect complex involving the carbon vacancy. For example in Ref. [3], the authors investigated this problem with positron lifetime spectroscopy, and report the vanishing of the carbon vacancy in the temperature range of 400–650°C. Nevertheless, a migration process

in the SiC-lattice has to be found, for which the activation energy can explain the extremely low temperatures which are in the discussion to be the annealing temperature of V_C .

The first process one may think of is that the vacancies themselves become mobile and migrate on their sublattices to surfaces or dislocations. The energies needed for activating these processes were calculated to be 4.8 eV for V_{Si} and 5.2 eV for V_C —much too high to explain the experimental results [2].

Another process that could cause the signals to vanish is the formation of defect complexes, possibly leading to significantly different signals. The silicon vacancy can be annealed out by one of its carbon neighbors migrating into the vacancy, thus forming a $C_{Si}-V_C$ pair defect, which has already been described experimentally and theoretically [4,5]. The calculated activation barrier of 1.7 eV can explain the 750°C annealing stage found in Ref. [2]. The analogue process for the carbon vacancy, though, is not possible, since the Si_C-V_{Si} pair defect has been calculated to be unstable, recombining to V_C without a barrier [4,6]. The annealing of carbon vacancies must therefore be attributed to a more complicated mechanism.

In this work, we investigated several processes involving silicon and carbon interstitials, which, by irradiation of the sample, are created in comparable

*Corresponding author. AG Theoretical Physics, Physics Department, University of Paderborn, D-33095 Paderborn, Germany. Tel.: +49-5251-602378; fax: +49-5251-603435.

E-mail address: rauls@phys.upb.de (E. Rauls).

amounts to silicon and carbon vacancies. The number of carbon and silicon atoms that are moved from their lattice sites depends on the irradiation energy. This determines also the average distances of the created interstitial–vacancy pairs. As shown in Ref. [7], low irradiation energies (in the range of 100 keV) lead to close Frenkel pairs. In samples irradiated with energies at 300 keV, carbon interstitials and carbon vacancies are spatially separated, while silicon atoms due to their higher mass still form close Frenkel pairs. Only when using high irradiation energies in the range of 2 MeV, the silicon interstitials and silicon vacancies are separated as well [7].

Hence, two different situations have to be considered: If being separated by just a few atomic distances, vacancy and interstitial are not independent of each other and the vacancy might capture the interstitial, resulting in a strong lowering of the total energy of the whole structure. On the contrary, higher irradiation energies cause the pairwise created interstitials and vacancies to be much farther separated. Here, for the recombination process, the determining quantity is the activation barrier for the migration of the interstitials through the lattice, before reaching the capture radius of a vacancy.

In this paper, we focus on the case of low irradiation energies, i.e. slight separation of vacancy and interstitial. Here, the question arises as to how long-ranged the influence of the vacancy on the interstitial is. By calculating the energy barriers for several structures with a vacancy and a carbon interstitial in different distances, we investigated up to which atomic distance interstitial recombination with the vacancy is the dominating process, before migration from one lattice site to the next prevails.

Our calculations with the self-consistent charge density functional based tight binding (SCC-DFTB) method have been performed in a $(5 \times 6 \times 1)$ supercell of 4H-SiC containing 240 atoms. Saddle point geometries and diffusion paths were obtained using a constraint conjugate gradient [8] and an uphill activation relaxation technique (ART) [9] followed by steepest descent relaxations into both minima.

2. Migration of C-interstitials

Carbon interstitials are stable as split interstitials on both carbon and silicon sites: on the carbon site as $(CC)_C$ and on the silicon site in the form of a mixed split interstitial $(CSi)_{Si}$. For neutral silicon interstitials only $(SiSi)_{Si}$ is a stable configuration in 4H-SiC. Consequently, the migration of carbon interstitials in 4H-SiC can, in contrast to the silicon interstitials, take place on both silicon and carbon sublattices.

The migration mechanism from $(CC)_C$ to $(CSi)_{Si}$ has been investigated for different charge states in the 3C polytype in Ref. [10]. Since the local environment is very

similar in the different polytypes, the results are not expected to vary significantly over the different cubic or hexagonal polytypes. For comparison, we have performed test calculations for several intrinsic defects in 3C- and 4H-SiC. In 3C-SiC, formation energies and diffusion barriers calculated within the SCC-DFTB scheme differ from the *ab initio* results in most cases by less than 0.2 eV. The differences between formation energies of the same defect in 3C-SiC and 4H- or 6H-SiC are for simple defects like vacancies or antisites, of the same order of magnitude.

In the case of the neutral $(CSi)_{Si}$ split interstitial, however, we find the formation energy to be 2.2 eV higher than that of $(CC)_C$. This clearly deviates from the *ab initio* result of ≈ 0.5 eV given in Ref. [10]. The energy barrier between these two configurations is found to be only 0.1 eV for the additional C-atom moving from the Si- to the C-site. Thus, the stability of $(CSi)_{Si}$ is underestimated in SCC-DFTB compared to the *ab initio* calculations. An explanation for the described discrepancies of these results may be found in the choice of the basis. In the SCC-DFTB calculations a minimal (sp-) basis has been used, which probably does not describe the overcoordinated Si-atoms occurring in the $(CSi)_{Si}$ structures correctly. To further investigate this open question, calculations with an extended spd-basis are currently under way. Hence, we limit the presentation of our results in this paper to structures, where this problem does not occur.

For a migration on the C-sublattice only, the split carbon interstitial has to move from one C-site to another, the inequivalent lattice sites in the hexagonal polytypes of SiC, this migration mechanism to a second nearest neighbor site depends on the crystal direction. The directions for which the migration paths have been calculated are depicted by arrows in Fig. 1.

Furthermore, the orientation of the interstitial has to be considered. For the interstitial oriented as in Fig. 1, the distance from one of the interstitial atoms to the second nearest neighbor is slightly shorter in the direction of the *c*-axis than along $[10\bar{1}0]$ or $[11\bar{2}0]$. Fig. 2 shows the diffusion paths for the three different crystal directions. The lowest barrier (2.9 eV) is found for a migration along (0001) .

This energy barrier is rather high and a migration process consisting of several of these steps can certainly not explain an annealing process starting at the experimentally observed temperatures around 200°C [2]. Thus, some other process has to be considered—possibly including a change of the sublattice. Such processes are currently being investigated and will be published elsewhere.

As already stated above, in case of low irradiation energies interstitials and vacancies will not be separated so much that they could be treated as isolated defects. With decreasing distance the influence of the vacancy on

Fig. 1. $(CC)_C$ in a 4H-SiC lattice. The arrows show the directions for which the migration paths are shown in Fig. 2. Solid arrow: migration along $[10\bar{1}0]$, dashed arrow: $[11\bar{2}0]$, dash-dotted arrow: $[0001]$.

Fig. 2. Diffusion paths for the movement of $(CC)_C$ to the next C-lattice site depending on the three lattice directions.

the interstitial grows, and activation barriers for recombination will decrease. For $(CC)_C$ this has been investigated up to a fourth nearest neighbor distance between vacancy and interstitial site.

3. Recombination with vacancies

The mechanisms presented in this section apply in two cases: if created by high irradiation energies, the interstitial may start its migration process as described above on the carbon sublattice. After several of these steps or in case of lower irradiation energies, the

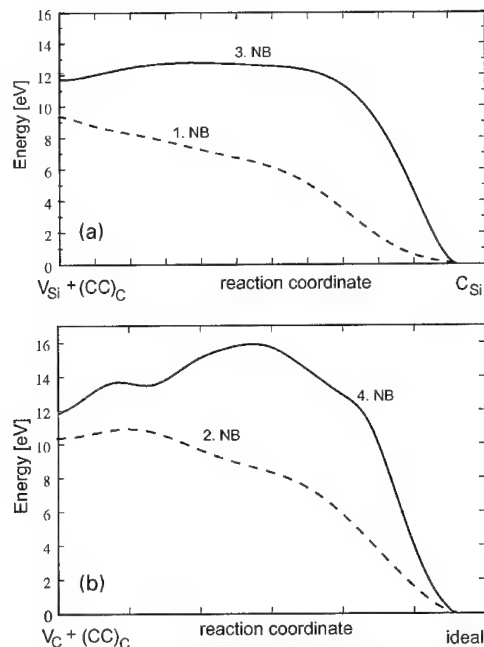

Fig. 3. Recombination of $(CC)_C$ with (a) V_{Si} and (b) V_C in several different distances. In (a), the energy during the migration process of the interstitial into the vacancy starting from a first neighbor (dashed line) or a third neighbor (solid line) position is shown. The structure $(CC)_C + V_{Si}^{1.NB}$ is metastable and recombines directly during relaxation. In (b) the same is shown for the carbon vacancy and the interstitial starting from a second (dashed) and a (fourth) neighbor distance, respectively.

interstitial reaches the capture area of either a silicon or a carbon vacancy. Then the height of the migration barriers for a direct recombination process compared to the barriers for the migration through the lattice determines whether migration continues by jumps along lattice sites or interstitial and vacancy recombine directly. The calculated diffusion curves are shown in Fig. 3.

Approaching the first neighbor site of V_{Si} , the C-interstitial becomes unstable and recombines with the vacancy without an energy barrier, see the dashed curve in Fig. 3(a). The resulting structure is a carbon antisite: $(CC)_C + V_{Si}^{1.NB} \rightarrow C_{Si}$, which is invisible by EPR and should, thus, explain the vanishing of the signals. For $(CC)_C$ at a second neighbor site to a carbon vacancy the barriers are with 0.5 eV still very low, see the dashed line in Fig. 3(b). For a third neighbor distance to V_{Si} we calculated a barrier of 1.08 eV (solid curve in Fig. 3(a)), which is still much lower than the lowest energy barrier for a migration on the C-sublattice (2.9 eV). In a fourth neighbor distance to V_C , the barrier approaches 4 eV (solid curve in Fig. 3(b)). Thus, starting from this position, the interstitial is unlikely to choose this

migration mechanism, but instead moves to a second neighbor C-site near the vacancy, and starts the described recombination process from this site. Thus, the lattice migration mechanism determines the necessary activation energy of the recombination. The influence of the vacancy on the interstitial is already negligible for a fourth neighbor separation. This is reflected by the formation energies of these structures, as well. For a fourth neighbor distance of these systems of a vacancy and a C-interstitial the limit for the sum of formation energies of an isolated vacancy and an isolated $(CC)_C$ is reached.

4. Conclusion

It has been investigated as to how interstitials, especially the carbon split interstitial $(CC)_C$, can contribute to the annealing of silicon and carbon vacancies in 4H-SiC. For migration on the carbon sublattice, diffusion paths along the three crystal directions have been calculated. The lowest activation barrier has been found for a migration along the *c*-axis of the crystal. Furthermore, the capture radius of vacancies has been examined by calculating activation barriers for a recombination with $(CC)_C$. We find that

such a process is favorable if $(CC)_C$ has approached at least a third nearest neighbor distance to the vacancy.

The ground state of silicon vacancies in 6H–SiC and 15R–SiC

Th. Lingner*, S. Greulich-Weber, J.-M. Spaeth

FB6-Experimental Physics, University of Paderborn, Warburger Str. 100, 33098 Paderborn, Germany

Abstract

We investigated irradiated 6H–silicon carbide (SiC) and 15R–SiC with the magnetic circular dichroism of the absorption (MCDA) and MCDA-detected electron paramagnetic resonance (EPR). In neutron- and electron-irradiated 6H–SiC, we observed two MCDA transitions at photon energies of 1.435 and 1.369 eV. Photoluminescence (PL) lines at these photon energies (the so-called V1 and V3 lines) are presently assigned to the neutral silicon vacancy at the two quasicubic lattice sites in 6H–SiC. In electron-irradiated 15R–SiC, which has three inequivalent quasicubic lattice sites, we observed three MCDA lines at 1442, 1438 and 1373 meV, respectively. At the photon energy expected for the hexagonal site in 6H–SiC (the so-called V2 PL line), no MCDA signal was observed. From the temperature and field dependence of the MCDA, a spin $S = \frac{1}{2}$ of the quasicubic sites was determined. EPR spectra detected via these MCDA lines consist of single EPR lines at $g = 2.005(2)$. We conclude that the ground state of V_{Si} giving rise to these optical transitions is paramagnetic with $S = \frac{1}{2}$, which is predicted theoretically for the ground state of the triply negative charge state. The previous assignment of the optical transitions to the neutral charge state must, therefore, be corrected. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon carbide; Vacancies; Electron paramagnetic resonance; Magnetic circular dichroism of the absorption

1. Introduction

Radiation-induced point defects in silicon carbide (SiC) have been studied for many years. But not even one of the most basic defects, the isolated silicon vacancy, is yet fully understood.

Photoluminescence (PL) spectra with zero phonon lines (ZPL) between 1.3 and 1.5 eV (the so-called V1, V2 and V3 lines) are frequently observed in irradiated 4H–SiC and 6H–SiC [1]. The number of ZPLs corresponds to the number of inequivalent lattice sites (two quasicubic and one hexagonal in 6H–SiC, and one quasicubic and one hexagonal in 4H–SiC). The intensity of the spectra is reduced after annealing above 750°C [1]. Sörman et al. detected several spin-triplet systems via the ZPLs with optically detected magnetic resonance

(ODMR) [1]. It was suggested that the ZPLs originate from the silicon vacancy in the neutral charge state. Later, Wagner et al. performed Zeeman experiments on these ZPLs [2]. No splitting of the lines in a magnetic field was observed, thus, it was concluded that the ground state and the excited states of the PL transitions in question were singlets and that the ODMR signals of the triplet systems had been detected indirectly via a shunt process [2,3].

To obtain information on the ground state of these optical transitions, we investigated irradiated 6H–SiC and 15R–SiC with the magnetic circular dichroism of the absorption (MCDA) and MCDA-detected electron paramagnetic resonance (MCDA-EPR). The MCDA technique is especially suited to investigate the ground state of an optical transition, because the MCDA signal of a paramagnetic center is proportional to the spin polarization of the ground state [3]. Saturation of the EPR transitions between the Zeeman levels of the ground state reduces the spin polarization and can be detected as a decrease in the MCDA signal (MCDA-EPR).

2. Experimental results

The MCDA spectrum of neutron- or electron-irradiated 6H-SiC (Fig. 1a) consists of two ZPLs at photon energies close to the energies of the V1 and V3 luminescence lines (Table 1). Such MCDA spectra were observed in n-type electron-irradiated, unannealed 6H-SiC as well as in neutron-irradiated and afterwards annealed ($T_{\text{ann}} = 600^\circ\text{C}$) n-type 6H-SiC. The MCDA lines disappeared after a 1000°C anneal. A similar MCDA-spectrum, but with three zero-phonon lines instead of two, was measured in electron-irradiated, unannealed n-type 15R-SiC (Fig. 1b). The intensities of the MCDA lines are field and temperature dependent and originate, therefore, from a paramagnetic ground state.

MCDA-EPR signals as in Fig. 2 were detected in all MCDA lines. The two 6H-SiC MCDA-EPR spectra consist of a single line at $g = 2.005(1)$. No anisotropy, fine structure, or hyperfine structure was resolved. However, the line is wide enough to contain a hyperfine structure as reported in Ref. [1]. MCDA-EPR

spectra with a single line at $g = 2.005(2)$ were also measured in 15R-SiC in the k_1 , k_2 and k_3 (quasicubic) MCDA lines. The spin S of the ground state can be determined from the temperature and field dependence of the MCDA intensity, using the Brillouin function [3]. We obtain $S = \frac{1}{2}$.

3. Discussion

In 6H-SiC, there are two and in 15R-SiC, there are three inequivalent quasicubic sites. We, therefore, tentatively attribute the three MCDA lines observed in 15R-SiC to the silicon vacancy at the three quasicubic sites.

The MCDA-EPR spectra measured in the V1 and V3 MCDA lines of 6H-SiC are not the spin triplet spectra reported in Ref. [1], which would be split by 2 mT. Assuming that according to Ref. [1], the luminescence ZPL assignment to the silicon vacancy at the different sites is correct, the ground state of the optical transitions of the quasicubic sites is indeed paramagnetic in contrast to Ref. [2], but its EPR spectrum is not the triplet spectrum reported in Ref. [1].

Fig. 1. MCDA spectrum of (a) neutron-irradiated 6H-SiC and (b) electron-irradiated 15R-SiC, measured with the magnetic field ($B = 2\text{ T}$) being parallel to the c -axis of the crystal at $T = 1.5\text{ K}$. The arrow indicates the position of the V2 luminescence ZPL for the hexagonal site in 6H-SiC as given in Ref. [1].

Fig. 2. MCDA-EPR-spectrum measured on the 1369 meV MCDA line of neutron-irradiated 6H-SiC at $T = 1.5\text{ K}$. The microwave frequency was 24.05 GHz. The magnetic field direction was parallel to the c -axis of the crystal.

Table 1
Zero phonon lines of the silicon vacancy in different polytypes of SiC

Site (label)	Photon energy (meV)			
	15R-SiC MCDA	6H-SiC MCDA	6H-SiC PL [2]	4H-SiC PL [2]
$h_1(\text{V2})$	—	—	1398	1352
h_2	—	—	—	—
$k_1(\text{V1})$	1438 ± 1	1435 ± 1	1433	1438
$k_2(\text{V3})$	1373 ± 1	1369 ± 1	1368	—
k_3	1442 ± 1	—	—	—

A spin $S = \frac{1}{2}$ ground state is possible for the silicon vacancy in the charge states +1 and -3 [4]. As the luminescence lines are always observed in n-type material [1,2] together with the EPR signal of the nitrogen donor [1], the charge state +1 is unlikely.

In tetrahedral symmetry, the silicon vacancy in SiC has an a_1 level and a higher lying t_2 level in the band gap [6]. The charge state $-3(a_1^2 t_2^3)$ has allowed optical transitions in the 1.4 eV range, as one electron from the a_1 level state can be optically excited into the t_2 level [6].

The absence of an MCDA signal at the position of the V2 line (which is assigned to the hexagonal sites [1]) in our samples can be explained by the silicon vacancies at the hexagonal sites being in the diamagnetic charge state $-4(a_1^2 t_2^6)$, while the vacancies at the quasicubic sites are at the same time in the charge state -3. This would mean that the charge transfer level -3/-4 of the quasicubic sites is above the charge transfer level -3/-4 of the hexagonal sites, and the Fermi level is in between these charge transfer levels. Such differences in charge transfer levels between the sites have been predicted theoretically [4,5].

In summary, we have to conclude that if the assignment of the V1, V2 and V3 PL lines to the silicon vacancy at the different sites according to Ref. [1] is correct, then the charge state giving rise to the V1 and

V3 luminescence lines of Table 1 is not zero but -3 with $S = \frac{1}{2}$. The previous assignment of the luminescence ZPLs to the neutral charge state of the silicon vacancy [1] must, therefore, be corrected.

Abstract

Co-implantation of Al ($2 \times 10^{18}/\text{cm}^3$) and C ($1 \times 10^{18}/\text{cm}^3$), Al/C, into 6H-SiC and subsequent annealing up to 1650°C were performed. Vacancy-type defects in the implanted layers were studied by positron annihilation spectroscopy. The mean size of vacancy-type defects produced by Al/C-implantation is found to be close to the size of divacancy. The mean size of vacancy-type defects is hardly changed by annealing below 600°C, and vacancy clustering occurs in an annealing temperature range between 600°C and 1000°C. At annealing temperatures between 1000°C and 1400°C, the mean size of vacancy-type defects decreases, and the major vacancy defects are annealed out above 1400°C. No significant difference is observed in the annealing behavior of vacancy-type defects between samples implanted with Al/C and only Al. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Silicon carbide (SiC) is regarded as a promising candidate for high-power and high-frequency devices owing to its excellent thermal and electrical properties [1,2]. In addition, since SiC has a strong radiation resistance [3,4], it is expected to be applied to electric devices used in radiation fields. For the fabrication of SiC devices, one of the key issues is the development of a selective impurity-doping technique. Donor or acceptor impurities have very low diffusion coefficients in SiC, and thus, thermal diffusion methods are not applicable for impurity doping into SiC. Therefore, ion implantation is considered as the most suitable technique. Since residual defects in implanted SiC layers act as carrier traps and/or scattering centers [5], understanding of

their annealing behavior is quite important. In previous studies [6,7], it was reported that the electrical activation of acceptors such as aluminum (Al) and boron in SiC was enhanced by co-implantation of carbon (C) ions. However, defects in co-implanted layers and their annealing behavior have not yet been clarified. In this study, we have investigated vacancy-type defects in 6H-SiC co-implanted with Al and C (Al/C) ions by positron annihilation spectroscopy (PAS) using monoenergetic positron beams.

2. Experiments

The samples used in this study were 5 µm thick n-type 6H-SiC epitaxial films grown on 6H-SiC substrates (3.5° off, Si-face). The net donor concentration of the epitaxial layer was $5 \times 10^{15} \sim 1 \times 10^{16}/\text{cm}^3$. Five-fold implantation of Al (20, 50, 110, 200 and 340 keV) was carried out at room temperature (RT) to form a box profile (depth: 0.5 µm) with a mean Al concentration of

$2 \times 10^{18}/\text{cm}^3$. A box profile of C atoms ($1 \times 10^{18}/\text{cm}^3$, $0.5 \mu\text{m}$ thick) was also formed by five-fold C-implantation (20, 60, 120, 190 and 270 keV) at RT or 800°C . The samples were annealed for 30 min up to 1650°C in argon (Ar) atmosphere after implantation. The hole concentration in Al-implanted layers was determined from the Hall measurements at RT.

PAS was carried out at the University of Tsukuba [8]. Doppler broadening profiles of annihilation γ -rays as a function of incident positron energy, E , were obtained by using monoenergetic positron beams. A spectrum of annihilation γ -rays (total counts of 5×10^5) was obtained using a Ge detector for each positron energy. The relationship between the S parameter (the ratio of the counts in $511 \pm 0.75 \text{ keV}$ to the total counts) and E (S - E curve) was analyzed with a computer code VEPFIT [9], which can solve a one-dimensional diffusion equation for positrons. The region sampled by positrons in ion-implanted 6H-SiC was divided into two or three blocks. From the calculations using the diffusion equation, the fractions of positrons annihilated at the surface, $F_s(E)$, and those in the i th block, $F_i(E)$, ($F_s(E) + \sum F_i(E) = 1$), were determined. The observed S - E curves were fitted to the following expression:

$$S(E) = S_s F_s(E) + \sum S_i F_i(E), \quad (1)$$

where S_s and S_i are the characteristic values of the S parameter for positrons annihilated at the surface and the i th block, respectively. The position of the boundary for each block and the diffusion length of positrons in each block were also determined by fitting. Details of the PAS measurements and analysis procedures have been reported in Ref. [8].

3. Results and discussion

Fig. 1 shows the depth profiles of S obtained for the 6H-SiC sample implanted with Al/C at RT and those subsequently annealed at 1000°C and 1300°C . For reference, the depth profile of Al atoms after implantation is also indicated. The S values are normalized by the S_b obtained for unimplanted 6H-SiC (S/S_b). The S values in shallow and deep damaged regions are referred to as S_{shallow} and S_{deep} , respectively. The positions of their boundaries are depicted as “the interface between the shallow and the deep blocks ($D_{s/d}$)” and “the interface between the deep block and the defect-free region ($D_{d/f}$)”. For the as-implanted sample, S_{shallow} and S_{deep} are obtained to be 1.075 and 1.065, respectively. This indicates that the open volume of vacancies in the shallow block, whose thickness is almost the same as the Al box profile, is larger than that in the deep block. Brauer et al. [10] reported that the normalized S value for divacancies, $V_{\text{Si}}V_{\text{C}}$, consisting of a silicon vacancy, V_{Si} , and a carbon vacancy, V_{C} , in 6H-SiC was 1.05. The

Fig. 1. Depth profile of S parameters obtained for 6H-SiC implanted with Al/C at RT and those subsequently annealed at 1000°C and 1300°C . The depth profile of Al atoms after implantation, which is determined from secondary ion mass spectroscopy, is also shown in the figure. The S values are normalized by the S_b obtained for the unimplanted one (S/S_b).

normalized S , which depends on the mean size of vacancy-type defects, was also reported to be 1.105 for $2-V_{\text{Si}}V_{\text{C}}$ or $3-V_{\text{Si}}V_{\text{C}}$ [10,11]. Taking into account the fact that several species of vacancy-type defects coexist in ion-implanted layers, we can say that the mean size of the residual vacancy-type defects in 6H-SiC implanted with Al/C at RT is close to the size of $V_{\text{Si}}V_{\text{C}}$. After annealing at 1000°C , S_{shallow} remarkably increases to be 1.115 whereas such a drastic increase is not observed in S_{deep} . This result indicates that large vacancy clusters are formed in the shallow block and that clustering of vacancies is suppressed in the deep block. No significant change of $D_{s/d}$ and a large shift of $D_{d/f}$ toward the surface suggest that damages are not annealed in the shallow region but recover in the deep region at 1000°C . A similar annealing behavior was reported in 6H-SiC implanted with phosphorus, P [11,12]. For the sample annealed at 1300°C , the S - E curve can be fitted using two blocks. A decrease of S_{shallow} and a further shift of $D_{d/f}$ toward the surface are observed. This result indicates that the mean size of vacancy-type defects decreases and further recovery of the damaged layer takes place on annealing at 1300°C .

Figs. 2 (a) and (b) show the annealing temperature dependence of S parameters and the position of the interface, respectively, for the samples implanted with Al and Al/C. No significant difference in the changes of S parameters and interface positions due to annealing is observed among all samples. Both S_{shallow} and S_{deep} are hardly changed by annealing up to 600°C . No significant change of $D_{s/d}$ and $D_{d/f}$ are observed below 600°C . Those results show that vacancy-type defects hardly migrate in this annealing temperature range. Between

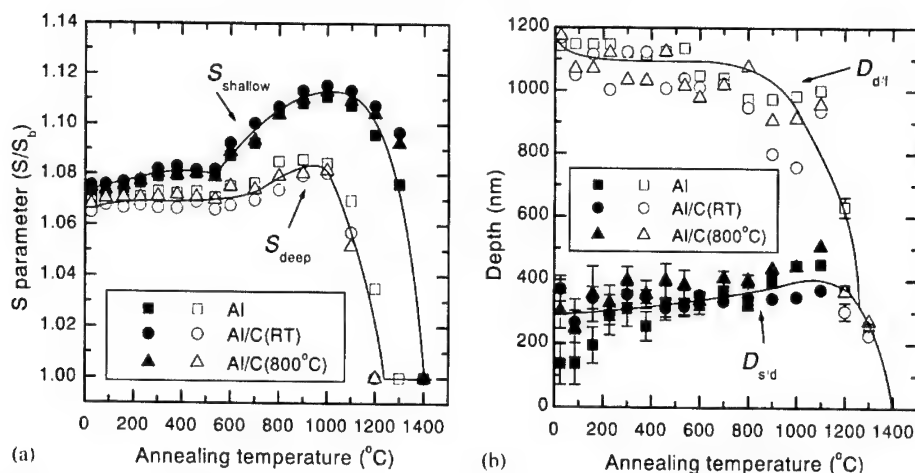

Fig. 2. (a) Annealing temperature dependence of S_{shallow} and S_{deep} obtained in 6H-SiC implanted with Al/C and Al ions. Al-implantation into all samples was carried out at RT. Squares, circles and triangles represent the results obtained in samples implanted with only Al, Al/C at RT, and Al/C at 800°C, respectively. Closed and open symbols represent S_{shallow} and S_{deep} , respectively. The S values are normalized by the S_0 obtained in the unimplanted sample (S/S_0). (b) Annealing temperature dependence of $D_{s/d}$ and $D_{d/r}$ obtained in 6H-SiC implanted with Al/C and Al ions. Closed and open symbols represent $D_{s/d}$ and $D_{d/r}$, respectively.

600°C and 1000°C, S_{shallow} remarkably increases with annealing temperature, though an increase of S_{deep} is not so large for all samples. In this temperature range, no significant shift of $D_{s/d}$ is observed in contrast to the shift of $D_{d/r}$. Those results suggest that clustering of vacancies occurs via the partial migration of vacancies from a deep region. The S_{shallow} and S_{deep} for all samples decrease with raising annealing temperature above 1000°C. A considerable shift of $D_{d/r}$ toward the surface is observed in this range. After annealing at 1400°C, the $S-E$ curves for all implanted samples are comparable to that for unimplanted sample, indicating that the concentration of vacancy-type defects are reduced below the detection limit of PAS by annealing at 1400°C. The results obtained above 1000°C are explained by annealing of damaged layers at such high temperatures. Similar observations were reported in P-implanted 6H-SiC [11,12]. The results of Hall measurements indicated the enhancement of the electrical activation of Al acceptors due to co-implantation, which is shown in Table 1. Taking into account the fact that the removal of vacancy-type defects by annealing at 1400°C is observed in all samples, the enhancement of the Al acceptor activation due to the co-implantation is not attributable to remaining defects which act as carrier traps. This supports the site competition model [6], i.e., the improvement of the electrical activation of Al is due to an increase of the number of Al atoms residing at Si sublattice sites, which act as shallow acceptors. However, the mechanism of the further improvement of the electrical activation of Al by co-implantation of C at elevated temperature is still unclear. To clarify this point, further investigations are necessary.

Table 1

Hole concentration (RT) in samples implanted with Al and Al/C. The samples were subsequently annealed at 1650°C in Ar

Ion species/ substrate temperature	Ion species/ substrate temperature	Hole concentration (/cm ³)
Al/RT		3×10^{16}
Al/RT	C/RT	4×10^{16}
Al/RT	C/800°C	8×10^{16}

4. Summary

Co-implantation of Al ($2 \times 10^{18}/\text{cm}^3$) and C ($1 \times 10^{18}/\text{cm}^3$) into 6H-SiC and subsequent annealing up to 1650°C were carried out. Vacancy-type defects in implanted layers were studied by PAS using monoenergetic positron beams. The mean size of vacancy-type defects in the sample implanted with Al/C or only Al is found to be close to the size of $V_{\text{Si}}V_{\text{C}}$. No significant difference in the annealing behavior of vacancy-type defects is observed between Al/C- and only Al-implanted samples. The mean size and depth profile of vacancy-type defects do not change significantly by annealing up to 600°C. Clustering of vacancies takes place by annealing between 600°C and 1000°C. Vacancy-type defects are annealed at temperatures above 1000°C and most of them are annealed out at 1400°C. Concerning the electrical properties of implanted layers, the electrical activation of Al acceptors is enhanced by co-implantation of C. The enhancement can be

explained by the site competition model, which has no discrepancy with the results obtained for defects remaining in SiC implanted with Al/C and Al.

Interstitials in SiC: a model for the D_{II} center

Alexander Mattausch*, Michel Bockstedte, Oleg Pankratov

Lst. für. Theor. Festkörperphysik, Universität Erlangen-Nürnberg, Staudtstrasse 7, D-91058 Erlangen, Germany

Abstract

In photo luminescence experiments, the D_{II} center shows strong carbon-like vibrational modes above the highest bulk phonon mode. We have performed ab initio DFT calculations of the localized vibrational modes (LVM) of defects in SiC possessing carbon-carbon bonds. Among these defects, only the carbon split interstitial-antisite complex is found to exhibit a LVM spectrum compatible with that of the D_{II} center. The formation energy of this complex compares to the formation energy of the most abundant interstitial defects, namely the carbon split interstitial and the carbon-silicon split interstitial. We find a high binding energy of 3.6 eV and above. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

For decades the D_I and D_{II} centers in SiC have been subject to thorough investigation. Though generated via ion implantation and subsequent annealing, both centers do not depend on the particular dopant and polytype and are stable at temperatures up to 1700°C and 1300°C, respectively. These properties indicate that the centers are intrinsic defects. While the microscopic structure of the D_I center still remains unclear, a di-interstitial configuration has been proposed for the D_{II} center by Patrick and Choyke [1,2]. This suggestion is based on photo luminescence experiments that exhibit five localized vibrational modes (LVM) above the highest SiC bulk phonon spectrum and two additional modes within the phonon band gap. The LVM-frequencies reach up to 40 THz, which is the same value as the highest phonon mode in diamond. For this reason, short carbon bonds have been suggested as the origin of these LVMs.

2. Ab initio calculation of LVMs and defect formation energy

We have analyzed the phonon frequencies of several possible candidates for the D_{II} center by employing density functional theory within the local density approximation and using norm-conserving pseudopotentials. The full dynamic matrix of the supercells with 64 atoms (3C-SiC) and 128 atoms (4H-SiC) has been calculated and diagonalized. This matrix is defined as

$$\Phi_{ij} = \frac{1}{\sqrt{m_i m_j}} \frac{\partial^2 E}{\partial Q_i \partial Q_j} = \frac{1}{\sqrt{m_i m_j}} \frac{\partial F_i}{\partial Q_j}.$$

With small displacements we numerically calculate the derivative $\partial F_i / \partial Q_j$. However, we have found sizable anharmonic effects. To obtain proper harmonic force constants, we have considered three different displacements for each atom and extracted the linear factor in a polynomial expansion of the forces. The forces have been calculated with software package FHI96SPIN [3]. A cut-off energy of 30 Ry and a special k-point-set to sample the Brillouin zone have been employed (except when the Jahn-Teller effect comes into play, then the Γ -point has been used). The forces have been converged to

E-mail address: alexander.mattausch@physik.uni-erlangen.de (A. Mattausch).

a relative accuracy of up to 10^{-4} . The resulting phonon spectra for the analyzed defects reveal vibrational modes in the band gap and above the highest bulk phonon mode which can be identified by comparison with a calculated bulk phonon spectrum. For the bulk spectrum, we find a slightly too small phonon band gap with 19.2 THz for the lower band edge (L and X point) versus 18.5 THz experimentally and 22.0 THz for the upper band edge at the L-point (23.1 THz experimentally). For the optical modes (LO, TO) at the Γ point we find 27.9 THz. In our calculation, we cannot distinguish between the TO and the LO mode at the Γ point (24.1 and 29.1 THz experimentally) due to the incompatibility of the macroscopic polarization of the crystal with the periodic boundary conditions imposed on the defect cell. This shortcoming, though, does not have any implications for the calculation of the localized defect modes. The results on defect energetics in 3C-SiC have been published previously [4].

3. Candidates for the D_{II} center

The relevant defect models for the D_{II} spectrum need a diamond-like environment to provide LVMs with frequencies as high as those experimentally found. The originally suggested di-interstitial is indeed a short carbon dimer, but we find a formation energy of approximately 12 eV which is much higher than that of other intrinsic defects. The most abundant defects with carbon bonds are the carbon antisite (C_{Si}), the carbon split interstitial $C_{sp}<100>$ (two carbon atoms sharing a carbon lattice site), the carbon–silicon split interstitial $C_{sp,Si}<100>$ (a carbon and a silicon atom on a silicon site) and the carbon split interstitial–antisite complex

$C_{sp,C_{Si}}<100>$ (two carbon atoms sharing a silicon site). The geometries of these defects are shown in Fig. 1.

In their undistorted structure, all split interstitials show degenerate defect levels in the electronic band gap. By occupying these levels, the Jahn–Teller effect causes a reduction of the symmetry and a splitting of these levels. In order to avoid the Jahn–Teller effect initially, we have considered the charge state 2^+ , in which the defect levels are unoccupied. For further investigation of $C_{sp,C_{Si}}<100>$, also the charge state 1^+ including Jahn–Teller distortion has been investigated. The carbon antisite C_{Si} exists only in the neutral charge state.

4. LVMs of D_{II} candidates

We have listed the results for all analyzed defects in 3C-SiC in Table 1. The antisite C_{Si} is the second most abundant carbon defect in SiC. Though it is surrounded by carbon neighbors, the phonon spectrum only shows a splitting of the bulk modes. The nearest neighbor atoms relax inwards and a shortening of the bonds can be identified, but they are still too distant to allow for the localized modes found in the D_{II} spectrum.

The carbon split interstitial $C_{sp}<100>$ has a carbon dimer (we find a distance between the two carbon atoms of approximately 2 Bohr) and is therefore closely related to the originally suggested carbon di-interstitial. It is the most abundant interstitial defect in SiC. The phonon spectrum, though, only shows a single LVM above the bulk spectrum with a frequency of 53 THz. The bonds to the neighboring silicon atoms are weak, the vibration decouples from its nearest neighbors and the split interstitial shows the behavior of a single C_2 molecule, which has a highest vibrational mode of 48.3 THz. Our

Fig. 1. Atomic structure of the investigated defects. From left to right: carbon antisite C_{Si} , carbon split interstitial $C_{sp}<100>$, carbon–silicon split interstitial $C_{sp,Si}<100>$, carbon split interstitial–antisite complex $C_{sp,C_{Si}}<100>$.

Table 1

Mode F	—	53.0	38.1	43.4	43.2	39.8

calculated result is higher than this value. However, significant anharmonicity already for small displacements is present as the saddle point for a migration of one of the atoms lies very close to the defect geometry. The silicon–carbon split interstitial $C_{sp, Si} \langle 100 \rangle$ is surrounded by carbon neighbors. This defect has the second lowest formation energy of all interstitial defects. Carbon bonds exist between the carbon atom of the split interstitial and its two nearest neighbor atoms. A more complex vibrational spectrum is hence expected. Indeed, we find three non-degenerate LVMs above the highest bulk mode. However, the number of LVMs does not match those of the D_{II} center. Since the defect's saddle point for migration also lies close to the defect geometry, anharmonicity should be relevant.

The carbon split interstitial–antisite complex $C_{sp, C_{Si} \langle 100 \rangle}$ is a stable defect complex with a formation energy comparable to that of the split interstitials. We find a high binding energy of 3.6 eV for the charge state 2^+ , rising up to 4.4 eV for the neutral charge state. Hence this complex should be stable up to high temperatures. The phonon spectrum shows five LVMs above the highest SiC bulk mode, with frequencies in agreement with the D_{II} spectrum. Furthermore, two gap modes can be identified. The amplitudes of the high frequency modes are well localized to the defect molecule comprised of the split interstitial and the neighboring carbon atoms. In the charge state 2^+ the modes D and E are degenerate (c.f. Table 1), whereas the D_{II} spectrum shows two distinct lines for this frequency region. This can be explained by symmetry. In the charge state 2^+ the defect's point group is D_{2d} and the defect possesses an unoccupied degenerate defect level in the electronic band gap. This changes for the charge state 1^+ . The degenerate orbitals become occupied and a Jahn–Teller distortion lowers the symmetry of the defect to C_{2v} . This implies a symmetry induced splitting of the vibrational modes. Indeed, for the charge state 1^+ we find five non-degenerate phonon modes in good agreement with the D_{II} spectrum. The transition level for this charge state $E(+ + / +)$ lies 0.4 eV above the valence band, allowing for the existence of this defect in C_{2v} already in p-type material. In the charge

state 2^- all defect states are occupied, a Jahn–Teller effect does not occur and the defect has D_{2d} symmetry again. The transition level $E(- - / -)$ is 1.5 eV above the valence band, well above mid-gap. Thus this defect exists in C_{2v} symmetry over a wide range of doping conditions—in p-type material as well as in n-type material.

Considering the defect molecule only, we find a similar result for 4H–SiC. For the charge state 2^+ the phonon spectrum of this defect shows five non-degenerate LVMs above the highest SiC bulk mode with frequencies comparable to those in 3C–SiC. The splitting of the LVMs D and E results from the lower symmetry of 4H–SiC. Our findings suggest an independence of the vibrational spectrum of the polytype for this defect.

5. Kinetic aspects

It is well-known from experiments that the concentration of the D_{II} center increases during the annealing and the spectrum persists to temperatures up to 1300°C. This suggests that the formation of the D_{II} center is kinetically driven and that it possesses a high binding energy. During implantation, an excess concentration of interstitials and vacancies is created. Considering diffusion processes [5], it is possible to construct a formation mechanism for the $C_{sp, C_{Si} \langle 100 \rangle}$ complex. The first step in this process is the formation of a carbon antisite. A possible process may start with a silicon vacancy. This defect is unstable against transformation into a carbon vacancy–antisite complex with a barrier of 1.6 eV in p-type material. As already noted, the carbon split interstitial is the most abundant interstitial defect in SiC. It also has a very low migration barrier of 1.7 eV. Such an interstitial can now recombine with the carbon vacancy of the vacancy–antisite complex to form an isolated carbon antisite. A further carbon split interstitial is now needed for the formation of the split interstitial–antisite complex. Due to its high binding energy of 3.6 eV and above, an attraction between the individual defects can be assumed.

From the above, we expect for $C_{sp,C_{Si}}\langle 100 \rangle$ the annealing kinetics comparable to that of the D_{II} center.

6. Summary

We have analyzed the phonon spectra of carbon related intrinsic point defects in order to identify the localized vibrational modes. For the carbon split interstitial–antisite complex $C_{sp,C_{Si}}\langle 100 \rangle$ we find good agreement between our calculated phonon frequencies and the D_{II} spectrum from PL-experiments. Its high binding energy suggests a high thermal stability. The other investigated defects do not show compatible phonon spectra. Besides, the high mobility of both split interstitials does not agree with the high thermal stability of the D_{II} spectrum. A possible annealing kinetics for this complex has been discussed.

Abstract

Defects in epitaxially grown 4H and 6H SiC induced by He-implantation have been studied by positron annihilation and deep level transient spectroscopy. Two major annealing processes of vacancy-type defects appeared at 500–800°C and above 1000°C irrespective of polytype and conduction type. In n-type samples, the latter process is dominated by two different types of defects. In n-type 6H SiC, $Z_{1/2}$ levels emerged after annealing at 800°C. The $Z_{1/2}$ levels disappeared around 1100°C with an appearance of $E_{1/2}$ levels. The $E_{1/2}$ levels are eventually annealed at 1500–1700°C. Similar annealing behavior was observed for the corresponding levels in n-type 4H SiC, i.e., $RD_{1/2}$ and $Z_{1/2}$ levels. The overall annealing behavior of vacancy-type defects by positron annihilation and the deep levels are in good agreement above 800°C suggesting that the above deep levels are related to the vacancy-type defects. © 2001 Elsevier Science B.V. 1. Introduction

Ion-implantation is an indispensable technique for the selective doping of SiC because of the extremely small diffusion constants of the dopant impurities. Residual defects induced by post-implantation annealing prevent the full activation of dopant impurities. After ion bombardment a series of deep levels have so far been observed in SiC [1]. In particular, two major peaks termed $E_{1/2}$ and $Z_{1/2}$ in 6H SiC and $Z_{1/2}$ and $RD_{1/2}$ in 4H SiC are important after a high temperature annealing above 1000°C [2]. These levels are thought to have the following correspondence: $E_{1/2}:6H \leftrightarrow Z_{1/2}:4H$ and $Z_{1/2}:6H \leftrightarrow RD_{1/2}:4H$ [1]. That is, the corresponding defects in these polytypes have the same atomic structures. Their origins are still unknown.

In this work, we investigated the annealing processes of vacancy-type defects in 4H and 6H SiC epilayers after He-implantation using positron annihilation spectroscopy (PAS). Deep level transient spectroscopy (DLTS) measurements have also been carried out on the same wafers [3]. From the correlation between PAS and DLTS data, we confirmed that $E_{1/2}$ and $Z_{1/2}$ levels in 6H SiC and $Z_{1/2}$ and $RD_{1/2}$ levels in 4H SiC are originating from vacancy-type defects.

2. Experimental

Samples were cut from chemical vapor deposition (CVD) grown 4H and 6H SiC films doped with nitrogen (n-type) or aluminum (p-type) with approximately 5 µm thick on the respective substrates. The net doping concentration was approximately $5 \times 10^{15} \text{ cm}^{-3}$. In order to generate a box-shape defect profile in the epilayers, the samples were implanted with He ions at

E-mail address: ak@taka.jaeri.go.jp (A. Kawasuso).

energies (doses) of 30 keV ($8 \times 10^{11} \text{ cm}^{-2}$), 100 keV ($9.5 \times 10^{11} \text{ cm}^{-2}$), 210 keV ($9.5 \times 10^{11} \text{ cm}^{-2}$), 350 keV ($9.5 \times 10^{11} \text{ cm}^{-2}$), 500 keV ($9.5 \times 10^{11} \text{ cm}^{-2}$), 650 keV ($1 \times 10^{12} \text{ cm}^{-2}$), 800 keV ($1.1 \times 10^{12} \text{ cm}^{-2}$) and 950 keV ($1.3 \times 10^{12} \text{ cm}^{-2}$) at room temperature. Isochronal annealing was conducted from 100°C to 1700°C for 30 min in vacuum or dry argon ambient. Positron annihilation Doppler broadening measurements were performed with the positron beam at an incident energy (E) below 40 keV. The energy windows for the peak intensity (S -parameter) and tail intensity (W -parameter) are 511.0 ± 0.9 and 516.0 ± 6.0 keV, respectively. Positron lifetime measurements were also carried out with a pulsed beam at $E = 17 \text{ keV}$. The time resolution of the spectrometer was approximately 260 ps. All the unimplanted samples showed a unique S -parameter at $E > 15 \text{ keV}$. Only one lifetime component (140–145 ps), which agreed with the SiC bulk lifetime [4], was found in unimplanted p-type samples though the spectra of unimplanted n-type samples that were strongly modulated due to the positron reemission effect. Thus, we use unimplanted p-type samples as references and suppose that S -parameter at $E > 15 \text{ keV}$ represents the bulk value.

3. Results and discussion

Fig. 1 shows the positron lifetime spectra for He-implanted samples with a reference sample (unimplanted p-type 6H). The positron lifetime shows a similar increase after implantation in both polytypes and conduction types. The average lifetime after implantation is determined to be approximately 210 ps for all the

Fig. 1. Positron lifetime spectra of an unimplanted p-type 6H SiC (as a reference) and of He-implanted samples.

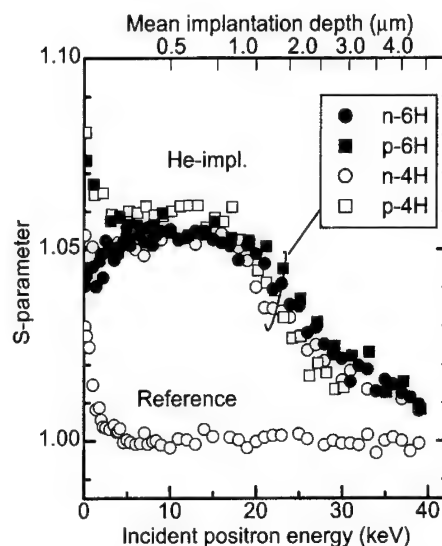

Fig. 2. S -parameter for the reference sample (unimplanted p-type 6H SiC) and for the He-implanted samples as a function of incident positron energy. The S -parameter is normalized to that of the reference sample at $E > 15 \text{ keV}$.

samples. Two-component analyses gave rise to the defect-related lifetime (τ_2) of $236 \pm 8 \text{ ps}$ with an intensity of 60–70%. Fig. 2 shows S -parameter after implantation (normalized to the bulk S -parameter) with that of the reference sample as a function of incident positron energy. After implantation, S -parameter increases homogeneously from the unimplanted level at $3 \text{ keV} < E < 17 \text{ keV}$ and approaches the bulk value with increasing energy. This indicates that vacancies are homogeneously distributed in the implanted region. The depth profiles of vacancies determined by the VEPFIT program considering the one-dimensional diffusion of positrons [5] actually agreed with that calculated from SRIM simulation [6]. The average S -parameter in the implanted region is 1.056. There are no significant differences between different polytypes and conduction types in both lifetime spectra and S – E relations. The absence of polytype dependence on S -parameter and lifetime shows that the same types of vacancies are generated as positron trapping centers irrespective of the polytype. The absence of conduction type dependence can be explained as the shift of the Fermi level towards the mid-gap in both n- and p-type samples so that positron-trapping centers are retained in the same charge states. The observed S -parameter (~ 1.06) and positron lifetime ($\tau_2 = 236 \text{ ps}$) in the damage region greatly exceed the specific values for isolated silicon vacancies (1.028–1.031 [7] and $\sim 190 \text{ ps}$ [8], respectively). This shows that both single vacancies and further vacancy agglomerates, such as divacancies, are

Fig. 3. S -parameter for He-implanted samples as a function of annealing temperature.

generated by implantation. This is naturally understood in terms of nuclear collisions near the ranges of He ions.

Fig. 3 shows the annealing behavior of the S -parameter in the damage region determined by the VEPFIT analysis. The annealing behaviors for 4H and 6H samples are quite identical. This again shows that the similar damages are created in both polytypes. One may divide the annealing process of S -parameter into three parts: (i) the first decrease at 500–700°C; (ii) a slight increase around 1000°C and (iii) a final recovery above 1100°C. In the first part, the defect-related positron lifetime was similar to that for the as-implanted sample ($\tau_2 = 236$ ps), while the intensity decreased from approximately 70% to 50%. The first annealing process is primarily interpreted as the disappearance of as the single vacancies. This is in good agreement with the previous report that isolated silicon and carbon vacancies are mobile below 1000°C [9]. The increase of the S -parameter in the second part implies the generation of complex defects. Probably, a part of mobile vacancies agglomerates or combines with other defects. The former two processes are commonly observed for both conduction types suggesting a lesser influence of dopant impurities. The S -parameter for the p-type samples decreases steeply around 1100°C and reaches the unimplanted level already at 1200°C. Contrary to this steep recovery for the p-type samples, the n-type

samples show a somewhat broad feature. This means that another type of defects, which cannot be seen in p-type samples, is detected in n-type samples above 1200°C. There are two possible ways to explain this result: (i) Only one type of defect exists in p-type samples, while two types of defects (one of them is common to p-type) exist in n-type, or (ii) Two types of defects acting as positron trapping centers exist in both n- and p-type samples. One of them, which has a higher thermal stability, is not detected in p-type samples due to the recovery of the Fermi level accompanying the disappearance of the majority of defects so as to charge positron-trapping centers more negatively and positively in n- and p-type samples, respectively. It is rather difficult to decide which of the above possibilities actually occur. However, in any case, two different types of defects contribute to the annealing process of n-type samples above 1000°C. The increase of S -parameter at 1000°C was not observed in the case of electron-irradiated samples [10]. It is assumed that He-implantation causes much more complicated damage structures than electron irradiation. Therefore, we suppose that such an effect preferentially appears with higher amount of damages. The final recovery of S -parameter above 1200°C for n-type samples is also observed in the electron-irradiated samples. Thus, the same type of defects should be responsible for this annealing process in He-implanted and electron-irradiated samples. From the detailed analyses of the electron-irradiated samples, we proposed that complex defects related to silicon vacancies are important. It is interesting to note that even in the case of He-implantation, which may resulting in a heavier damage than electron irradiation, all the vacancy-type defects detected by positron annihilation vanish after annealing at 1700°C as well as in electron irradiation case.

We compare the above-described positron annihilation and DLTS experiments. After annealing above 700°C, $E_{1/2}$ and $Z_{1/2}$ levels in 6H and $Z_{1/2}$ and $RD_{1/2}$ levels in 4H are observed [3]. The concentrations of these levels are determined by $C-V$ characteristics. Fig. 4 shows the annealing behavior of these levels with the respective S -parameters. The concentrations of $Z_{1/2}$ in 6H and $RD_{1/2}$ in 4H samples slightly increase at 1000°C and drastically decrease until 1200°C. The concentrations of $E_{1/2}$ in 6H and $Z_{1/2}$ in 4H increase from 1000°C along with the decreases of $Z_{1/2}$ in 6H and $RD_{1/2}$ in 4H and finally decrease above 1400°C. One can immediately find that these successive annealing behaviors of $E_{1/2}$ and $Z_{1/2}$ levels in 6H and $Z_{1/2}$ and $RD_{1/2}$ levels in 4H are in good agreement with what we observed for the S -parameter. That is, increase in the concentrations of $Z_{1/2}$ in 6H and $RD_{1/2}$ levels in 4H closely matches with that of S -parameter at 1000°C. The decrease in the concentrations of $E_{1/2}$ in 6H and $Z_{1/2}$ levels in 4H coincides with the final recovery of S -parameter at

Fig. 4. Annealing behavior of the S -parameter and concentrations of the observed deep levels ($E_{1/2}$ and $Z_{1/2}$ levels in 6H and $Z_{1/2}$ and $RD_{1/2}$ levels in 4H SiC) for He-implanted samples in the annealing temperature range above 800°C.

1200°C. Thus, the above electronic levels should be related to vacancy-type defects detected by positron annihilation. Recently, we also proposed that $E_{1/2}$ in 6H and $Z_{1/2}$ in 4H should be silicon-vacancy-related defects using electron-irradiated epilayers [10]. This proposal is again supported here.

4. Summary

In summary, we investigated the annealing process of vacancy-type defects in 4H and 6H SiC CVD epilayers after He-implantation. There are no essential differences

between 4H and 6H samples in their annealing process. From the comparison between n- and p-type samples, it was found that two types of vacancies contribute to the annealing process above 1000°C in n-type samples. The overall annealing behavior for vacancy-type defects agrees with the successive annealing of $Z_{1/2}$ and $E_{1/2}$ levels in 6H and $Z_{1/2}$ and $RD_{1/2}$ levels in 4H SiC.

Abstract

Vacancy-type defects produced by 100 keV Al⁺ ion implantation in epitaxial 4H–SiC have been studied by positron annihilation spectroscopy. The implantation dose varied from 3×10^{13} to 1×10^{15} /cm² and the implantation temperature was 25–800°C. From the experimental results it is clear that the implantation at elevated temperatures reduces the number of vacancy type defects. Furthermore, the defect-cluster size depends on the implantation temperature, suggesting that the vacancies involved are mobile. The positron annihilation experiments also suggest that the defect profile extends deeper into the samples than expected from the deposited energy distribution and from previous Rutherford backscattering/channeling measurements. © 2001 Elsevier Science B.V. Keywords: Vacancies; Implantation; Positron annihilation

1. Introduction

During the last decade much interest has been drawn towards silicon carbide, due to its versatility as a base for electronic and optoelectronic devices. Owing to its material properties, SiC devices can operate under extreme conditions, e.g. high electric power, high temperatures, etc. It has previously been shown that Al implantation is an adequate technique to produce sharp p⁺ doped regions in SiC [1–3]. An evident disadvantage of this technique is the production of implantation induced defects, such as vacancies and interstitials. In order to maintain the electrical properties of the crystal these defects have to be annealed. These anneals often require very high temperatures [4], but if the implantation damage is too heavy, the electrical properties of the crystal cannot be restored [5]. In order to reduce the implantation damage and allow point defects to recombine, the implantation can be performed at elevated temperatures.

Positron annihilation spectroscopy (PAS) has successfully been used to identify and characterize vacancy-type point defects in semiconductors [6]. In this study we apply PAS in the Doppler broadening mode to study ion implantation induced defects in 4H–SiC. Previous studies have identified the silicon and carbon mono-vacancies in irradiated SiC [7] and some studies on implantation related defects have also been done [8,9]. The PAS results are compared to measurements done with Rutherford backscattering spectrometry (RBS) in the channeling mode from the same samples.

2. Experimental

The samples used in this study were epitaxial 4H–SiC layers with thicknesses of more than 10 µm grown by chemical vapour deposition on 4H n-type SiC substrates. The samples were implanted with 100 keV Al⁺ ions, the dose varied between 3×10^{13} and 1×10^{15} /cm². The implantation temperature was 25–800°C.

In order to study the vacancy-type defect distributions in the implanted samples, we used a monoenergetic positron beam. Positron spectroscopy is a powerful tool to study vacancy-type defects. Positrons in materials

E-mail address: jonatan.slotte@hut.fi (J. Slotte).

science can either be taken directly from a β^+ source or, as in this case, be moderated and then accelerated to the desired implantation energy. After thermalization the positron diffuses in the sample until it annihilates with an electron. Neutral and negative vacancy-type defects in the lattice act as positron traps. When a positron is trapped by such a defect, its lifetime increases and the positron–electron momentum distribution narrows due to reduced electron density.

The momentum of the annihilating positron–electron pair can be detected as Doppler broadening of the 511 keV annihilation line. In order to detect this broadening we used a Ge detector with a energy resolution 1.3 keV at 511 keV. The shape of the broadened annihilation line is usually described by the parameters S and W . The low momentum parameter S is the fraction of counts in the central part of the line and thus it describes annihilation with low momentum valence electrons. Correspondingly W is the high momentum parameter obtained as the fraction of counts in the wing region of the annihilation line and it thus describes annihilation mainly with core electrons. Consequently an increase/decrease in S/W parameter indicates the presence of vacancy-type defects. The measured S/W parameter is a superposition of the S/W parameter of the bulk and the parameters of the different defects in the sample. Near the surface, the annihilation of the positron at the surface also has to be accounted for. This gives the following equations for the S/W parameter:

$$S = \eta_B S_B + \sum \eta_{Di} S_{Di}, \quad (1)$$

$$W = \eta_B W_B + \sum \eta_{Di} W_{Di}. \quad (2)$$

If a sample contains only one type of defect, the S – W plot of the measurement should form the segment of a line between the defect and the bulk state.

3. Results and discussion

Fig. 1 shows the S and W parameters as a function of positron implantation energy for Al⁺ implantations at 25°C (3×10^{13} and 5×10^{14} Al/cm²) and at 800°C (5×10^{14} Al/cm²). The mean positron implantation depth is also indicated in the figure. As can be seen for the samples implanted at RT, the S and W parameters behave as expected in the implanted region, i.e. higher dose results in higher S parameter. A previous work [10] where the implantation damage was studied by RBS/channeling showed that for samples implanted with 1×10^{15} /cm² Al at RT the sample was almost amorphized to a depth of approximately 300 nm. This trend can also be seen in the large S parameter values obtained near the maximum of the Al implantation profile for the samples measured with PAS. For the sample implanted at 800°C

Fig. 1. S and W parameters as a function of positron implantation energy for samples implanted at room temperature and at 800°C. The doses are indicated in the figure as well as the mean positron implantation depth.

in Fig. 1 the elevated implantation temperature does not seem to have a positive effect on the reduction of implantation induced defects. However, as we will show the high S parameter values obtained in the samples implanted at elevated temperatures is due to defect clustering.

Fig. 2 shows the S – W plot for the sample implanted at 800°C, in the figure the S/W parameters of the silicon vacancy [11] is also shown. As can be seen the parameters fall on the same line, suggesting that only one type of defect of the same kind is present in the sample, also the S/W parameters of the Si vacancy fall on this line. Since some measured S parameters are higher and some measured W parameters are lower than that for the Si vacancy and still on the same line we do not think that this is a sign of a single vacancy type present in the samples. Rather mono-vacancies and larger vacancy-type defects coexist. Since the carbon atom is much smaller than the silicon atom and has much fewer electrons, the influence of the carbon atoms on the S and W parameters is insignificant. This results in the parameters falling on the same line. In Fig. 2 is also shown the turning point from the bulk–defect line to the defect–surface state line for the samples implanted with 5×10^{14} Al/cm² at 400°C as well as the turning

Fig. 2. S - W plot for the sample implanted at 800°C with $5 \times 10^{14} \text{ Al/cm}^2$. The parameters for the silicon vacancy are from Ref. [11]. In the figure is also shown the turning points from the bulk-defect line to the defect-surface line for different implantations.

Fig. 3. Displaced silicon atoms versus depth calculated from RBS/channeling measurements for samples implanted with $5 \times 10^{14} \text{ Al/cm}^2$ at RT, 200°C and 400°C [10].

points for samples implanted with 3×10^{13} , 5×10^{14} and $1 \times 10^{15} \text{ Al/cm}^2$ at RT. As can be seen the turning point moves to higher S parameters value/lower W parameter value with increasing temperature, indicating increasing defect size. From the turning points of the samples implanted at room temperature, Fig. 2 also indicate, as expected, that the amount of damage increases with increasing implantation dose.

Fig. 2 can be compared to the RBS/channeling result shown in Fig. 3. The concentration of displaced silicon atoms is decreasing with increasing implantation temperature. For samples implanted at temperatures above 400°C the RBS/channeling analysis is not sensitive

enough to detect displaced atoms. A quick comparison of Figs. 2 and 3 could result in the interpretation that the PAS and channeling results contradict each other, since the PAS study indicate more/larger defects with increasing implantation temperature and the channeling analysis indicate a decrease in defects with increasing implantation temperature. However, PAS is sensitive to vacancy-type defects and channeling is sensitive to displaced atoms. The correct interpretation of Figs. 2 and 3 is that with increasing implantation temperature, the recombination of vacancies and interstitials created in the implantation process is increasing, but at the same time vacancy migration results in vacancy clustering and thus in larger vacancy-type defects and in the turning point moving to higher S parameter values.

When Fig. 1 is compared to the Srim 98 [12,13] simulation of the Al implantation in Fig. 4 and to the RBS/channeling measurement in Fig. 3, the following observation can be done: The S/W parameters do not reach the bulk value even at the maximum positron implantation energy of 25 keV for any of the implanted samples. At this energy less than 5% of the implanted positrons annihilate in the Al implanted region, these 5% include the positron diffusion length of approximately 200 nm in bulk SiC [8]. This is not enough to cause the relatively high S parameter at 25 keV. Evidently, the defect distribution extends deeper in the sample than expected from Figs. 3 and 4. At this stage we can only speculate over the phenomenon behind this effect, but a possible explanation could be the channeling effect combined with the feeding effect [14]. Previous studies of Al implantation in 6H-SiC in channelled

Fig. 4. Srim 98 simulation of the Al^+ 100 keV implantation.

directions have shown that the range is significantly extended when compared to random implantation [15]. Another explanation would be an electric field which would drive the positrons into annihilating in the implanted region, this would distort the interpretation of the results in Fig. 1. However, this does not seem likely since the Al need to be activated in order to produce this electric field and the annealing temperatures needed for this are significantly higher than the implantation temperatures used in our experiments.

4. Conclusions

We have studied the formation of vacancy-type defects in Al implanted 4H-SiC, both as a function of implantation dose and implantation temperature. As expected the amount of damage induced in the samples depend on the implantation dose. The results also indicate that the defect distributions extend deeper into the samples than expected. Further studies are planned to verify and investigate this phenomenon. The recovery process of the samples implanted at elevated temperatures shows signs of vacancy migration and vacancy clustering.

Abstract

We have used pulsed-slow-positron-beam-based positron lifetime spectroscopy to investigate the nature of acceptors and charge states of vacancy-type defects in low-energy proton-implanted 6H–SiC(H). We can infer from the temperature dependence of the lifetime spectra that neutral and negatively charged vacancy clusters exist in the track region. Depending on annealing, they give rise to positron lifetimes of 257 ± 2 , 281 ± 4 and 345 ± 2 ps, respectively. The 281 ps cluster has likely an ionization level near the middle of the band gap. By comparison with theory, the 257 and 280 ps are identified as $(V_C-V_{Si})_2$ and $(V_C-V_{Si})_3$ clusters, respectively. In addition, other acceptors of ionic type act as strong trapping centers at low temperature ($T < 150$ K). Neutral monovacancy-like complexes are also detected with a lifetime of 160 ± 2 after 900 °C annealing. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Slow positron annihilation; Silicon carbide; Proton implantation; Vacancy defects

Silicon Carbide is a large band gap semiconductor, with fast switching times suitable for high power and high temperature applications. It occurs in different polytypes [1], the hexagonal 4H and 6H ones are the most important for microelectronic applications. Defects in the different SiC polytypes have been studied by different techniques, including deep level transient spectroscopy [1,2], electron spin resonance [1,3] and positron annihilation spectroscopy [4–11]. In 6H–SiC, passivation [12], doping [13] and the Smart Cut process [14,15] have been all achieved using hydrogen implantation. However, the role and type of defects controlling the electrical properties in 6H–SiC(H) is far from fully understood.

We use positron annihilation to investigate the nature of acceptors and the charge states of vacancy-induced

defects in 6H–SiC. We focus here on the track region of low-energy protons after 900 °C and 1300 °C annealing.

The two studied layers were initially 4 μm thick n-type 10^{17} cm^{-3} nitrogen doped 6H–SiC grown epitaxially on n-type ($3.5 \times 10^{18} \text{ cm}^{-2}$) substrates from CREE. As detailed in Ref. [16], they were implanted with approximately $4 \times 10^{16} \text{ cm}^{-2} \text{ H}^+$ at 1 μm depth and then annealed at 900 °C (H900) and 1300 °C (H1300). After annealing, the doping of the initially n-type epitaxial layers was still compensated, indicating the presence of acceptor-like defect states surviving the annealing.

Slow positron beam based Doppler broadening spectroscopy, which gives information on the electron momentum distribution, has been used to investigate the defect distribution as a function of depth at room temperature. In both layers the fitting by VEPFIT of the data in Fig. 1 reveals three broadly different regions: the track region, between the surface and the hydrogen peak at 1 μm; the cascade region, around the hydrogen peak at 1 μm; and the beyond cascade region. In H900, the track region is homogeneous and the size of vacancy

Fig. 1. Low momentum fraction $S = N_A([0 - |2.88|] \times 10^{-3} m_0 c) / N_A([0 - |27.32|] \times 10^{-3} m_0 c)$ and high momentum fraction $W = N_A([11.27] - |27.32| \times 10^{-3} m_0 c) / N_A([0 - |27.32|] \times 10^{-3} m_0 c)$ as a function of positron beam energy in H^+ implanted 6H-SiC layers annealed at 900°C or 1300°C. The mean implantation depth in SiC is $z(E) \text{ (nm)} = 9.17 \times E^{1.7} \text{ (keV)}$ [19]. A modified version of VEPFIT is used to consistently fit (dots lines) the $S(W)$ curves from 2.5 keV in the annealed layers with a model of several homogeneous layers (3 for H900 and 4 for H1300, see details in Ref. [16]).

defects is big as suggested by the high value of the low momentum annihilation fraction (S) and the low value of the high momentum annihilation fraction (W) found in the fitting ($S/S_{\text{ref}} = 1.088$, $W/W_{\text{ref}} = 0.766$). After 1300°C annealing the track region is divided into 2 regions: the first region from the surface to around $0.3 \mu\text{m}$ is less damaged than the second region extending from 0.3 to $1.05 \mu\text{m}$.

The positron lifetime measurements were performed using the pulsed low-energy positron system at the Universität der Bundeswehr München [17]. The positron lifetime spectra $N(t, E, T)$ were recorded as a function of the incident positron energy E (see details in Ref. [20]) for different temperatures T between 75 and 375 K for H900 and 300 K for H1300. We could use a conventional analysis of the lifetime spectra in terms of exponential components due to the short positron diffusion length in these layers: the energy dependence reflects only the stopping profile in the track region and the surface contribution vanishes quickly at energy $\geq 5 \text{ keV}$. The lifetime spectra in 6H-SiC could be decomposed into a sum of two exponential decay

components (I_1, τ_1) , (I_2, τ_2) (see details in Ref. [20]) where the mean lifetime $\tau(E, T) = [1 - I_2(E, T)] \times \tau_1(E, T) + I_2(E, T) \times \tau_2(E, T)$ is equal to the center of mass. In both layers, the mean lifetime τ as a function of E exhibits a plateau in the energy range corresponding to the proton track region 6–10 keV in H900 and 9–13 keV in H1300. In these energy ranges the positron mean lifetimes are temperature dependent and vary from $255 \pm 2 \text{ ps}$ at 300 K to $247 \pm 1 \text{ ps}$ at 75 K in H900 and from, respectively, 276 ± 5 – $235 \pm 2 \text{ ps}$ in H1300. One can thus conclude that positrons in the track region see a homogeneous distribution of vacancy-type defects where the trapping rates vary with temperature. To investigate the vacancy distribution, we monitor the temperature dependence of the lifetime spectra, in the track region 180–600 nm sampled by 8–10 keV positrons [19].

In the two layers, the values $\tau^*(T) = [(I_1(T)/\tau_1(T) + I_2(T)/\tau_2(T))^{-1}]$ are calculated to check the validity of the one defect trapping model. At all temperatures the $\tau^*(T)$ values are much longer than the lifetime 141 ps in 6H-SiC lattice [6–8]. This indicates that positrons are trapped by different types of defects [18]. In both layers the lifetime $\tau_2(T)$ vary from a low to a high temperature plateau. It sharply increases by 24 ps from 257 ± 2 to $281 \pm 4 \text{ ps}$ in the range 175–225 K in H900. It strongly increases by 60 ps from 285 ± 5 to $345 \pm 2 \text{ ps}$ in the range 150–250 K in H1300. The variation of $\tau_2(T)$ with temperature indicates that different types of vacancy clusters exist after annealing. Assuming that the charge of defects is constant as a function of temperature in the semi-insulating layers, we conclude that a small cluster is detected at low temperature and a bigger one at high temperature. The trapping coefficient of vacancy-clusters is known to increase with the size of the cluster [18]. In order to compete with the trapping in the biggest defect, the trapping coefficient μ at the smallest cluster has to increase when temperature decreases. This property is fulfilled for negatively charged defects where μ is known to change in $T^{-1/2}$ [18]. We propose that, the low temperature τ_2 lifetimes values, 257 ps in H900 (Fig. 2c) and 280 ps in H1300 (Fig. 2g), arise from negatively charged vacancy clusters. The τ_2 lifetimes values, 280 ps in H900 and 345 ps in H1300 observed at high temperature, arise from neutral vacancy clusters. Another interesting point is that the 280 ps lifetime arises from a neutral defect above 225 K in H900 and from a negatively charged defect below 150 K in H1300. This suggests that the 280 ps lifetime is due to a defect which has an ionization level $-/0$ near the middle of the band gap. The Fermi level is above the ionization level in the H1300 where a higher fraction of defects than in H900 is expected to recover. We assigned the 257 and 280 ps lifetimes to $(V_C - V_{Si})_2$ and $(V_C - V_{Si})_3$ clusters, respectively, on the basis of calculations using the superimposed atomic model [9].

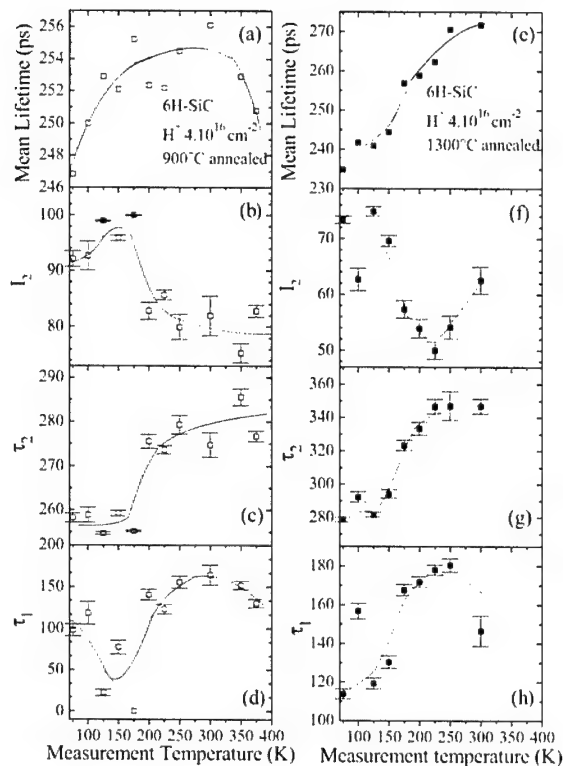

Fig. 2. Temperature dependence of the positron lifetime parameters in 6H-SiC implanted with a proton fluence of $4 \times 10^{16} \text{ cm}^{-2}$ at $1 \mu\text{m}$ and annealed at 900°C (\square) and 1300°C (\blacksquare). The values are a weighted average of data around an incident positron energy of 9 keV, probing a depth range between 180 and 620 nm: (a) and (e) mean lifetime, (b) and (f) intensity of the longest component, (c) and (g) its lifetime and finally (d) and (h) lifetime of the shortest component for H900 and H1300 samples, respectively. The solid lines are guides to the eye.

The $\tau_1(T)$ values (Fig. 2d and h) are longer or close to the lifetime 140 ps in 6H-SiC lattice at 75 K and above 200 K in H900 and at all temperatures in H1300. It means that the short component $\tau_1(T)$ is due to annihilations in a mixing of vacancy-like defects and negative ions. The 160 ps lifetime in H900 corresponds to neutral vacancy-like defects. At low temperature, the values τ_1 indicate that the negative ions become active traps. In both annealed layers, the lifetimes $\tau_2(E, T)$ are much higher than the value 243 ± 1 ps in as-implanted 6H-SiC(H) (to be published). This increase indicates that the size of the vacancy clusters trapping positrons increases as the annealing temperature increases from room temperature to 1300°C . Assuming that the 243 ps clusters cannot diffuse, the growth of the cluster size implies that, during annealing, small vacancy clusters emit mono-vacancies to the benefit of bigger clusters. We propose that, during the vacancy diffusion induced

by cluster reorganization, mono-vacancies get trap at nitrogen atoms due to the high nitrogen concentration in these layers. It follows that the positron trapping at the vacancy–nitrogen complex can give rise to the 160 ps lifetime.

In summary, we have identified two negative charge states of the $(V_C-V_{Si})_2$ and $(V_C-V_{Si})_3$ clusters that we have associated to the 257 and 280 ps lifetime by comparison with lifetimes calculations. We proposed that the $(V_C-V_{Si})_3$ cluster has a ionization level 0/- near the middle of the band gap. We associate the lifetimes of 160 ps to a neutral vacancy-like complex and of 345 ps to a neutral vacancy-cluster.

Abstract

An intrinsic defect (ID) has been identified in as-grown 4H–SiC by electron paramagnetic resonance (EPR). The EPR parameters of an ID measured in our nominally semi-insulating material are similar to the literature data of the EI5 defect produced in p-type 4H and 6H–SiC by 2.5 MeV electrons and assigned to the carbon vacancy (N.T. Son, P.N. Hai, E. Jansen, Phys. Rev. B 63 (2000) 201201). However, comparison of the ID and EI5 centers reveals that the as-grown and radiation-induced centers exhibit different annealing behavior. Photo-induced EPR locates the ID level 0.9 eV above the valence band edge. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Deep level defects are known to control the conductivity and carrier lifetime in semiconductors [1–3]. For example, semi-insulating 4H–SiC is produced by doping with amphoteric vanadium, which provides the donor ($E_v + 1.6$ eV) and acceptor ($E_c - 0.8$ eV) levels [4,5]. Intrinsic defects (IDs) produced by high energy irradiation or during the crystal growth may also influence the doping efficiency [6]. However, many radiation-induced defects are thermally unstable and anneal at 200–800°C [4,5,7,8]. Such defects may not be suitable for making SiC for high temperature applications. On the other hand, defects formed during a 1500–2200°C growth process may possess the natural high temperature stability.

An ID in high-purity 4H–SiC has been detected by electron paramagnetic resonance (EPR) [9]. The EPR spectrum is similar to the EI5 center produced by

2.5 MeV electron irradiation of p-type 4H and 6H–SiC [10]. The EI5 center has C_{3v} symmetry and was assigned to the positively charged carbon vacancy (V_C^+) with an electron spin $S = \frac{1}{2}$. Recently, Cree Inc. announced the production of high-quality semi-insulating 4H–SiC without using vanadium, and it is possible that an ID reported in Refs. [9,10] is responsible for the charge compensation in that material [11].

The present paper reports an EPR study of the ID center in as-grown, semi-insulating 4H–SiC. The paper focuses on a comparison of the ID and EI5 centers and briefly discusses the position of the ID level in the SiC band gap.

2. Results and discussion

High-purity, as-grown (0001) 4H–SiC wafers grown by the seed sublimation method and provided by Cree Inc. were used in this study. The samples were $0.35 \times 3 \times 15$ mm³ bars cut along the (1100) plane. The EPR spectra were recorded using a Bruker 200 spectrometer (9.75 GHz) equipped with an Oxford ESR

900 flow cryostat. The reproducibility of the EPR signal amplitude was $\pm 5\%$ and the error in the g -value determination was $\pm 5 \times 10^{-5}$. When measured in the dark, we can distinguish between three types of samples according to their EPR spectra: (1) nominally n-type samples exhibiting only the N donor signal; (2) nominally p-type material exhibiting only the shallow B acceptor signal and (3) nominally semi-insulating samples exhibiting only the anisotropic ID center. The density of N (B) in sample set 1 (2) was 10^{14} – 10^{15} cm^{-3} . All samples contain a 3 G wide isotropic line at $g = 2.003$ which is similar to the surface damage signal [12]. Additional support for the surface origin of this line was provided by a 1 h 850°C anneal in air, which reduced the line intensity by a factor of 3 but did not affect the other EPR signals. Except for Mn with concentration $\leq 10^{13} \text{ cm}^{-3}$, none of the other common impurities such as V, Cr, Ti, etc. [3,13] were detected.

Figs. 1a and b show the dark EPR spectra of the ID at 77 K and the angular dependence of the zero-crossings upon rotating the magnetic field in the (11 $\bar{2}$ 0) plane. The $B_{\parallel c}$ -axis spectrum consists of a 0.4 G wide central line A, a smaller line B and 6 pairs of satellite lines. When the sample is rotated from the position $\theta = 0^\circ$ ($B_{\parallel c}$ -axis), the lines 2–2' and 3–3' split into 3 and 2 smaller lines, respectively, with intensities approximately 3 and 2 times less than those of the initial lines at $\theta = 0^\circ$. The A, 1–1' and 2–2' overall line intensities do not depend on the angle (taking into account the line splitting). However, the intensities of the 5–5' and 6–6' lines are reduced at $\theta > 25^\circ$, which suggests an anisotropic line width. At 4 K, the ID spectrum is similar to the 77 K one, but lines B and 3–3' disappear, and upon rotating the sample line A splits into 2 lines at 90 and into 3 lines at intermediate angles.

The measured angular dependence of the ID-1 spectrum can be simulated using axial g - and hyperfine (hf) A -tensors, depending on the angle [14]:

$$g = (g_{\parallel}^2 \sin^2 \theta + g_{\perp}^2 \cos^2 \theta)^{1/2} \quad (1)$$

$$A = (A_{\parallel}^2 \sin^2 \theta + A_{\perp}^2 \cos^2 \theta)^{1/2}, \quad (2)$$

For lines A, 1–1' and 4–4', relations (1) and (2) fit the g and A angular dependencies with the parameters presented in Table 1. Unfortunately, our present samples are not suitable to rotation in two additional planes; thus, the full g - and hf-tensors were not determined. We plan to complete that study in the near future.

From the similarity of angular dependence and their effective g -values, 1–1', 2–2', 5–5' and 6–6' lines can be assigned to the hf splitting of the central line A due to the nuclei with spin $I = \frac{1}{2}$. We will denote this set of lines as ID-1 center. Also, the similarity of the g -values suggests that the 4–4' lines are associated with B forming an ID-2 center, and the 3–3' pair make-up an ID-3

Fig. 1. (a) The upper and lower frames show the dark EPR spectra of the 4H-SiC obtained at 77 K for $B_{\parallel c}$ -axis and $B_{\perp c}$ -axis, respectively. The middle frame displays the angular dependence of the zero-crossings measured for rotation of the magnetic field (B) in the (11 $\bar{2}$ 0) plane. (b). The extended central part of Fig. 1a.

center. Individual satellite lines of the ID-1 center can be assigned to the magnetic nuclei using the line intensities and the natural abundance of magnetic isotopes ^{29}Si

(4.67%) and ${}^{13}\text{C}$ (1.11%). The pairs 1-1', 2-2', 5-5' and 6-6' were assigned to the $1 \times {}^{29}\text{Si}$, $3 \times {}^{29}\text{Si}$, $12 \times {}^{13}\text{C}$ and $6 \times {}^{29}\text{Si}$ magnetic nuclei, respectively (see Table 1). The lines B and 4-4' form a triplet which can be assigned to a defect interacting with an $I = 1$ nucleus such as nitrogen.

The EPR parameters for the ID-1 center in our semi-insulating 4H-SiC (see Table 1) coincide with parameters of the EI5 center produced by 2.5 MeV electron irradiation in p-type 4H and 6H-SiC [10]. In agreement with the model presented in Ref. [10], our assignment of neighboring atoms corresponds to the deformed carbon vacancy with C_{3v} symmetry with 1 unique and 3 equivalent Si nearest neighbors (NN). In addition, we assigned the 5-5' and 6-6' lines not reported in the earlier work to 12C and 6Si next nearest neighbors (NNN) of the vacancy (see Fig. 2). Non-equivalency of the 4 NN Si atoms may result from a Jahn-Teller distortion of the charged vacancy, where the upper Si atom is shifted along the c -axis (Fig. 2). A larger hf splitting on the unique Si atom (66.4 G) compared to the 3 lower plane Si atoms (39.7 G) suggests that more electron spin density is localized in the upper plane. This would explain why the hf splitting of the Si NNN is due to only 6 atoms, presumably the 6 upper plane Si atoms. When the angular dependence is measured at 4 K, the central line A exhibits splitting not apparent at 77 K. The behavior suggests that the electron spin density becomes more localized at lower temperature. The temperature dependence merits further investigation.

Despite the similarity of their EPR spectra, the ID-1 and EI5 centers exhibit several differences: (1) In our work, ID-1 is seen only in samples which do not exhibit a B or N signal under dark conditions (the semi-insulating samples), while EI5 is observed in the p-type irradiated SiC. (2) The ID-1 intensity did not change after the 850°C anneal, but the EI5 intensity decreased at least several times by 500°C. (3) The ID-1 can be observed between 4 and 300 K, but the EI5 disappears below 25 K. Detection of the defect in our semi-insulating SiC weakens earlier arguments that the charge state of the vacancy is positive which was based on the

Fig. 2. A schematic of a carbon vacancy in SiC. The Si atoms are indicated by black circles and the C atoms by white circles.

observation of the EI5 in p-type material [10]. Another possibility for a carbon vacancy with $S = \frac{1}{2}$ is a negative charge state, V_C^- . The different annealing behavior could be caused by the presence of interstitial carbon trapped not far from the radiation-induced carbon vacancy, favoring defect annihilation as the sample is heated. The thermal instability observed for the radiation-induced carbon vacancy above 500°C suggests that material containing this defect will not be suitable for high temperature applications. Finally, the disappearance of the EI5 center below 25 K may be attributed to the presence of an additional level close to the vacancy in irradiated SiC. Clearly, our data demonstrates significant differences between the as-grown and radiation-induced vacancies which deserve further exploration.

The dependence of the photo-induced EPR signals on the photon energy has been used to locate the energy level of the ID-1 with respect to the band edges [15]. The illumination with sub-band gap light (750–1500 nm) quenched the ID-1 signal and produced an approximately equal amount of shallow paramagnetic boron. Electrons are excited from the valence band to the ID level making it non-paramagnetic and the hole formed

in the valence band is captured by a B acceptor making it paramagnetic. A model based on the photo-induced EPR data places the ID defect level 0.9 eV above the valence band.

3. Conclusion

Our work has identified an intrinsic defect (ID-1) in as-grown nominally semi-insulating 4H-SiC with EPR parameters similar to the EI5 center found by others in p-type 4H and 6H-SiC irradiated with 2.5 MeV electrons. The EI5 has been assigned to the positively charged carbon vacancy, V_C^+ , with electron spin $S = \frac{1}{2}$ [10]. Although analysis of data for the ID-1 is in agreement with the carbon vacancy model, detection of the center in our semi-insulating material makes the charge state assignment less certain. The ID-1 and EI5 centers demonstrate different thermal annealing behavior. The former is stable until at least 850°C, while the latter begins to anneal below 500°C. The annealing of the EI5 may be caused by the release of radiation-induced interstitial carbon trapped in the vicinity of the vacancy. The disappearance of the EI5 center below 25 K, in contrast to the persistence of the ID at 4 K, suggests the presence of an additional level close to the vacancy in irradiated SiC. Photo-induced EPR identified the ID defect as a deep level 0.9 eV above the valence band edge.

Defects in 4H silicon carbide

J.P. Bergman*, L. Storasta, F.H.C. Carlsson, S. Sridhara, B. Magnusson,
E. Janze'n

Department of Physics and Measurement Technology, Linköping University, S-58183 Linköping, Sweden

Abstract

We present experimental results related to several different intrinsic defects that in different ways influence the material properties and are therefore technologically important defects. This includes the so-called D1 defect which is created after irradiation and which is temperature stable. From the optical measurements we were able to identify the D1 bound exciton as an isoelectronic defect bound at a hole attractive pseudo-donor, and we have been able to correlate this to the electrically observed hole trap HS1 seen in minority carrier transient spectroscopy (MCTS). Finally, we describe the formation and properties of a critical, generated defect in high power SiC bipolar devices. It is identified as a stacking fault in the SiC basal plane. It can be seen as a local reduction of the carrier lifetime, in triangular or rectangular shape, which explains the enhanced forward voltage drop in the diodes. The entire stacking faults are also optically active as can be seen as dark triangles and rectangles in low temperature cathodo-luminescence, and the fault and their bounding partial dislocations are seen and identified using synchrotron topography. © 2001 Elsevier Science B.V. Keywords: SiC; Defects; Stacking faults

1. Introduction

During the last decade silicon carbide has attracted increasing interest. The reason for this is that SiC has material properties which makes it attractive for device applications. This includes particularly high power devices, high frequency devices and sensor devices needed to operate at high temperatures or in harsh environments. In the recent years, SiC has also been important as substrate material for the growth of epitaxial nitride structures.

The increasing interest in SiC was related to the development of commercially available substrate material, first conducting substrates in the 6H polytype and later the 4H polytype were followed by semi-insulating substrates. This was followed by the development of epitaxial growth techniques, like the hot wall CVD technique to grow thick low doped layers needed for high voltage bipolar components and thin well con-

trolled n- and p-type doped layers for sensors or MESFET applications. Currently, one of the main obstacles for SiC devices to reach a larger production scale is to understand and to control the residual defects in the material.

SiC is consequently a very interesting material for defect studies. From a fundamental point of view the polytype formation provides a unique possibility of studying the same defects in different lattice matrixes, where the large and indirect bandgap provides narrow emission lines and a large number of possible bandgap states. The defects are also of large applied interest which provides further motivation for detailed defects studies.

In this presentation, we will describe some of the most interesting and important defects in our opinion, both from a scientific and applied point of view. We will focus on three different types of defects, which are all of intrinsic nature. The first are the intrinsic defects with associated bound excitons in the near bandgap region. These are created by all kinds of irradiation, including ion-, electron-, neutron- and proton-irradiations, but

E-mail address: ped@ifm.liu.se (J.P. Bergman).

can sometimes also be seen in as-grown material. The fact that some of those are temperature stable and can be produced by ion-implantation makes them of applied interest since they will remain after such a process step and influence the performance of the device. The second type of intrinsic defects is seen by absorption and photoluminescence in semi-insulating material grown by high temperature CVD (HTCVD). This material has very low concentrations of Vanadium which is the usual dopant in semi-insulating SiC, and it is believed that these yet unidentified deep intrinsic defects are giving the HTCVD material its semi-insulating properties. Finally, we will discuss the effect of intrinsic structural defects, such as dislocations and stacking faults, in SiC.

The results discussed are all on 4H SiC, even if several of the defects are present with similar properties also in the other polytypes. All material is grown by hot wall CVD or high temperature CVD.

2. Near bandgap bound excitons at intrinsic defects

The low temperature near bandgap photoluminescence (PL) emission from 4H epitaxial SiC layers is normally dominated by the recombination of free excitons (FE) and of bound excitons (BE) at the neutral nitrogen donor, and in the case of p-type or compensated material of excitons bound at the Al acceptor. After particle irradiation, with ions, electrons, neutrons or protons, additional emissions, labeled as the Ea spectra [1], appear which dominate the near bandgap spectrum. It consists of about 40 sharp no-phonons lines at energy between 2.8 and 2.9 eV, accompanied by a broad phonon assisted structure, as shown in Fig. 1. Using temperature dependent measurements, photoluminescence excitation spectroscopy and time resolved

spectroscopy [2] the lines have been shown to come in groups of two to four lines, with one ground state and several excited states, giving approximately 12 groups of emissions. The time resolved measurements have shown that the decay times of the ground state emissions are relatively long with values of several hundred microseconds at low temperatures. The decay from the excited states is considerably faster with decay times in the order of a few microseconds. The fact that the excited states can be seen at low temperatures indicates a very slow relaxation process down to the ground state. The measured decay time could either be the time for the relaxation or the time for the recombination rate of the bound excitons, or a combination of both. The slow times also indicate that there is no competing Auger process as observed for the donor bound and acceptor bound excitons. The bound excitons in the Ea series are therefore believed to be electron hole pairs bound at isoelectronic defect centers. About half of the lines can be observed after low energy (200 keV) electron irradiation that is below the displacement energy of creating Si vacancies (225–250 keV) [3] and no Si vacancy-related signal is either seen in the IR. This indicates that these lines are related to carbon centers, where a vacancy-interstitial pair could be a good candidate, but this remains to be proven. The fact that the high-energy lines are not observed after low energy irradiation indicates that these might be Si related, but their absence could also be an intensity or irradiation dose effect. A fact is, however, that the defects anneal at different temperatures starting from 750°C and are completely quenched at 1200°C.

When the Ea spectrum disappears, it is replaced by the emission labeled as D1, Fig. 2. This is not seen directly after irradiation but is sometimes seen as a

Fig. 1. A low temperature photoluminescence spectra of 4H SiC showing the Ea spectrum, present after particle irradiation.

Fig. 2. A photoluminescence (PL) and photoluminescence excitation (PLE) spectra of 4H SiC showing the D1 spectrum, observed after particle irradiation and high temperature annealing.

residual emission in as-grown material. The D1 center is stable up to CVD growth temperatures and should be considered as a process induced defect that will remain and influence any device. In the turn-over range between the Ea and the D1 spectrum, i.e. at annealing temperatures between 800°C and 1200°C, a new and so far not further studied emission is observed at 4340 Å [4]. The D1 spectra has previously been studied in detail using PL [5,6], PL excitation, temperature dependent PL [5], time resolved PL [5] and Zeeman measurements [6], and recently the properties and the electronic structure have been studied in detail [7]. The PL and PLE spectrum are shown in Fig. 2. The ground state (L1) has two strong excited states (M1 and H1). A series of lines is observed at higher energies. The final states of the transitions corresponding to these lines were interpreted as effective-mass-like excited electron states well described by exciton theory. This was interpreted as the D1 defect being a pseudo-donor, where the defect has a neutral state in the bandgap, which contains no charge particles but still has a hole attractive potential, either from the electronegativity difference or from the local strain field. Once a hole is bound the defect is positively charged and attracts an electron via Coulomb interaction. The observed BE emission from the D1 defect is the recombination between the loosely bound electron and the strongly localized hole at the defect. At higher temperatures, the electron can be thermally emitted to the conduction band. This model of the D1 BE predicts an energy level for the primarily bound hole about 0.35 eV above the valence band. This level, denoted as HS1, has recently [8] been observed using minority carrier transient spectroscopy (MCTS). The correlation between the D1 and the HS1 hole trap was further shown by comparing the relative PL intensities and hole trap concentrations as a function of annealing temperature. This result also shows that the D1 is not correlated with the Z1/2 electron trap seen in DLTS as was previously assumed.

All characteristic properties of the D1 defect are also observed for the BE in the Ea spectrum and for the 4340 Å BE, and it is also very natural to assume that these BEs are related to similar isoelectronic defects described within a similar pseudo-donor model.

None of the above described BE have been correlated with the defects observed by ODMR or EPR, and their atomistic structure has to be determined.

3. Deep intrinsic defects

Another important defect that at the moment is subject to an extensive study, is the deep probably intrinsic defect that imparts semi-insulating properties to SiC. Generally, semi-insulating properties can be obtained by introducing vanadium, but in our high

temperature CVD (HTCVD) process low doped and semi-insulating material can be obtained without the intentional introduction of deep defects. The origin of the residual defects causing this is not yet fully understood but the presence of deeper defect states has been seen using FTIR and PL spectroscopy.

In Fig. 3 an FTIR absorption spectrum of an as-grown 4H SiC sample is shown. In this sample, a yet unidentified defect line (UD1) is observed. These lines are also seen in HTCVD grown semi-insulating 6H SiC and sometimes in commercial p-type substrates. The UD-1 center consists of two narrow no-phonon lines with different polarization [9]. The linewidth of UD1 lines is less than 0.5 meV, which is typical for luminescence lines in the infrared originating from deep defects in SiC. In other samples, some weaker additional lines were also observed [10].

The UD1 defect is temperature stable for annealing temperatures up to 1600°C, HTCVD material showing this line has very good semi-insulating properties with resistivities above $10^{10} \Omega \text{cm}$ measured at 200°C. The resistivity does not change after high temperature annealing.

Using the HTCVD technique it is also possible to grow crystals where the Si vacancy is the dominating observable defect. Also, these samples have semi-insulating properties but are not as stable after high temperature annealing as samples with the UD1 defect dominating. The reduction of the measured resistivity

Fig. 3. Infrared absorption measurement of semi-insulating HTCVD grown 4H SiC. The spectrum was recorded at low temperature (10 K) using the FT technique.

after 1600°C annealing corresponds to the decrease of the Si vacancy signal. However, we have found that the Si vacancy does not have the same annealing behavior in as-grown material as in irradiated material. In our samples, the Si_V is stable at 800°C, a temperature where it anneals out in irradiated samples. A reason for this could be that the disappearance of the Si_V is related to the diffusion of Si interstitials (Si_I). In irradiated material these species are created in an equal number, and possibly, at a very close distance to the vacancies. When the interstitial becomes mobile it has a very high possibility to annihilate with the vacancy. In as-grown material it is, however, not obvious that interstitials are present in a corresponding number to the vacancies, thus the annihilation of Si_V could be caused by a completely different mechanism.

4. Structural defects

Structural defects in the form of dislocations and other extended defects are always present in every semiconductor material except Si. There is, however, relatively very little knowledge about the electronic properties and influence of extended defects. In SiC, the so-called micropipes have been of major concern for several years. These are open hollow core screw dislocations which were shown to be detrimental to device operations. In recent years, the micropipe density could be considerably reduced and they are now no more considered as a serious problem. Attention has instead been focused on other dislocations, and their influence has for example been seen in large area carrier lifetime mappings [10]. These mappings have shown a correlation between extended defects such as small angle boundaries and screw dislocations with measured minority carrier lifetime. This indicates that extended structural defects are active as recombination centers in SiC.

A second and more important influence of structural defects in the form of stacking faults has recently been shown. In this case, a change in the electrical performance, in the form of an increase of the forward voltage drop, of bipolar devices was observed [11]. A material study showed that structural defects were created during the device operation [12]. These defects were identified as stacking faults in the epitaxial layer. The stacking faults are in the basal plane [0001] and propagate through the entire epitaxial layer, which is grown on an 8° off angle from the basal plane. Since a typical epitaxial layer is about 30 µm thick the stacking fault has a height, as seen from the top, of about 250 µm, and typically has a triangular shape. This is macroscopically observable with different techniques, such as lifetime mapping, cathodo-luminescence, X-ray topography and electro-luminescence. Fig. 4b, shows a panchromatic CL image over the area where a diode was processed. The stacking faults are seen as darker triangles gradually reduced towards one direction corresponding to the extension of the basal plane into the epitaxial layer. The stacking faults are only seen on diodes stressed with a high forward current, and are not present in the original epitaxial layer.

Stacking faults are also observed and identified using synchrotron white beam XRD (SWBXT) as can be seen in Fig. 4b, that shows the same diode as in Fig. 4a. The boundaries of the diodes are clearly seen, probably due to the stress introduced between the p+ layer and the n-base layer. White dots in the image are elementary screw dislocations, while no micro-pipes are observed on this image. A clear correlation between the structural defects observed with SWBXT and the optical features seen in CL can be seen by comparing Fig. 4a and b.

A more detailed spectral analysis using CL and PL shows that a new and previously not reported emission band is related to the stacking faults, as shown in Fig. 5. This emission is observed in the entire stacking fault area and increases in intensity with increasing temperature. The emission has an intensity maximum at about

Fig. 4. Panchromatic cathodoluminescence image (left) of stacking faults generated in bipolar diodes. SWBXT image (right) of the same diode showing the stacking faults as dark triangles. The white spot is an elementary screw dislocation.

Fig. 5. PL spectra measured at different temperatures on an epitaxial layer where a stacking fault has been identified using CL or SWBXT. The emission in the range from 415 to 430 nm is attributed to recombinations at the stacking fault.

150 K, and is thermally quenched at higher temperatures with an activation energy of 280 meV.

We propose that the stacking fault in 4H SiC gives rise to a local potential fluctuation corresponding to a reduction of the bandgap. This potential attracts and binds carriers and excitons which then recombine with phonon participation and give rise to the observed emission. Since the stacking fault has a two-dimensional extension this will give a “quantum well” situation. The temperature quenching of the emission is related to the thermal escape of carriers from the “well”.

5. Summary

We have described and shown the properties of several types of intrinsic defects in SiC. These defects

are interesting both from a fundamental physics point of view as well as from an applied point of view since they have a strong influence on the properties of the material. Even if several defects are observed, there is very little detailed knowledge, especially on the atomistic defect identification, their electronic structure, and their influence on the material properties.

The importance of structural extended defects such as dislocations and stacking faults have been shown, and the study and further understanding of such defects will be of high priority in the future.

Abstract

High-field pulsed and continuous-wave electron paramagnetic resonance (EPR) techniques at 95 GHz have been used to investigate radiation defects in neutron-irradiated SiC. In the temperature range between 1.2 and 300 K three types of EPR spectra were observed in 4H- and 6H-SiC crystals that are attributed to the neutral silicon vacancy, the negatively charged silicon vacancy, and the carbon vacancy. In the EPR spectra of V_{Si}^- in 4H- and 6H-SiC an anisotropic splitting of the EPR lines is observed. This splitting is assumed to arise from small differences in the g -tensor of the quasi-cubic (k) and hexagonal (h) sites. The g -factor for the k site $g(k)$ is found to be isotropic with $g(k) = 2.0032$ and the g -factor of the h -site is found to be slightly anisotropic with $g(h) = g(k) - 0.00004$ and $g_{\perp}(h) = g(k) - 0.00002$. The 95 GHz EPR spectra at 1.4 K show that the ground state of V_{Si}^0 is a triplet state. Additional 9.5 GHz EPR experiments reveal signals that are attributed to the carbon vacancy on the basis of the observed hyperfine splitting. The results demonstrate that V_{Si}^- , V_{Si}^0 and V_{C} are dominant defects after neutron irradiation of SiC to doses up to 10^{19} cm^{-2} . © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

The primary defects that can be produced in the binary compound SiC are vacancies, interstitials and antisites. In contrast to silicon [1] the primary defects in SiC seem to be stable at and even far above room temperature. The principal experimental tools for the identification and study of the defects in SiC are electron paramagnetic resonance (EPR) and optically detected magnetic resonance (ODMR) [2–15]. EPR investigations have revealed two charge states of the Si vacancy [5–7,9–12] but the identification of carbon vacancies is presently still under debate [14,15]. In addition sophisticated EPR

investigations have shown the existence of Si-related Frenkel pairs in SiC [13].

The dominant EPR spectrum with a g -factor $g = 2.0032$ that can be observed in irradiated 4H- and 6H-SiC crystals up to room temperature was attributed to the negatively charged isolated silicon vacancy V_{Si}^- with $S = \frac{3}{2}$ [5–7,9,12]. An anisotropic hyperfine (hf) structure caused by the interaction with the four nearest-neighbor carbon atoms (the first shell) and an almost isotropic hyperfine structure caused by the interaction with 12 next-nearest-neighbor silicon atoms (the second shell) were observed in the EPR spectra. No site dependence was detected for V_{Si}^- .

The second type of EPR spectra that was observed by several groups [4,8,10–12] is related to a center with a triplet state ($S = 1$) with an isotropic g -factor $g = 2.0032$ and a site-dependent zero-field splitting parameter D . In Refs. [8,10,11] these spectra were detected by ODMR by

*Corresponding author. Fax: 31-71-527-5819.

E-mail address: orlinskii@molphys.leidenuniv.nl (S.B. Orlinskii).

monitoring the zero-phonon lines (ZPL's) at 1.438 and 1.352 eV in 4H-SiC and at 1.433, 1.398, and 1.368 eV in 6H-SiC. The authors of [10,11] were the first to attribute these EPR spectra to the neutral Si vacancy (V_{Si}^0) on the basis of the characteristic hf structure with the 12 Si atoms of the second shell that looked similar to the hf structure for the negatively charged isolated silicon vacancy V_{Si}^- . The assignment of the triplet EPR and ODMR spectra to the various sites was made on the assumption that the hexagonal site experiences a stronger axial crystal field than in the quasi-cubic sites. However, it remains unclear why the zero-field splitting for the hexagonal site is larger in the 6H polytype than in the 4H polytype that exhibits a larger axial crystal field. In addition, the order of the ZPL in the 6H polytype, with the ZPL for the hexagonal site placed between the two quasi-cubic lines, is not clear.

In the case of the negatively charged silicon vacancy V_{Si}^- , there is now consensus between theory and experiment [5,6,9] that the ground state corresponds to the high-spin configuration. In the case of the neutral isolated silicon vacancy V_{Si}^0 however, there exist two opposite points of view that support respectively a singlet [4,10,11,16,17] and a triplet [12,18,19] ground state. In particular, the theoretical studies predict a spin singlet [16,17] as well as a spin triplet [18,19] for the ground state of V_{Si}^0 . This raises the question of whether the triplet spectrum observed by several groups belongs to the ground state or a thermally populated excited state.

In this contribution, we present the results of a series of EPR measurements on V_{Si}^- and V_{Si}^0 in neutron irradiated 4H- and 6H-SiC at 9 GHz (X-band) and 95 GHz (W-band) at temperatures ranging from 1.4 to 300 K. The EPR results at 1.4 K show that the ground state of V_{Si}^0 corresponds to a triplet state. Further the EPR spectra at 95 GHz of V_{Si}^- in 4H- and 6H-SiC confirm that the spin multiplicity $S = \frac{3}{2}$ and that the signals from defects in the different sites can be resolved even for this system with a g -tensor that deviates only slightly from that of a free electron.

2. Experimental

The samples used in this study were Lely grown n -type 4H-SiC and 6H-SiC crystals with concentrations of uncompensated nitrogen in the range of 10^{16} – 10^{17} cm $^{-3}$. These samples were irradiated at room temperature with neutrons with doses ranging from 10^{15} to 10^{20} cm $^{-2}$. The advantage of the n -irradiated samples is that the irradiation produces a homogeneous distribution of defects in the sample. EPR measurements were performed on a homemade W-band (95 GHz) pulsed electron spin echo (ESE) spectrometer over a temperature range between 1.4 and 300 K [20] and on a Bruker

X-band (9.5 GHz) and W-band (95 GHz) continuous wave (cw) EPR spectrometer. The samples having the shape of platelets with sizes of about $4 \times 8 \times 0.1$ mm 3 for X-band and $0.4 \times 0.8 \times 0.1$ mm 3 for W-band were oriented for rotation in the $\{11\bar{2}0\}$ plane.

3. Results and discussion

In Fig. 1 the angular dependences of the ESE detected EPR spectra at W-band at 190 K (a) and 1.4 K (b) of the n -irradiated 4H-SiC (10^{18} cm $^{-2}$) sample are presented. The experimental spectra are only shown for the orientation with the magnetic field parallel and perpendicular to the c -axis. In 6H-SiC similar spectra and angular dependences were observed. It is seen that the triplet EPR lines for $B_0 \parallel c$ (Fig. 1b) at high field is much stronger than at low field (the reverse is true for $B_0 \perp c$) as a result of the high spin polarization at 1.4 K and 95 GHz. This effect allows us to decide that the

Fig. 1. Angular dependences of the 95 GHz EPR spectra observed in n -irradiated 4H-SiC (10^{18} cm $^{-2}$) at 190 K (a) and 1.4 K (b). The central line is related to V_{Si}^- whereas the outer, orientation-dependent lines are caused by the triplet state of V_{Si}^0 .

D -parameter is positive. We conclude, especially from the results at 1.4 K that the ground state of V_{Si}^0 corresponds to a triplet state.

In Fig. 2 the cw W-band EPR spectra of V_{Si}^- are shown as observed at 300 K in n-irradiated 4H-SiC (10^{18} cm^{-2}) with the magnetic field parallel and perpendicular to the c -axis. The spin multiplicity of V_{Si}^- was determined as $S = \frac{3}{2}$ by measuring the difference in amplitude of two $2\pi/3$ mw-pulses needed for the maximum echo signals of V_{Si}^- ($S = \frac{3}{2}$) and V_{Si}^0 ($S = 1$). A very small splitting is observed that is more pronounced with the magnetic field parallel to the c -axis. This splitting is assumed to arise from the small difference of the g -tensors in the quasi-cubic and hexagonal sites. The anisotropy of the g -tensors is only of the order of 10^{-5} but becomes visible owing to the high magnetic field of 3.4 T used for the 95 GHz EPR measurements. The g -tensor for the k site is found to be isotropic with $g(k) = 2.0032$ and the g -factor of the h -site is found to be slightly anisotropic with $g_{\parallel}(h) - g(k) = 0.00004$ and $g_{\perp}(h) - g(k) = 0.00002$. The assignment of the sites is based on the expectation that a defect at an hexagonal site experiences a stronger axial crystal field than a defect in quasi-cubic site. To derive the sign and the value of these small changes in position of the line we used the EPR signal of the V_{Si}^- vacancy in n-irradiated cubic 3C-SiC as a g -marker because in this crystal the g -tensor is isotropic.

In Fig. 3, we present the cw X-band EPR spectrum observed at 40 K in n-irradiated 4H-SiC (10^{18} cm^{-2}) with the magnetic field parallel and perpendicular to the c -axis that we attribute to the carbon vacancy. A closer inspection of the spectra reveals a hf structure when the magnetic field is parallel to the c -axis. This hf structure can be explained by the presence of a set of four Si atoms in the first neighbouring shell (one non-equivalent

Fig. 2. CW 95 GHz EPR spectra of the V_{Si}^- vacancy observed at 300 K in n-irradiated 4H-SiC (10^{18} cm^{-2}) for the magnetic field parallel and perpendicular to the c -axis.

Fig. 3. CW 9.5 GHz EPR spectra observed at 40 K in n-irradiated 4H-SiC (10^{18} cm^{-2}) with the magnetic field parallel (a) and perpendicular (b) to the c -axis. The central EPR line of V_c is indicated by an arrow.

and three equivalent) and 12 C atoms in the second shell. With the magnetic field perpendicular to the c -axis the hf structure caused by the Si nuclei in the first shell can be recognized. The g -tensor and hf splitting with the Si atoms in the first shell are identical to the parameters obtained by Son et al. and Bratus' et al. [14,15] for electron-irradiated SiC crystals that were attributed to the carbon vacancy-related defect. The small linewidth allowed us to study in more detail the central part of the spectrum. An additional weaker hf structure was observable that allowed us to further support our assignment. In case of an isolated carbon vacancy the additional hf structure is expected to be caused by the interaction with 12 carbon atoms in the second shell.

4. Conclusions

Our EPR and ESE studies show that V_{Si}^- , V_{Si}^0 and V_c are the dominant defects in SiC generated by neutron irradiation with doses up to 10^{19} cm^{-2} . For the V_c defect it could not be decided whether this defect is positively or negatively charged. The simultaneous observation of all of these defects show that the positions of their energy levels are close and all lie in the bandgap.

The 95 GHz EPR results at 1.4 K prove that the ground state of V_{Si}^0 correspond to a spin triplet state. The zero-field splitting parameter is found to be positive.

In the EPR spectra of V_{Si}^- in 4H- and 6H-SiC a splitting of the EPR lines is observed that is assumed to

arise from small differences in the g -tensor of this defect in the quasi-cubic and hexagonal sites. Pulsed EPR experiments confirm that the spin multiplicity of V_{Si}^- is $S = \frac{3}{2}$ in agreement with the previous ENDOR measurements [1].

The EPR parameters of V_c are identical to those of Son et al. and Bratus' et al. [14,15]. The weak hf structure observed on the central line could be explained as arising from 12 carbon atoms in the second shell and served to further confirm the assignment as an isolated carbon vacancy.

Abstract

Defects in SiC films and bulk crystals are detected by Raman scattering. It is found that the observation of defect activated transverse optic bands at a Raman forbidden configuration is useful for the detection of small amount of defects. The shape of the defect activated Raman band is discussed in relation to structures of the defects. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: SiC; Raman scattering; Defects; Stacking faults

1. Introduction

Defects in crystals occur during crystal growth and processing of the device fabrication. The defects can be examined by various techniques, such as X-ray diffraction, electron microscopy, ion beam analyses, optical spectroscopy, resonance spectroscopy in magnetic fields and so on. The optical spectroscopies have widely been used for characterization of defects, because it is a non-destructive method and no contact is required. Raman spectra are sensitive to the phonon properties, which reflect the microscopic structures of crystals, and have been actively used to obtain information on the nature and microscopic structure of defects. In the present work, we have tried to establish a Raman scattering technique for sensitive detection of defects in SiC crystals.

2. Defect activated Raman scattering

For the phonon Raman scattering process, the wave vector selection (conservation) rule and the polarization selection rule hold strictly in perfect crystals. The former rule restricts the wave vector of the phonons detected in

the Raman scattering process to almost zero when visible laser light is used as an excitation source [1,2]. This is a reason why sharp phonon Raman bands are observed nevertheless there are a number of phonons with different frequencies and wave vectors in crystals. The defects produce a loss of the periodicity, reduction of the crystal symmetry and a topological disorder of crystals. Therefore, they induce a breakdown of the selection rules for the wave vector, the polarization and a reduction of the phonon lifetime. For SiC crystals containing stacking faults (stacking errors), which are typical defects in SiC crystals, the partial breakdown of the wave vector selection rule causes the activation of phonon modes with wave vectors different from $q = 0$, and thereby gives rise to an asymmetric band shape [3]. The breakdown of the polarization selection rule causes the appearance of Raman bands at a forbidden configuration, and the reduction of the phonon lifetime due to the defects causes a broadening of phonon Raman bands. Accordingly, one can characterize defects using Raman parameters as bandwidth, intensity, frequency shift and polarization properties of the Raman bands.

In the past, the Raman study of defects was limited to crystals which contain a high density of defects and impurities, because the sensitivity of the systems for detection of defects was not high enough and also the spectral analysis was not well established so far.

E-mail address: nakashima-s@aist.go.jp (S. Nakashima).

However, the recent development in multichannel detectors has enabled us to detect small amounts of defects in crystals. More recently, an attempt to analyze such weak defects was tried for 6H-SiC crystals [4]. In the present work, we developed a Raman scattering technique for sensitive detection of defects in crystals and applied this technique to SiC, especially 3C-SiC having a zinc blende structure.

3. Detection of defects in 3C-, 4H- and 6H-SiC

Samples were irradiated by laser beams (488 nm) with a power level of 200 mW through an objective lens with a numerical aperture of 0.45. Scattered light was dispersed using a triple spectrometer with $f = 0.6$ m and then detected by a cooled CCD detector.

We observed Raman spectra of a 3C-SiC film at the back scattering geometry using the (001) face. The heteroepitaxial films used in this experiment were grown on Si (001) and then removed from the substrate. These films contained stacking faults, dislocations and anti-phase boundaries at around the interface of SiC and Si. The transverse optic (TO) and LO modes are Raman forbidden and allowed, respectively, at this scattering geometry. On the other hand, for the back scattering geometry using the (110) surface, the TO and LO bands are Raman active and forbidden, respectively. As shown in Fig. 1(a), the intensity of the TO band is very weak at this forbidden geometry, being a percentage of the intensity at the allowed geometry. We obtained TO signals with a good signal noise ratio after a long exposure to the CCD detector. As shown in Fig. 1(b), the TO band has a tail at the low frequency side for the forbidden configuration. For comparison, we show also a Raman spectrum of the TO band at 796 cm^{-1} measured for the (110) cross section. The shape of the forbidden band at the high frequency side is almost the same as that of the allowed band. This result indicates that the asymmetric TO band observed at the forbidden geometry results from the breakdown of the wave vector and polarization selection rules due to the stacking faults. At some places, a broadening at the high frequency side is found for the forbidden TO band. This fact indicates that the defects and the stacking faults accompanying partial dislocations make the phonon lifetime short and contribute to the broadening of the phonon Raman bands.

To confirm that the observed TO band at the forbidden configuration is activated by defects, we investigated TO bands in various places in several 3C-SiC heteroepitaxial films and obtained the bandwidth as a function of the intensity. As shown in Fig. 2, there is a strong correlation between the band width and intensity: The band width increases almost linearly with increasing intensity.

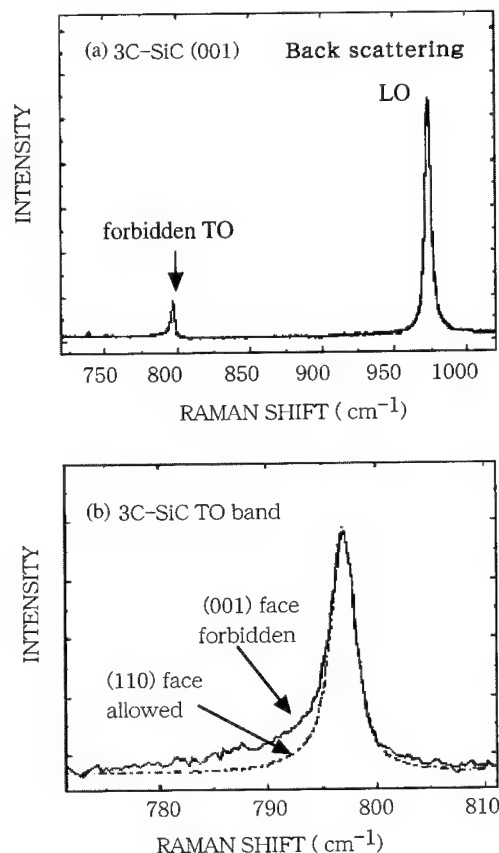

Fig. 1. (a) Raman spectrum of a 3C-SiC film taken at the back scattering geometry and (b) the spectrum of the forbidden TO band obtained by long time exposure of the CCD detector. The dashed line is a spectrum measured using the (110) face.

Fig. 2. The width of the forbidden TO band in 3C-SiC/Si (001) is plotted versus the intensity I of the TO band, normalized to the LO band.

It should be noted that the phonon polariton mode, which arises from reflected light from the back surface of the thin films, prevents observation of the defect induced

Fig. 3. Raman spectra of TO bands in the 4H polytype crystals, containing stacking faults.

TO bands. A cross polarization geometry ($e_i \perp e_s$, $e_i \parallel \langle 110 \rangle$) was used to avoid this phonon polariton mode.

The TO mode at 796 cm^{-1} in 6H- and 4H-SiC corresponds to phonon mode at the Γ point in 3C-SiC

and is called FTO(0) mode. This mode is forbidden for the back scattering geometry using the (0001) face. However, the FTO(0) band appears weakly for these polytypes containing stacking faults as shown in Fig. 3, where the result for the 4H polytype is shown. The appearance of the FTO(0) band in 6H-SiC is considered to be due to the breakdown of the wave vector selection rule by stacking faults as interpreted in Ref. [4].

Abstract

Implants of Er, Al and N with energies ranging from 120 keV to 2 MeV were carried out in n- and p-type 6H-SiC. The aim is to identify electrically active defects in the bandgap which can be associated with the 1.54 μm Er^{3+} luminescence in 6H-SiC. Measurements are conducted by means of deep level transient spectroscopy (DLTS) as well as low temperature photoluminescence (LTPL). In n-type 6H-SiC implanted with Er, we find well known DLTS damage levels whereas strong characteristic lines of Er^{3+} , near 1.54 μm , are seen in the photoluminescence. In p-type 6H-SiC implanted with Er two DLTS peaks can be uniquely associated with the Er^{3+} , on the other hand, *no* luminescence is observed. Conversion of such p-type 6H-SiC into n-type, by nitrogen implantation, recovers the photoluminescence. We conclude that the Er-associated defect levels in the lower half of the gap are likely not involved in the energy transfer mechanism which is responsible for the 1.54 μm luminescence. © 2001 Elsevier Science B.V. Keywords: Erbium-related centers; 6H silicon carbide; DLTS; LTPL

1. Introduction

A number of electrical and optical experiments on various polytypes of SiC, doped with Er, by means of ion implantation or during growth have been reported in the literature [1–4]. It is the purpose of this report to further elucidate the nature of the defect centers that are believed to play a part in the energy transfer process which ultimately leads to the observed Er^{3+} spectra. DLTS and LTPL measurements are applied to n- and p-type 6H-SiC to clarify this issue.

2. Experimental

To achieve a rectangular Er profile to a depth of 0.4 μm , we conducted a sevenfold Er^{3+} -implantation

with integral fluences of 9×10^{10} to $3 \times 10^{12} \text{ cm}^{-2}$ resulting in a mean concentration of 1.6×10^{16} to $4 \times 10^{17} \text{ cm}^{-3}$ as calculated by the TRIM cascade program. As reference element for the implantation damage Xe was implanted in corresponding concentrations. For changing the conduction type from p- to n-type, nitrogen implantations were performed with a resulting average concentration of $3 \times 10^{17} \text{ cm}^{-3}$. Aluminum implants were used to influence the net acceptor concentration of the epilayers. The anneals were performed at atmospheric pressure in a furnace with a closed SiC crucible (1700°C anneal) under argon ambient.

Prior to the preparation of Schottky contacts, a reactive ion etching (RIE) process was performed to remove the surface damage, after that a standard chemical cleaning of the sample was performed using acetone, aqua regia and hydrofluoric acid. For the DLTS investigations, Schottky contacts with a diameter of 1.0 mm were fabricated by evaporation of nickel. The DLTS spectra were taken in a temperature range of 100–700 K with a digital DLTS system (FT1020 by

E-mail address: mpap05@physik.uni-erlangen.de (O. Klettke).

PhysTech). For the figures in this paper a double box-car correlation was chosen, defining the temperature position of the peaks. The net donor concentration was determined at room temperature ($f = 1$ MHz) by the $C-V$ method.

3. Results

DLTS spectra were taken on n-type and p-type 6H-SiC epilayers which were implanted with different Er^{3+} doses (Table 1). To separate implantation-induced defects from those which were caused by Er-related levels in the bandgap, Xe was implanted as the noble gas with an atomic-mass close to that of erbium. After implantation all samples were annealed in the same way at 1700°C for 30 min.

Fig. 1a shows the DLTS spectrum of a n-type sample implanted with Er^{3+} (curve 2) in comparison with the same material implanted with the electrically inactive Xe (curve 3) and the non-implanted epilayer (curve 1). In the non-implanted sample no electrically active defects could be found in the upper half of the bandgap. In contrast, the Er-implanted as well as the Xe-implanted sample show three pronounced peaks. The temperature positions and the calculated activation energies, shown in Table 2, when compared with reference [5] show that these defects are identical to the well-known intrinsic defects ID_6 , ID_7 and Z_1/Z_2 . No Er-related defect level was detected in n-type material.

On the other hand for the p-type epilayers (Fig. 1b) where no intrinsic defects have been observed as yet, a strong peak at 330 K named $\text{Er}(\text{p})_1$ was observed in the DLTS spectrum. This peak could not be seen in the non-implanted epilayer as well as in the Xe-implanted sample. This is a strong evidence that this peak is related to a defect center caused by erbium. More over

the peak height, which is proportional to the concentration of the defect, scales linearly with the implanted Er^{3+} dose. A five time higher implanted Er concentration results in a five times higher peak. The same is true for the smaller $\text{Er}(\text{p})_2$ peak at 370 K. Thus two Er-related deep centers are detected in p-type material.

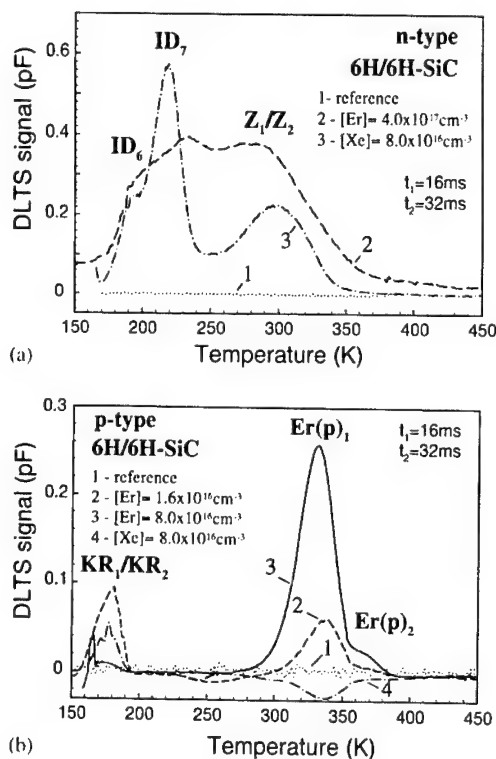

Fig. 1. (a) DLTS spectra taken on n-type 6H-SiC epilayers. Curve 1 is a none implanted epilayer. (b) DLTS spectra taken on p-type 6H-SiC epilayers. Curve 1 is a none implanted epilayer.

Table 1
Parameters of investigated 6H-SiC epilayers

Sample No.	Conductivity type of epilayer	Doping level of epilayer (cm^{-3})	Implanted elements (cm^{-3})			
			Er	Al	Xe	N
01	p	3.4×10^{15}	—	—	—	—
12	p		1.6×10^{16}	—	—	—
02	p		8.0×10^{16}	—	—	—
05	p		—	—	8.0×10^{16}	—
23	p		1.6×10^{16}	—	—	3.0×10^{17}
24	p	5.0×10^{17}	1.6×10^{16}	4.0×10^{17}	—	3.0×10^{17}
08	n		—	—	—	—
09	n		8.0×10^{16}	—	—	—
10	n		4.0×10^{17}	—	—	—
11	n		—	—	3.0×10^{16}	—

Table 2

Trap parameters of defect centers observed in DLTS spectra of Er-implanted 6H-SiC samples

Defect	Conductivity type	Peak temperature (K) ($t_1/t_2 = 16/32$ ms)	Activation energy (meV)
ID ₆	n	190	414 ± 15
ID ₇	n	220	463 ± 25
Z ₁ /Z ₂	n	300	550 ± 60
KR ₁ /KR ₂	p	170/180	450 ± 100
Er(p) ₁	p	335	789 ± 25
Er(p) ₂	p	365	780 ± 35

An interesting feature of these DLTS measurements is that the peaks KR₁/KR₂ near 170 K (Table 2) appear in the Er- as well as in the Xe-implanted samples in p-type material. None of these defects have been published in the literature to our knowledge.

2, 77 and 295 K photoluminescence measurements were taken on n- and p-type epi-grown 6H-SiC implanted with various fluences of Er and subsequently annealed at 1700°C for 30 minutes. In Fig. 2 (a), we have implanted $8 \times 10^{16} \text{ cm}^{-3}$ Er into p-type 6H-SiC and no $1.54 \mu\text{m}$ $^4\text{I}_{13/2}$ to $^4\text{I}_{15/2}$ transitions ($1.54 \mu\text{m}$) are observed. In contrast in panel (c) of this figure, we have a strong $1.54 \mu\text{m}$ spectrum despite a five-fold reduction of the Er fluence and using twice the resolution as in panel (a). To further demonstrate the dependence on the n- and p-type doping, we have taken an n-type sample implanted with the same fluence as in panel (c) and further implanted it with Al ions to compensate some of the N donors. We see the result in panel (b) where the $1.54 \mu\text{m}$ spectrum is considerably weaker despite using a lower resolution than in panel (c). These experiments clearly indicate that the Er^{3+} spectra are seen in n-type and not in p-type Er-implanted 6H-SiC.

4. Discussion

Our DLTS measurements on n- and p-type 6H-SiC clearly show that the defect levels that are found in Er-implanted n-type material can be attributed to well-known defect centers, however, in Er implanted p-type material two DLTS peaks can definitely be associated with Er. On the other hand, the optical data clearly shows that the Er^{3+} $1.54 \mu\text{m}$ spectra in 6H-SiC are confined to n-type material. A model was given in Ref. [2] which proposed that the excitation of the Er^{3+} 4f electrons occurs through the collapse of an exciton at an Er-related defect in the upper half of the gap. Our new results appear to require a revision of this model in so far that the defect at which

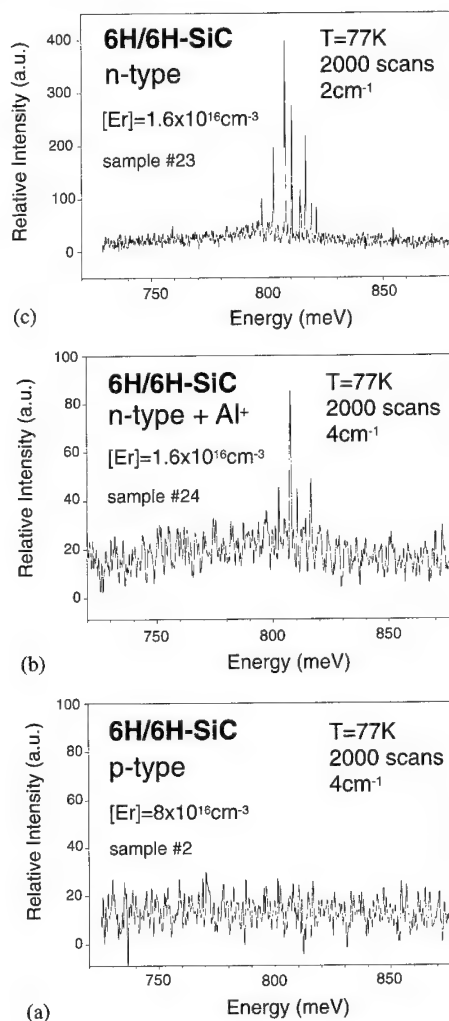

Fig. 2. LTPL signals taken at 77 K of Er-implanted 6H-SiC epilayers with different doping levels and conductivity types.

the energy transfer to the 4f electrons occurs is one of the well-known damage defects rather than an Er-related defect. Whether the Er defects found in the lower half of the gap (p-type 6H-SiC) play any role in the energy transport to the 4f electrons is presently unknown.

Abstract

Semi-insulating (SI) silicon carbide is important for applications in high-power, high-frequency electronics, such as SiC MESFETs and GaN FETs. In this work, we discuss the use of low-temperature electron paramagnetic resonance (EPR), room- and low-temperature FTIR and photoluminescence as potential screening probes. In addition, the improved materials quality enhances the resolution of such spectroscopic measurements to better understand the material. The EPR spectra reveal the expected V^{4+} as well as the shallow boron center, suggesting inhomogeneities in the B and/or V distribution. We observe significant reduction in the free-carrier absorption compared with n-type material and the intra-3d-shell E_2-T_2 IR absorption. In addition, we observe an N-related gap mode which may serve as a quantitative probe of the N content. The photoluminescence from the V-doped sample exhibits weak donor-bound excitons and shows a broad structured band near 3.0 eV related to recombination between photoneutralized N-donors and photoneutralized acceptors. 1. Introduction

Silicon carbide has become an important semiconductor for high power, high frequency and high temperature devices [1,2] and 4H–SiC has emerged as the superior polytype, owing to a wider band gap and higher mobilities. Semi-insulating (SI) substrates are required for a number of these applications and, as with SI GaAs and InP in which optical absorption plays an important role in wafer screening [3], contactless, nondestructive methods are needed to select acceptable wafers. The improved materials quality (from a number of different growers) has opened the door to renewed application of spectroscopic probes. The spectral lines are often sharper and with the decrease in the residual

defects and impurities, additional centers become important to the electronic properties of the materials. In this paper, we discuss the application of a number of spectroscopic probes to these materials with the overall goal of developing useful contactless screening techniques as well as a better understanding of the defects important to this material.

2. Electron paramagnetic resonance

The electron paramagnetic resonance (EPR) measurements were all performed in a Bruker 9.5 GHz spectrometer, typically at 4–20 K. The signal due to the V^{4+} is seen in Fig. 1. The $V^{5+}-V^{4+}$ transition occurs near mid-gap, pinning the Fermi level there [4]. As has been previously reported [4], there are two ^{51}V ($I = 7/2$, 100% abundant) hyperfine split octets due to the V_{Si} on the cubic and hexagonal sites, as indicated in Fig. 1.

Fig. 1. The EPR spectrum of the V^{4+} ion in the SiC. There is no indication of the V^{3+} ; the central line is due to boron acceptors that are discussed in the text. B is parallel to c .

In addition to the expected V^{4+} signal, we observe the shallow boron signal in this sample, as seen in Fig. 2. This is unanticipated because the electron from the V^{4+} is expected to compensate the B acceptors. Considerable effort was applied to assure that the sample was in thermal equilibrium: e.g., the sample was left in the dark at room temperature overnight and no change was observed in the signal. We, therefore, conclude that there are nonuniform regions of the sample where the V does not completely compensate the B and, in those regions, the Fermi level is nearer the boron acceptor level (~ 300 meV above the valence band) rather than near the mid-gap. The boron spectrum is extremely sharp and this presents us with some opportunities to better understand this center. The integrated intensity of the boron lines on the cubic site is almost an order of magnitude larger than that for the hexagonal site (particularly apparent for $B \parallel c$), suggesting that the energy level of the cubic site is deeper than that of the hexagonal site. This is in general agreement with the thinking of Evwaraye et al. [5] and Duijin-Arnold et al. [6] who have argued that the hexagonal site is the shallowest. This could be the most definitive measurement of which of the two levels is deepest since the EPR provides a fingerprint and an intensity measurement. However, there is one caveat. In some SI samples, it does appear that the B on the hexagonal site has a stronger signal. Furthermore, we are assuming that the B occupies the cubic and hexagonal sites with equal probability and it may be that under certain growth conditions one or the other is preferred. Clearly, additional careful measurements are required to resolve this apparent contradiction.

In addition to the two sets of four lines (one for each site), we also observe a number of weaker lines which are not commonly observed in simple EPR for isolated B in

Fig. 2. The EPR signal of the shallow B acceptor for B perpendicular (bottom) and B parallel (top) to the c -axis. The sharp lines to the right in the upper plot and to the left in the lower one are due to the hexagonal site while the other structure is due to the cubic site.

the SiC. These are especially apparent for the hexagonal site. Some of the structures between the ^{11}B hyperfine split lines may be due to hyperfine splitting due to the ^{10}B ($I = 3$, 20% abundant and with a nuclear moment about $\frac{1}{3}$ that of the ^{11}B) and positions for those lines are marked in Fig. 3. The superhyperfine structure from the neighboring ^{29}Si could also account for some of the structure. We also note that the lines are exceptionally sharp ($\sim 10 \mu\text{T}$) and so, much more detail is observed in conventional EPR than has typically been seen and the data clearly require further analysis.

3. Infrared spectroscopy

Near-infrared studies were conducted at room temperature with a Bomem MB-155 FTIR. Samples were wedged to minimize interference effects. In Fig. 4, we compare the near-IR transmission for an SI vanadium-doped sample with an n-type sample. We observe the $V E_2-T_2$ intra-3d-shell IR absorption in the SI sample (expanded and shown in the dashed ellipse in Fig. 4). This is a signature of the SI vanadium-doped material in that the V must be in the neutral state. This is not seen in the n-type sample, where the absorption is dominated by free-carrier absorption. The free carriers absorb radiation at low-infrared frequencies (long wavelengths). This absorption can be used as a nondestructive

Fig. 3. The weak multi-line spectrum of the shallow B-center with B perpendicular to the c -axis. The arrows indicate the positions of the ^{10}B hyperfine structure.

Fig. 4. The near-IR absorption spectra for a V-doped SI sample and an n-type sample. The dashed line is a fit of the free-carrier absorption with $n=1 \times 10^{18} \text{ cm}^{-3}$ and $\mu=200 \text{ cm}^2/\text{Vs}$. The intra-3d-transition is expanded and shown in the ellipse.

measurement of carrier concentration of conductive wafers. The sample here is strongly absorbing below the TO phonon frequency ($\sim 780 \text{ cm}^{-1}$) but can be modeled above the TO phonon to extract an indicated carrier concentration of $1 \times 10^{18} \text{ cm}^{-3}$. The SI wafers are transparent below the TO phonon frequency and intermediate resistivity wafers can be studied below the TO phonon frequency to extract similar information.

Between the optical and acoustic phonons, we observe a localized nitrogen gap mode at 611 cm^{-1} as shown for two 4H samples in Fig. 5. This study was carried out near 4.2 K with a Bomem DA8 FTIR and again the sample was wedged to minimize interference. The one sample has a relatively high nitrogen concentration while the second is semi-insulating with over an order of magnitude less nitrogen. SIMS measurements are currently under way to further quantify this technique that could provide a relatively quick nondestructive probe of the N content in a wafer.

4. Photoluminescence spectroscopy

The photoluminescence (PL) spectra were obtained with samples in a cryostat at 6 K. The 325 nm line of a HeCd laser was used for excitation and the PL was analyzed by a 0.85 m double spectrometer and detected with a UV-sensitive photomultiplier. The low temperature PL spectrum of N-doped 4H-SiC is dominated by recombination processes involving N-donor-bound

Fig. 5. The IR absorption due to a nitrogen gap mode for two samples. The ratio of intensities indicates a factor of 24 difference in the N concentration.

Fig. 6. A comparison of the PL for an n-type sample (top) and an SI V-doped sample (bottom).

excitons. The samples doped with V show a considerable quenching of the band edge emission related to the N-donors as shown in Fig. 6. This is attributed to the high degree of compensation of the N-donors. A broad structured emission band near 3.0 eV is also found in the V-doped sample. This PL has been ascribed to a recombination process involving photoneutralized N-donors and photoneutralized acceptors [7]. Optically Detected Magnetic Resonance experiments are under way to provide more detailed information on the nature of this PL.

5. Summary

We have shown that we can apply a number of spectroscopic measurements such as the EPR, FTIR and PL to analyze V-doped 4H-SiC samples and define their

semi-insulating character. Notably, the observation of an EPR signal due to shallow B suggests that V and/or B are not uniformly distributed resulting in inhomogeneities in the Fermi level relative to the valence band. In addition, we observe super-hyperfine structure on the boron center due to the ^{29}Si and/or ^{51}V . In the near IR we observe the V E_2 - T_2 intra-3d-absorption in the SI sample and, as expected, a significant decrease in free-carrier absorption. A nitrogen gap mode is observed and may serve as a measure of N concentration. In V-doped samples, the excitonic emission is quenched and a broad PL band at ~ 3 eV is observed.

Abstract

The evolution of deep levels that depend upon annealing temperature is investigated for *p*-type 6 H SiC–Al Schottky barriers. Several samples, cut from the same wafer, have been annealed at 400°C, 600°C and 800°C, in air, while on one sample no annealing has been done. Deep level transient spectroscopy (DLTS) has been used to investigate deep levels in all four sets of samples. The results show that only electron traps can be detected in the temperature range 220–440 K. Defects with activation energies having values between 0.12–0.37 eV are detected by DLTS. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Silicon carbide (SiC)-based semiconductor electronic devices and circuits are presently being developed for use in high-temperature, high-power, and/or high-radiation conditions under which conventional semiconductors cannot adequately perform. Silicon carbide is expected to enable significant improvements to a variety of applications and systems, such as high-voltage switching [1–3] and powerful microwave electronics for radar and communications [4].

Due to the fact that SiC has a low diffusion coefficient of the impurities, the commonly used process to dope the material is by ion implantation. There is radiation damage left which introduces electrically active defects. For example, Al implantation in 6H–SiC introduces both deep acceptor ($E_T = E_V + 0.26$ eV) and donor ($E_T = E_C - 0.44$ eV) states [5,6].

Doping the material with Al or N during growth is used to obtain *p*- and *n*-type material, respectively, resulting also in defect creation. One of the resulting defects, due to N residing at the C lattice site, has activation energies in the range 0.08–0.150 eV [7].

Other defects are created as a result of incorporation of residual impurities present in the growth systems. Independent of the polytype, B residing at a Si lattice site forms a deep level at approximately $E_V + 0.30$ eV, while a complex of one B atom at a C site and a neighboring intrinsic defect such as V_{Si} and V_C , forms a deep level (D defect) at approximately $E_C - 0.65$ eV [8,9]. Vanadium forms deep levels at 0.35, 0.7 eV and near midgap in 4H- and 6H–SiC material [10].

The large number of defects investigated by numerous groups, cited above, indicates that growth conditions as well as post-growth processing of the substrates might play an important role in the creation and evolution of the deep defects in SiC.

The material used in this study, 6H–SiC acquired from Cree Corp., doped with Al ($p = 3.6 \times 10^{18} \text{ cm}^{-3}$) has been cut in four pieces. Three of these have been annealed in air for 30 min at 400°C, 600°C and 800°C, respectively, while on the fourth piece no heat treatment has been applied. After annealing, all samples have been cleaned in HF: deionized water (1:2) for 5 min, then rinsed in deionized water and dried in inert gas. After cleaning, the samples have been placed in a standard Edwards evaporator system for Al Schottky contact deposition through masks with circular dots with diameters of 0.5 mm. On each sample, 12 dots have

*Corresponding author. Fax: +1-740-593-0433.

E-mail address: perjeru@helios.phy.ohiou.edu (F. Perjeru).

been deposited resulting in the formation of 12 Schottky barriers (thickness of the contact 400 nm). Ohmic contacts have been formed by evaporation of Al on the back of the samples (contact thickness of approximately 1000 nm).

To test the properties of the Schottky barriers thus obtained, current–voltage measurements (I – V) were performed at 300 K using a Keithley 236 source measure unit. Capacitance–voltage (C – V) and deep level transient spectroscopy (DLTS) measurements were performed in vacuum at a pressure of 1×10^{-3} Torr and at a frequency of 1 MHz using a SULA Technologies DLTS. DLTS analysis have been performed for several junctions on each sample in the temperature range 220–440 K. A reverse bias of 3–5 V was applied to the junctions. The traps were filled by decreasing the bias to 0 V. The duration of the filling pulse was 5 ms.

2. Results

I – V measurements were performed for each barrier on every sample. The junctions were characterized by ideality factors close to 2, and leakage currents of the order of 2.0×10^{-8} A cm $^{-2}$ at 5 V reverse bias. From C – V measurements, values for the built-in voltages of 3.3 eV and $(1.3\text{--}1.4) \times 10^{18}$ cm $^{-3}$ for the carrier concentration were obtained. Within the depth sampled by the spreading charge region, 200 nm from the surface, the free carrier concentration remained constant.

Fig. 1. DLTS for p-type SiC annealed at 600°C. There are signatures from two defects, both electron traps. One trap cannot be followed using the available rate windows to be able to extract the activation energy.

Fig. 2. Activation energies for traps in p-type SiC.

An example of DLTS spectrum on a sample that has been annealed at 600°C is shown in Fig. 1. The activation energy was determined from Arrhenius plots for all defects (using a temperature independent capture cross-section approximation). DLTS results for all samples are shown in Fig. 2 and are listed in Table 1. It has been seen that only electron traps are active in the temperature range investigated and that more than one trap is present for all samples. For one trap the activation energy could not be extracted because a temperature higher than could possibly be used was necessary, as seen in Fig. 1.

For the sample annealed at 400°C it has been observed that besides the trap that cannot be reached, depending upon the rate window chosen, there are two traps that occur in the same temperature range, with activation energies of $E_c - E_T = 0.37 \pm 0.02$ and (0.21 ± 0.02) eV, respectively. Both are electronic traps. All traps have uniform distribution within the region of the bulk sampled (200 nm).

3. Discussion

In terms of I – V and C – V measurements, the results are similar with those obtained by other groups on similar samples [11–13]. In general, for SiC is not trivial to obtain ideality factors close to unity. The process in general requires extensive cleaning and etching of the surface oxides [11,14].

The defects found in this study have minority carrier DLTS signatures and are therefore, electron traps. Some defects have been detected by other groups, for

Table 1
Activation energies and concentrations for traps in p-type SiC

	As grown	400°C	600°C	800°C
Name and activation energy (eV)	PE1 0.12 ± 0.2	PE2 0.21 ± 0.2 PE3 0.37 ± 0.2	PE4 0.21 ± 0.2	PE5 0.33 ± 0.2
Concentration (cm^{-3})	PE1 $(2-3) \times 10^{14}$	PE2 $(3-4) \times 10^{15}$ PE3 $(1-3) \times 10^{15}$	PE4 $(5-6) \times 10^{14}$	PE5 $(1-1.5) \times 10^{15}$

example, the PE1 defect, which is close to the L1 electron trap found by Ballandovich [15]. The PE2 and PE4 defects, present in the samples annealed at 400°C and 600°C are probably the same defect with an intrinsic nature, especially since after annealing at temperatures higher than 600°C their signature is no longer present. This conclusion is further supported by the fact that the concentration of this defect decreases with annealing temperature, from $(3-4) \times 10^{15} \text{ cm}^{-3}$ at 400°C, to $(5-6) \times 10^{14} \text{ cm}^{-3}$ at 600°C. It is known that simple point defects, such as single vacancies and Frenkel pairs are annealed out in the range 100–750°C [15].

The PE3 and PE5 defects might be different defects, especially since they are active at different temperatures. A defect with activation energy of $E_C - 0.32 \text{ eV}$, has been detected by Kobayashi et al. [16] as well, but no hypothesis has been formulated regarding its nature [16]. Vanadium impurities are found to introduce defects with activation energy of $E_C - E_V = 0.35 \text{ eV}$ [10]. Either PE3 and PE5 might be related to such residual V impurities. Another hypothesis regarding these two defects is that they could be related to deep center observed by Zhang et al. [17], which showed that actually there are two centers, and that it is difficult to resolve the energy position of these centers when recording DLTS spectra. Based on data in which T^2 corrections were used, the activation energy was calculated to be 0.35–0.39 eV [15]. In these conditions, both PE3 and PE5 might be related to these centers.

One defect that appears at higher temperatures could not be reached with the experimental apparatus and samples. This could be a defect with activation energy $> 1 \text{ eV}$ below the conduction band. Such defects have been observed by Kobayashi et al. [16]. The fact that no other defects have been detected in this temperature range could be a consequence of their concentration being below the detection limit of our apparatus.

In conclusion, defects in p-type 6H-SiC samples have been investigated and results displayed in Table 1. Several defects were found, depending upon the annealing temperature of the sample. From carrier concentration and activation energy, some of the defects have been tentatively associated with defects published in literature.

Abstract

Several samples of semi-insulating (s.-i.) 4H-SiC have been studied by Electron Paramagnetic Resonance (EPR) at 37 GHz and by photoluminescence (PL). One set of samples revealed EPR spectra of vanadium. The signs of fine structure constants D were determined, at 4.2 K, to be positive. In the second set of samples the EPR signals from nitrogen, boron and a deep center, P, with $g_{\parallel} = 2.0048$ and $g_{\perp} = 2.0030$ appeared in the EPR spectrum after photo excitation of the sample. The P center is postulated to be the deep donor reported previously to be a dominant center in s.-i. 4H-SiC. Intercenter charge transfer processes between nitrogen and the P center are shown to be very efficient. Both sets of samples revealed the well known vanadium intracenter PL emission lines near 0.95 eV. In addition, a broad band located at 2.43 eV along with sharp near-band-edge luminescence lines has been observed for the samples containing large amounts of vanadium and at 2.38 eV with a shoulder at 2.14 eV in the samples with low levels of vanadium. © 2001 Elsevier Science B.V. Keywords: Semi-insulating SiC; Photo EPR; Photoluminescence

1. Introduction

There is currently interest in deep levels in SiC for the production of semi-insulating (s.-i.) substrates for microwave devices. Although considerable progress has been made in the technology of s.-i. SiC material, information on the dominant recombination centers, including their nature, energy levels and influence on the s.-i. properties of SiC, is limited. Mitchel et al. [1] have demonstrated that, in addition to vanadium, another level at $E_C - 1.1$ eV may dominate some s.-i. material. This level must be taken into consideration as lifetime limiting recombination center as well as a deep level responsible for the s.-i. feature of this material.

2. Experimental

To investigate the deep levels in SiC, two sets of s.-i. 4H samples have been studied by photo EPR

and photoluminescence (PL). Photo EPR measurements using photo excitation and photo quenching techniques are a good method for determining the charge state of impurities and defects. Also, conclusions about the level positions in the band gap of the defects and impurities, and on charge exchange processes, can be obtained. Photoluminescence provides further information on the electronic levels present in the material through the recombination of free carriers.

The samples were bulk semi-insulating 4H-SiC grown by physical vapor transport. The first set had high vanadium concentrations as determined by SIMS ($> 10^{17} \text{ cm}^{-3}$) while the second set had a smaller concentration ($< 10^{16} \text{ cm}^{-3}$).

EPR measurements were performed on Q-band EPR spectrometer. The photo excitation and quenching experiments were performed using a 250 W high-pressure mercury vapor lamp and a 100 W halogen lamp combined with interference filters and a prismatic monochromator for a wavelength range of 380–1000 nm.

3. Results

Prior to illumination, the first set of samples revealed the EPR spectra of vanadium in the $V^{3+}(3d^2)$ charge state ($S = 1$, $I = 7/2$) from the cubic and hexagonal sites in the temperature interval from 4.2 to 77 K. The two hyperfine octets arising from cubic site V taken at 4.2 K and 37 GHz for $H \parallel c$ are shown in Fig. 1. The parameters of the spin Hamiltonian obtained from an analysis of the angular dependence of the EPR spectra for a rotation of the magnetic field in the $(1\bar{1}\bar{2}0)$ plane, listed in Table 1, are very similar to those obtained in Ref. [2] at 9 GHz. The signs of the fine structure parameters D were determined to be positive for the two V spectra from the difference in the intensity of the low and high field resonance transitions which, as seen in Fig. 1, are enhanced by raising the frequency and lowering the temperature to 4.2 K.

After illumination with above-band-gap UV light, two lines at $g_{\parallel}^h = 2.0019$ and $g_{\parallel}^k = 2.0063$ appeared in the EPR spectrum. These lines are due to the boron acceptor on hexagonal and cubic sites [3]. At the same

time, the vanadium spectrum itself does not change with illumination.

In the dark, the second set of samples showed only a weak cubic site boron EPR signal without the vanadium lines. Excitation of the sample with UV light resulted in the neutralization of the shallow donors and acceptors and as a result the EPR signals from nitrogen and boron appeared. Fig. 2 shows the EPR spectrum measured at 37 GHz and 77 K during illumination with UV light. The spectrum consists of two lines with unresolved hyperfine structure due to the two inequivalent sites of shallow boron, I_k^B with $g_{\perp} = 2.0046$ and I_h^B with $g_{\perp} = 2.0070$ corresponding to the two inequivalent sites, which have C_{3v} symmetry at temperatures higher than 50 K [3] and cubic site nitrogen, I_k^N , which is easily recognized by the characteristic three line hyperfine pattern and $g_{\perp} = 2.0013$ [4].

After the UV light was turned off, the hexagonal and cubic boron resonances decreased slowly to about 0.4 and 0.7 of their values under illumination, respectively. The nitrogen EPR lines decayed to about 0.07 of their value under illumination after 21 h in the dark. At the same time, as was seen in Fig. 2b, a new single line, labeled I_p , with $S = 1/2$, and $g_{\parallel} = 2.0048$, $g_{\perp} = 2.0030$ appeared in the EPR spectrum. The intensities of the photo-induced EPR signals indicate that the lifetimes of electrons and holes at $T = 77$ K are very long and that the recombination rate of the photo-excited carriers is

Fig. 1. Vanadium $V^{3+}(3d^2)$ EPR spectrum in s.i. 4H-SiC measured at $T = 4.2$ K, 37 GHz and $H \parallel c$. The two hyperfine octets belong to the $V^{3+}(3d^2)$ cubic site. The energy level scheme for a triplet system in a static magnetic field is shown for $D > 0$.

Parameters of vanadium $V^{3+}(3d^2)$ EPR spectra in 4H-SiC, measured at 4.2 K and 37 GHz

	I_h	I_k
g_{\parallel}	1.962 ± 0.008	1.959 ± 0.005
g_{\perp}	1.958 ± 0.008	1.958 ± 0.005
D (GHz)	10.5 ± 0.1	2.65 ± 0.05
A_{\perp} (G)	63.0 ± 1.0	64.0 ± 1.0
A_{\parallel} (G)	68 ± 1.5	65 ± 1.5

Fig. 2. Photoresponse of EPR spectra in s.i. 4H-SiC measured at 77 K and $H \perp c$. (a) UV light excitation; (b) spectra 21 h after UV illumination; (c) visible light excitation; (d): UV quenching of visible light induced signal.

very small. The nitrogen and boron resonances can be quenched by shining below-band-gap light of various wavelengths on the sample. The time dependence of the decay of the nitrogen resonance line for four different quenching photon energies is plotted in Fig. 3. This figure shows that a substantial enhancement of the recombination rate of the photo-created carriers starts at about $\Delta E_q = 2.36$ eV, which corresponds to the energetic distance of the deep donor level from the valence band: $E_g = \Delta E_q + \Delta E_{DL} \cong 2.36$ eV + 0.9 eV $\cong 3.26$ eV. Starting from 2.36 eV the number of the electrons released from nitrogen increase and hence the donor-acceptor recombination process becomes more efficient. During quenching, the I_P line first appears when the intensity of the nitrogen EPR line decays to about 0.3 of its light-on value, independent of the energy of the quenching light. This indicates that the release of electrons from nitrogen is responsible for the appearance of the P center in the quenched EPR spectra.

The I_P line also appeared in the EPR spectrum after direct excitation with below-band-gap light as shown in Fig. 2c. When the below-band-gap light was turned off, I_P and the boron lines persisted for more than 14 h without a noticeable change in intensity, showing that no recombination processes occurred between the P center and boron. Subsequent illumination of the sample with UV light quenched the P center, restored the nitrogen EPR spectrum and enhanced the boron line to

Fig. 3. Time dependence of the decay and rise of the nitrogen (A) and P center (B) EPR resonance lines for four different quenching photon energies.

Fig. 4. PL spectra for two 4H-SiC samples. Sample A contains vanadium while V is undetectable by SIMS in sample B. The feature labeled figure caption is an artifact due to a change in filters during the experiment.

its maximum intensity, as seen in Fig. 2d. The rise and decay times of the intensity of the EPR signals of nitrogen, boron and the P center were found to depend on the intensity of the irradiating UV light. Under low intensity UV illumination the nitrogen and boron EPR lines increased slowly to their maximum values approximately for 15 min while the I_P line completely vanished for this time, showing a correlation between the rise and decay of the EPR signals of nitrogen and the P center.

In the PL experiments, both sets of samples revealed spectra in the 0.95 eV region from the intra-3d-shell transitions of vanadium which show the polytype to be 4H [2]. In addition, as shown in Fig. 4, a broad band near 2.4 eV has been observed along with the typical near-band-edge sharp luminescence lines. For the first set of samples, which contains higher concentrations of V, the peak position of the 2.4 eV band is located at 2.43 eV. For the sample in which SIMS was unable to detect V, the peak shifts to 2.38 with a shoulder at 2.10 eV.

4. Discussion

The excitation and quenching spectra of the nitrogen and boron EPR signals may be explained by a recombination process between nitrogen and boron that involves the P center. The P center, observed only in the second set of samples after illumination, is suggested to be a donor due to the sense of the g -anisotropy (i.e. $g_{\parallel} > g_{\perp}$) which coincides with that found for donor paramagnetic centers in SiC. Since the P center showed a slight anisotropy ($\Delta g = 1.8 \times 10^{-3}$) compared to that for nitrogen ($\Delta g = 4.5 \times 10^{-3}$) it was concluded that the P center should have an energy level deeper than nitrogen [4].

The excitation and quenching EPR spectra can be understood as due to two competing processes. One is the recombination process between nitrogen and boron and second is the charge transfer process occurring between shallow nitrogen and deep donors resulting in the appearance and subsequent disappearance of I_P in the quenched EPR spectra. As was shown in Ref. [5] the efficiency of the intercenter charge transfer process in SiC is enhanced by increasing the concentration of deep donors and by lowering the Fermi level to midgap after which the nitrogen donors tends to interact less with the conduction band and more with states below them.

It should be noted that the lifetime of electrons trapped on the P center is very long, 15–20 h. Taking into account that the boron lines also persist in the quenched EPR spectrum, we conclude that the recombination between nonequilibrium carriers is impeded by the presence of P center. Thus, the P center is strongly involved in the trapping and recombination (TR) process and is possibly the dominant lifetime controlling defect at low temperature in these samples.

The luminescence properties of the samples were found to correlate with the paramagnetic properties. As seen in Fig. 4, the samples with the lowest intensity vanadium PL band exhibited a shoulder peaking at about 2.14 eV, which is close to band gap, minus the activation energy of the P center. The Fermi level in these samples was pinned at the 1.1 eV level.

Defect correlated emission and electrical properties of 4H- and 6H-SiC epitaxial layers doped by nuclear transmutation doping (NTD)

H. Heissenstein*, H. Sadowski, R. Helbig

University of Erlangen-Nürnberg, Lehrstuhl für Angewandte Physik, Staudtstr. 7/A3, D-91058 Erlangen, Germany

Abstract

We have investigated 4H-SiC and 6H-SiC epitaxial layers after doping by nuclear transmutation doping (NTD). N-type layers on n-type substrates were characterized by low-temperature photoluminescence (LTPL) and p-type layers on p-type substrates with I - V , C - V and Hall effect measurements. Resulting from irradiations with thermalized neutrons of different energy spectra the samples were doped with phosphorous. Our experiments show defects which are generated by fast neutrons which inevitably exist in the energy spectra of reactor neutrons. We characterized samples by LTPL at temperatures of measurement between 2 and 72 K in the visible range as irradiated and annealed up to 1200°C. I - V curves of pn-junctions which are annealed at 1500°C and 1600°C with varied fluences of fast neutrons are presented. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Nuclear transmutation doping (NTD) of SiC is based on the reaction [$^{30}\text{Si}(n,\gamma)^{31}\text{Si} \xrightarrow{\beta^-} ^{31}\text{P}$] and therefore, it is basically useful to produce the phosphorous donor in volumes of SiC. The phosphorous doping of SiC also was analysed after ion-implantation [1]. First attempts applying NTD on SiC were made with respect to the behaviour of SiC in radiative environments [2] and in order to get higher doping levels for ESR-investigations [3]. In the last years NTD is introduced in SiC technology as doping technique [4–6]. The electrical characteristics of irradiated samples are influenced by defects due to fast neutrons, which are incorporated inevitably by NTD using neutrons with energy spectra from nuclear reactors [4].

2. Experimental

We irradiated different 4H and 6H epitaxial layers on Cree Substrates (n- and p-type) in different positions of several reactors with a fluence of thermal neutrons of $4 \times 10^{19} \text{ cm}^{-2}$ and fluences of fast neutrons (energy $> \text{MeV}$) of $8 \times 10^{16} \text{ cm}^{-2}$ and $5 \times 10^{15} \text{ cm}^{-2}$.

The samples were characterized after irradiation and after different annealing steps (for details of sample preparation see [4]). We investigated low-temperature photoluminescence (LTPL) (for apparatus details [7]) with a HeCd laser at 325 nm for excitation. The studies of the electrical behaviour were carried out after preparing mesadiodes of 6 mm in diameter without any special surface or edge preparation techniques. The mesadiodes were contacted by aluminum on the n-type layer and by Ni on the p-type substrate. Diodes prepared from the same chip were annealed at 1400°C, 1500°C, 1600°C to generate the pn-junctions in the previously p-type on p-type samples. I - V measurements

were carried out with a Keithley 6517 and a curvetracer Sony 370 A.

3. Results

LTPL is a powerful tool for non-destructive characterization of samples. Directly after irradiation LTPL spectra are to be detected if the applied fluence of fast neutrons is low (e.g. $<10^{16} \text{ cm}^{-2}$). For samples irradiated with higher fluences of fast neutrons luminescence is not detectable until applying annealing temperatures above 1000°C .

At samples with low applied fluences of fast neutrons we measured the emission after NTD and after several annealing steps. In addition the emission spectra for increasing temperatures from 2 up to 72 K were measured.

In the visible region, there is a small band of lines in both polytypes which is shifted on the energy scale towards each other (Fig. 1) corresponding to the different energy gaps. There is another emission band strongly correlated to defects in the near IR [5, 6H: 8] which shall not be discussed here.

The experiments where the temperature of the measurements is directly increased after NTD show impressive changes between 6, 7 and 21 K, respectively (Fig. 2 for 4H; Fig. 3 for 6H). Obviously the lines can be divided into three groups. First there are stable (s) lines over a wide range of temperatures, other lines vanish (v) with increasing temperature and there are rising (r) ones. In both polytypes there are groups of lines of type v (4H: lines at 4250, 4274, 4278, 4284, 4290, 4294, 4299, 4306, 4311, 4328, 4346, 4348, 4352 (Å); 6H: lines at 4711, 4719, 4724, 4728, 4738, 4741, 4745, 4750, 4755, 4759, 4767 (Å)) at the high-energetic side and at the low-energetic side (4H: 4384, 4389, 4405, 4417 (Å); 6H: 4831, 4836, 4843, 4846, 4849, 4854, 4857, 4862, 4867, 4896, 4904 (Å)). The stable lines are in 4H: 4372, 4466,

Fig. 1. LTPL spectra (at 2 K) in the visible range of photoluminescence of 4H- and 6H-SiC directly after neutron irradiation.

Fig. 2. LTPL spectra of 4H-SiC directly after neutron irradiation at different temperatures of measurement: (a) 2 K, (b) 7 K, (c) 21 K, (d) 43 K, and (e) 68 K.

Fig. 3. LTPL spectra of 6H-SiC directly after neutron irradiation at different temperatures of measurement: (a) 2 K, (b) 6 K, (c) 21 K, (d) 43 K, and (e) 72 K.

Fig. 4. LTPL spectra at 2 K of 4H-SiC directly after neutron irradiation and after different annealing temperatures: (a) as irr., (b) 600 °C, (c) 700 °C, and (d) 1200 °C.

4495 (Å) and in 6H: 4792, 4875, 4908 (Å). At 21 K we detect type r (4H: 4262, 4266, 4273, 4288, 4293, 4301, 4316, 4332, 4337, 4341, 4346, 4372 (Å); 6H: 4766, 4777, 4839, 4846 (Å)).

Furthermore we measured spectra after annealing at low temperatures (Fig. 4 for 4H; Fig. 5 for 6H). Most lines arise after annealing at less than 600 °C, only few decrease in this range. After annealing above 1000 °C all these lines are vanishing and only the well known D_1 -defect [9] is detected. The D_1 -defect correlated emission consists in 4H-SiC of one line L_1 (4276 Å). In 6H-SiC it consists of three lines L_1 (4724 Å), L_2 (4789 Å), L_3 (4825 Å). Amazingly the D_1 -defect emission arises already at annealing temperatures < 600 °C. Especially in 6H-SiC in the well-known intensity distribution between the three lines; due to the fact that in 6H-SiC one hexagonal lattice site and two cubic lattice sites exist, whereas in 4H-SiC one cubic lattice site and one hexagonal site exist. Thus in 6H-SiC more emission lines are expected. But the experimental result that in 4H-SiC only one emission line for the D_1 -defect was observed is still not understood.

After small applied fluences of fast neutrons the well-known intensity distribution of the L lines dominates the LTPL spectrum at annealing temperatures above 1000 °C. After higher fluences of fast neutrons (approx. 10^{18} cm^{-2}) the distribution has changed [4] and after further annealing the distribution of the L-lines changes to the well-known spectrum.

After irradiation both spectra (Figs. 4 and 5) show three intensive lines (4H: 4348, 4372, 4417 (Å); 6H: 4792, 4876, 4908 (Å)). At the high energetic part of the spectra

Fig. 5. LTPL spectra at 2 K of 6H-SiC directly after neutron irradiation and after different annealing temperatures: (a) as irr., (b) 700 °C, (c) 750 °C, (d) 800 °C, and (e) 1000 °C—here the intensity of the D_1 -defect is reduced by a factor of five.

there is a group of weak lines (after the thermal behaviour designed as type v). In 6H-SiC we find in between the strong lines some weaker ones at 4796, 4803, 4813, 4816, 4818, 4822, 4825, 4831, 4836, 4839, 4843, 4846, 4849, 4854, 4857, 4862, 4867, 4891, 4896, 4904 (Å). As well at the lower energetic side (4H: 4466, 4495; 6H: 4932, 4937, 4947, 4955, 4960, 4965, 4970, 4974, 4980, 4983, 4987, 4991, 4997, 5002, 5009, 5023, 5031, 5057 (Å)).

Electrical measurements on 4H-SiC pn-junctions (Fig. 6) were carried out, demonstrating that the pn-junction generated with few fast neutrons has in forward direction below the built-in potential a very low current density. The sample with a higher applied fluence of fast neutrons shows after annealing at 1500 °C a comparably low forward current density even above the built-in potential. After annealing at 1600 °C there is no current flow beneath the built-in potential within the detection limit.

4. Discussion

After irradiation with thermal neutrons the SiC samples are expected to have numerous defects of

Fig. 6. Current density over voltage in forward direction for samples with equal net doping but with different applied fluences of fast neutrons and different annealing temperatures: (a) $8 \times 10^{16} \text{ cm}^{-2}$ fast neutrons and 1600°C , (b) $5 \times 10^{15} \text{ cm}^{-2}$ and 1500°C , (c) $8 \times 10^{16} \text{ cm}^{-2}$ and 1500°C .

different nature. Applying thermal energy with different annealing temperatures the SiC becomes the chance to reorganize the defects in terms of the formation energies of single defects. This process ends with a nearly ideal structure and with some residual complex defect structures. In this sense, it is not surprising that one gets first a big zoo of lines from LTPL investigations which end up in the D_1 -defect above 1000°C . But it is amazing that SiC, praised to show long time stability up to 700°C [10,11], obviously begins to recover defects at much lower temperatures, if radiation defects are previously introduced.

Additionally we found pn-junctions with nearly ideal I - V curves in forward direction after annealing at 1600°C . After an annealing step of 1400°C with the

applied fluence of fast neutrons of $8 \times 10^{16} \text{ cm}^{-2}$ the pn-junction is not created yet. After 1500°C annealing the comparison of samples with applied fluences of fast neutrons which differ by a factor of 16 show a big difference in forward direction although the fast fluence is just a factor 2×10^{-3} of the thermal fluence necessary for doping.

Acknowledgements

We thank the irradiation groups of the FRG and the FRJ and the BER-reactors at the GKSS, KFA, HMI in Geesthacht, Jülich, Berlin for good cooperation. Further we thank Dr. K.P. Frohmader and Mr. Wadehn for their support with photolithography.

Characterization of deep centers in bulk n-type 4H–SiC

Z.-Q. Fang^{a,b}, D.C. Look^{a,b}, A. Saxler^a, W.C. Mitchel^{a,*}

^a Air Force Research Laboratory, AFRL/MLPS, W-PAFB, 3005 P. St. Rm243, OH 45433-7707, USA

Abstract

Nitrogen-related shallow centers and defect- and impurity-related deep centers in nitrogen doped bulk n-type 4H–SiC were characterized by high temperature Hall effect and deep level transient spectroscopy (DLTS) measurements. Two nitrogen centers at $E_c - 0.048$ and -0.098 eV, with a concentration close to each other, and a poorly resolved deep donor level, with activation energy of 0.58 eV, were found by fitting the Hall-effect data. A dominant DLTS deep center is observed at $E_c - 0.61 - 0.63$ eV due to electric field effect, with a concentration of $\sim 1.2 \times 10^{15} \text{ cm}^{-3}$. The center is believed to be the Z_1 center (also called $Z_1/Z_2(4H)$), which is often observed in as-grown and implanted or irradiated 4H–SiC epilayers and is speculated to be a vacancy-type defect. Correlation between the Hall effect deep donor and Z_1 suggests that Z_1 is donor-like. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Bulk 4H–SiC; Nitrogen levels; Intrinsic and extrinsic defects; DLTS

1. Introduction

Silicon carbide (SiC) is of interest for high-temperature, high-power, and high-frequency devices. Besides shallow dopants, intrinsic and extrinsic defects are present in SiC, giving rise to deep centers in the band gap. These deep centers may act as electron and hole traps or recombination centers, and affect the performance of devices. Electrical data obtained mainly from deep level transient spectroscopy (DLTS) studies on intrinsic deep centers and extrinsic deep centers in the 3C-, 4H-, and 6H-SiC polytypes have been well reviewed [1,2]. Most of the materials mentioned in the reviews are epilayers, grown by chemical vapor deposition (CVD). It is desirable to study deep centers in the substrates as well and to understand their origins. In this study, Schottky barrier diodes (SBDs) made on a bulk n-type 4H–SiC sample were characterized by capacitance–voltage ($C-V$), DLTS measurements, and temperature dependent Hall effect (TDH) measurements were

performed on an adjacent sample. From fitting Hall-effect data, two nitrogen related centers at near $E_c - 0.05$ and -0.1 eV, and a poorly resolved deep donor level with activation energy of 0.58 eV can be revealed. A dominant DLTS deep center at $E_c - 0.61 - 0.63$ eV, with a concentration of $\sim 1.2 \times 10^{15} \text{ cm}^{-3}$, was found and is believed to be related to the intrinsic defect-related Z_1 center (also referred to as $Z_1/Z_2(4H)$). This is believed to be the first correlation between DLTS and Hall effect for a deep level in SiC. Also, the correlation suggest that, contrary to previous reports, the Z_1 level is donor-like.

2. Experimental and results

The samples used in this study were cut from an n-type 4H–SiC boule, grown along the c -axis by physical vapor transport technique at Cree Inc. A square sample approximately 0.75 cm on a side was cut for resistivity and Hall effect measurements. Contacts were Au on Ni/Cr annealed at 925°C. For the SBD sample, Schottky contacts were unannealed Al dots with diameters of 500 μm , which were surrounded by a large area Al ohmic contact. A Bio-Rad DL4600 system with a 100 mV test signal at 1 MHz was used to take $C-V$ and DLTS data.

*Corresponding author. Tel.: +1-937-255-4474; fax: +1-937-255-4913.

E-mail address: william.mitchel@wpafb.af.mil (W.C. Mitchel).

To determine the activation energy E_T of deep centers, the DLTS spectra were taken at different rate windows, from 4 to 200 s⁻¹, and were analyzed by the standard Arrhenius technique.

TDH measurements from 40 to 1000 K were made at a magnetic field of 5 KG. The electron concentration is plotted as a function of the reciprocal temperature in Fig. 1. From a least-squares fit of the charge neutrality equation, we are able to determine nitrogen donor activation energies and concentrations. The activation energies of nitrogen donors, N_h and N_c , substituting at hexagonal and cubic lattice sites, were found to be 0.048 and 0.098 eV, respectively. The corresponding nitrogen donor concentrations are 4.7×10^{16} and 4.3×10^{16} cm⁻³, with a ratio of concentrations (N_h/N_c) close to unity, which is expected for 4H-SiC [3]. In addition to two shallow nitrogen levels, a deep level with a concentration in the 10^{15} – 10^{16} cm⁻³ range and an activation energy of 0.58 eV can be poorly resolved.

Al-Schottky diodes show low leakage currents (~ 400 nA) at a reverse bias of -10 V, which enabled us to perform measurements at higher reverse biases and to observe electric-field effect on deep centers. To determine the near-surface carrier concentrations, we measured C - V characteristics at different temperatures, and carried out $1/C^2$ vs. V analyses. Plots of $1/C^2$ vs. V , obtained at temperatures of 200–400 K, are very good straight lines. Assuming a dielectric constant of 9.7 for 4H-SiC, the carrier concentrations at 200, 300, and 400 K are 4.1 , 4.2 , and 4.3×10^{16} cm⁻³, respectively. As compared to Hall-effect data, C - V results show a weaker temperature dependence, which we do not understand at present. From the intercept at $1/C^2 = 0$, 1.25 V at 300 K, the barrier height of Al on the n-type 4H-SiC was determined to be 1.43 eV. A typical DLTS

spectrum, measured at a reverse bias (V_b) of -9 V, a forward filling pulse height (V_f) of 0 V, and a filling pulse width (W_f) of 1 ms, is shown in Fig. 2. We see a dominant trap C at around room temperature, and some other traps at high temperatures (A and B) and at low temperatures (trap D and unsolved traps E, and F). The concentration of trap C can be as high as 1×10^{15} cm⁻³, while the concentrations of other traps are in low 10^{14} cm⁻³ range. Arrhenius plots of T^2/e_n vs. $10^3/T$ for traps A, B, C, and D are presented in Fig. 3, from which their activation energies were determined to be 0.89, 0.74, 0.61, and 0.40 eV, respectively. To investigate the electric-field effect on the dominant center, we performed DLTS measurements in two different ways. One set of spectra was measured by varying V_f , but keeping V_b (-9.0 V) unchanged; and the other by changing V_b , but keeping V_f constant at 0 V. The resultant DLTS spectra, measured as a function of V_f and V_b , are shown in Figs. 4a and b, respectively. In two cases, we see a peak shift of the dominant center to lower temperatures, as V_f increases from -6 to $+1$ V (Fig. 4a), and as V_b changes from -2 to -9 V (Fig. 4b). Both shifts

Fig. 2. Typical DLTS spectrum measured at the temperature range from 150 to 420 K.

Fig. 1. Carrier concentration vs. inverse temperature from Hall effect. Solid line is fit to charge neutrality equation for three donor levels. Inset: expanded view of high temperature data showing presence of deep level after full activation of the nitrogen levels.

Fig. 3. Arrhenius plots of T^2/e_n for deep centers observed in the bulk 4H-SiC sample.

Fig. 4. DLTS spectra measured (a) as a function of V_f and keeping V_b ($-9V$) unchanged; and (b) as a function of V_b and keeping V_f ($0V$) constant.

correspond to an increase of average electric field in the depletion region. Under a high electric field, a trap peak should shift to lower temperatures due to the effective lowering of the potential well. The activation energies of the dominant trap were determined to be 0.61 eV for the high average field case, and 0.63 eV for the low average field case. The average electric fields are $3.5 \times 10^5\text{ V cm}^{-1}$ for the former case and $<1 \times 10^5\text{ V cm}^{-1}$ for the latter case.

3. Discussion

A center at $E_c - (0.63\text{--}0.68)\text{ eV}$, named the Z_1 center, has been reported in previous DLTS studies on 4H-SiC epilayers [1,2]. This defect has activation energy similar to that of a double-peak trap in bulk 6H-SiC, named the Z_1/Z_2 center, discovered by Zhang et al. [4]. In high quality CVD-grown 4H-SiC epilayers, Kimoto et al. [5] revealed that the Z_1 center was the only residual defect with concentrations in the 10^{13} cm^{-3} range. While in 4H-SiC epilayers, Lebedev et al. [6] reported that the Z_1 concentration was shown to fall with decreasing net donor concentration and to be lower in layers with a high dislocation density. Here, in this study with n-type bulk 4H-SiC, we found a dominant trap with activation energy similar to that of Z_1 center and with a higher concentration compared to that in the epilayers. By trap fingerprint comparison (see Fig. 3), we believe that the dominant trap here is due to the Z_1 center. To understand the nature of the Z_1 center, many ion-implantation and irradiation studies have been performed [2]. It has been demonstrated that the Z_1 center, induced by H^+ -implantation, is acceptor-like and is

thermally stable up to 2015°C [7]. However, a recent report indicated that Z_1 (or $Z_{1/2}$) centers, generated by 2.9 MeV H^+ -irradiation, show a concentration drop at annealing temperature of 1300°C [8]. A current consensus is that the Z_1 center is related to a vacancy-type defect, however, whether it is a C-Si nearest-neighbor divacancy [9] or a C vacancy [10] is still an open question. The conclusion of acceptor-like nature of Z_1 was deduced from double DLTS investigations, where the peak position of Z_1 showed no change with varying electric field [7]. This observation is in contrast with what we found in this study. The fact that the activation energy of trap C shows a clear dependence on electric field implies that the Z_1 center might consist of two components, each with an opposite charge state. The fact that the Z_1 center is the only deep center observed in this material with concentration high enough to correspond to the deep donor seen in Hall effect experiments suggests that the two experiments are observing the same defect level. This suggests that Z_1 is donor-like, since an acceptor-like defect would not be observed in Hall effect in n-type material.

Transition metals produce electrically active deep centers in the band gap of semiconductors. In an early study of SiC substrates, V, Cr, Fe and Ti were found in high concentration compared to other residual impurities [11]. By V^+ - and Ti^+ -implantation [2], and Cr-isotope doping [12], the deep centers, induced by these metals in 4H-SiC epilayers, were characterized by DLTS. Vanadium is an amphoteric impurity, leading to formation of both donor and acceptor levels. An acceptor-like deep center V_1/V_2 at $E_c - (0.88\text{--}0.97)\text{ eV}$ in V^+ -implanted 4H-SiC epilayers was reported [2]. Recently, V doping, known as a compensating donor,

was demonstrated to be useful in growth of semi-insulating SiC crystals [13]. Three Cr-related deep centers at $E_c-0.15$, -0.18 and -0.74 eV were reported [12]. By comparing with these literature data, two deep traps found in this study, A at $E_c-0.89$ eV and B at $E_c-0.74$ eV, might be due to residual impurities V and Cr, respectively. The trap D and unsolved traps, E and F, at or below $E_c-0.40$ eV, might be related to impurity-defect complexes or simply intrinsic defects, as suggested in Ref. [2].

4. Summary

Nitrogen-related centers and deep centers in nitrogen doped bulk 4H-SiC were characterized by TDH and DLTS measurements. Two nitrogen-related centers, each with a concentration of $\sim 4.5 \times 10^{16} \text{ cm}^{-3}$, were found at $E_c-0.048$ eV and $E_c-0.098$ eV, respectively. A poorly resolved deep center with activation energy of 0.58 eV was also revealed by the TDH measurement. A dominant DLTS center in the material is at $E_c-0.61-0.63$ eV and with a concentration of $\sim 1.2 \times 10^{15} \text{ cm}^{-3}$, which shows a clear electric field effect and is believed to be an intrinsic defect-related Z_1 center. The Z_1 center is believed to be donor-like. Two deeper centers, observed at $E_c-0.74$ and -0.89 eV and with concentrations in the low- 10^{14} cm^{-3} range, might be due to residual impurities Cr and V, respectively. Other centers, found at or below $E_c-0.40$ eV and with concentrations also in the low 10^{14} cm^{-3} range, are thought to be associated with defect-impurity complexes.

Abstract

Beryllium was implanted into both n- and p-type 6H-SiC and the samples were subsequently annealed at 1600 °C. Photoluminescence (PL) measurements were performed and PL lines at 420 and 472 nm were observed. The PL lines at around 420 nm have been detected from various ion implanted SiC samples and have been attributed to transitions involving some implantation induced intrinsic defect labeled as D_{II}. The present observation of the PL lines at 420 nm from Be implanted 6H-SiC supports the intrinsic model that D_{II} might be a carbon-di-interstitial defect. The lines at 472 nm labeled as D_I in the PL spectra have previously been identified as divacancy defect (V_{Si} – V_C). We note that it was suggested that the electron traps labeled Z₁/Z₂ observed in deep level transient spectroscopy (DLTS) were due to the same divacancy defect. In our experiments, while the D_I series PL lines are prominent, DLTS results from the same samples show no Z₁/Z₂ related peaks. The PL and DLTS results seem to be against the possibility that Z₁/Z₂ arise from the same defect. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Ion implantation is an important process for silicon carbide (SiC) device technology as it allows selective doping of n- and p-type dopants. The detection and identification of dopants and implantation induced defects is one of the major tasks in order to control the characteristics of SiC material for device design and fabrication. Together with the electrical methods such as the Hall effect and deep level transient spectroscopy (DLTS), the optical photoluminescence (PL) method is powerful and successful in this kind of investigation.

SiC doped with aluminum (Al), gallium (Ga), and boron (B), etc. has been intensively investigated by using electrical and optical measurement methods in the past

[1–6]. Recently, beryllium (Be) was successfully applied in the fabrication of SiC diodes [7,8]. A better forward characteristics was obtained in comparison with Al and B implanted pn junctions [7]. Electrical measurements such as current–voltage, DLTS, Hall effect on Be implanted or diffused 6H-SiC have been reported [7–9]. However, data from optical measurement like PL are relatively scarce. Be has been reported to be an effective luminescence activator when diffused into 6H-SiC [10]. Further, more than three series of PL lines were detected and are thought to be related to Be implantation [7]. Detailed assignment concerning the PL lines from either Be dopant or implantation induced intrinsic defects is still lacking. In the present work, Be was implanted into both n- and p-type 6H-SiC with both high and low doses at room temperature followed by annealing at 1600 °C. In this article, we report PL observations of the Be implantation induced intrinsic defects in 6H-SiC samples.

2. Experiment

The SiC samples used in our experiment are commercially available epiwafers from CREE Research Inc. For the starting n-type 6H-SiC (0001), a 10- μm -thick nitrogen doped epilayer was grown on n^+ -type 6H-SiC substrate with chemical vapor deposition (CVD). The nitrogen (N) donor concentrations were 1×10^{16} and $8 \times 10^{17} \text{ cm}^{-3}$ in the epilayer and the substrate, respectively. For the p-type 6H-SiC (0001), there is a 5- μm -thick Al doped epilayer grown on p^+ -type 6H-SiC substrate. The Al acceptor concentrations were 1×10^{16} and $1 \times 10^{18} \text{ cm}^{-3}$ in the epilayer and substrate, respectively. 50–590 keV Be implantation was carried out at room temperature to obtain a box-shaped profile with a mean concentration of Be about $1 \times 10^{19} \text{ cm}^{-3}$ (termed “high-dose Be” implantation hereafter) both into n- and p-type samples. To repair the implantation induced damage and activate the Be dopant, post-implantation annealing was performed in flowing argon gas at 1600°C for 1 min using a rapid thermal annealing (RTA) system.

For a comparison study, a lower Be concentration of about $1 \times 10^{18} \text{ cm}^{-3}$ (termed “low-dose Be” implantation hereafter) were also implanted into both n- and p-type 6H-SiC samples. The same multiple energy implantation schedule as for the high-dose Be implantation was employed. RTA was performed at 1600°C for 30 s under similar conditions as stated previously. Table 1 presents an overview of the preparation parameters for the different samples.

For PL measurements, the excitation was done with a He–Cd laser operating at a wavelength of 325 nm. PL measurement was performed at temperature $T = 3.5 \text{ K}$. The PL emission was analyzed with a SPEX750 M single gratings (1200 lines/mm) monochrometer and detected with a Hamamatsu R928 photomultiplier.

3. Results and discussion

A comparison of the PL spectra at 3.5 K of the high- and low-dose Be implanted n- and p-type 6H-SiC samples is shown in Fig. 1. The lines labeled by $4N_0$ from n-type samples are related to bound exciton

recombination at a four-particle neutral nitrogen donor at the three inequivalent lattice sites. On the other hand, the PL lines labeled by $4Al_0$ from p-type samples are attributed to the bound exciton recombination at a four-particle neutral Al acceptor lattice sites of the 6H-SiC unit cell. Both groups of PL lines have been intensively investigated and clearly identified in previous literatures [1,2], and are commonly used as indicators for the presence of N and Al dopants in SiC, respectively.

The PL peak at around 420 nm is detected in both n- and p-type Be implanted samples. At higher spectral resolution, the 420 nm peak can be resolved into at least two lines at 420.3 and 420.5 nm. Compared with $4N_0$ or $4Al_0$, the PL line intensity are stronger in high-dose Be implanted samples, indicating the dependence on the ion implantation doses. It should be noted that there is a weak line relative to $4N_0$ at 420.3 nm in the PL spectra of the control samples as also reported in most literatures [1,2], which was labeled by I_{77} at the same wavelength. The I_{77} line was identified as a recombination at a free exciton (FE). It is a good indicator of

Fig. 1. PL spectra of Be implanted n- and p-type 6H-SiC. (1) Low-dose Be implanted n-type 6H-SiC; (2) High-dose Be implanted n-type 6H-SiC; (3) Low-dose Be implanted p-type 6H-SiC; (4) High-dose Be implanted p-type 6H-SiC. Implantation was at room temperature and annealing was carried out at 1600°C.

Table 1

Preparation conditions of various Be implanted n- and p-type 6H-SiC samples

Sample number	1	2	3	4
Sample type before implantation	n-type	n-type	p-type	p-type
Sample terms as mentioned in the text	Low-dose Be n-type	High-dose Be n-type	Low-dose Be p-type	High-dose Be p-type
Mean con. of Be (atoms/ cm^{-3})	$\sim 1 \times 10^{18}$	$\sim 1 \times 10^{19}$	$\sim 1 \times 10^{18}$	$\sim 1 \times 10^{19}$
Duration of annealing at 1600°C	30 s	1 min	30 s	1 min

crystal quality [11]. However, in the present Be implantation experiment, the PL lines at 420.3 and 420.5 nm which depend on the ion doses should be attributed to Be implantation induced new PL activator rather than the I_{77} free exciton with the same wavelength.

Recently, based on the observation of the same spectrum in different ion implanted 6H-SiC samples, the PL lines were proposed to be due to an intrinsic defect labeled as D_{II} induced by ion implantation. Moreover, together with the observation of high energy localized modes beyond the lattice limit of 120 meV, the D_{II} center was suggested to be carbon-di-interstitial [6]. The present PL spectrum of Be implanted 6H-SiC gives further information and strongly supports the intrinsic modes of D_{II} center induced by ion implantation. Subsequently, the high intensity of 420.3 and 420.5 nm lines from high-dose Be implantation samples is expected since high-dose ion implantation will produce more such defect centers.

The PL emission lines labeled as L_1 , L_2 , and L_3 at around 472 nm are prominent in the PL spectrum as shown in Fig. 1. These lines called D_I -center were regularly found in 6H-SiC after implantation of ions, electrons, etc. and subsequent annealing at $T > 900^\circ\text{C}$. [1,2] Although the microscopic structure of this D_I -center is still a matter for discussion, there is a mounting evidence that it is due to the $V_{Si}-V_C$ divacancy [12]. On the other hand, it should be pointed out that deep levels at $E_c-0.62/0.72$ eV labeled as Z_1/Z_2 in DLTS spectra have been reported and speculated as the same as divacancy ($V_{Si}-V_C$) on inequivalent lattice sites in as-grown, high-energy particle irradiated or ion implanted SiC [13,14]. Zhang et al. demonstrated that the Z_1/Z_2 centers can be generated either by irradiation with high-energy electrons or by ion implantation and that it is thermally stable up to at least 1700°C [13]. However, recently the identification was questioned based on the studies of thermal annealing behaviors of Z_1/Z_2 that almost disappear with post-irradiation annealing temperature below 1000°C [14,15]. In the present experiment, we have conducted DLTS study of the identical samples. Fig. 2 displays the DLTS spectrum of the low-dose Be implanted 6H-SiC with post-implantation annealing at 1600°C . It can be seen that no obvious DLTS peaks related to Z_1/Z_2 was observed. However, as shown in Fig. 1, the L_1 , L_2 and L_3 lines of D_I -center are dominant in the PL spectra from all samples. These results are consistent with those observed for helium ion implanted n-type 6H-SiC using DLTS and PL techniques by Frank et al. [14] and strongly support the argument against that of Z_1/Z_2 and D_I -center was due to the same defect.

The microstructure of Z_1/Z_2 is still a matter for discussion. Aboelfotoch et al. reported that the two levels at $E_c-0.62/0.64$ eV which were associated with the

Fig. 2. DLTS spectrum of beryllium (low-dose Be) implanted n-type 6H-SiC with subsequent annealing at 1600°C .

Z_1/Z_2 centers in electron-irradiated n-type 6H-SiC were annealed out at around 850°C [16]. Based on the thermal annealing behaviors the two levels were assigned to be a defect involving a silicon vacancy occupying inequivalent sites in the 6H-SiC lattices.

Abstract

Photoluminescence (PL), thermally stimulated luminescence (TSL) and their photo-excitation spectra in hexagonal type SiC were studied between the temperatures of 5 and 300 K. Titanium related TSL glow peak is observed close to 140 K in compensated crystals 6H–SiC with corresponding thermal ionisation energy of a trap close to 170 meV. The spectral distribution of TSL has a maximum at 1.8 eV in 6H–SiC and 2.43 eV in 4H–SiC. A specific structure in the photo-excitation spectrum of PL close to the exciton gap $E_{\text{ex}} = 3.023$ eV is revealed, exclusively in 6H–SiC material. This indicates an essential role of excitons in the resonance energy transfer to the Ti-related centers in silicon carbide. The results are discussed in a model of isoelectronic centers composed of either individual Ti atoms or Ti–N pair representing a complex of the electronic trap and recombination center. © 2001 Elsevier Science B.V. Keywords: Defect state; Silicon carbide; Transition metals; Titanium

1. Introduction

In the photoluminescence (PL) spectrum of silicon carbide (SiC) a broad ‘green’ band with maximum at 2.43 eV is observed [1]. This band is accompanied with a set of narrow lines on the short-wavelength shoulder at low temperatures. These lines have been named as ABC-spectrum and has a relevance to Ti impurity. The PL spectrum of the green band is similar in SiC polytypes while the ABC-spectrum is various. The origin of the green luminescence in 6H–SiC has been a subject of numerous investigations. Three narrow zero-phonon lines (ZPLs) A_0 , B_0 and C_0 were interpreted as bound exciton recombination at a neutral isoelectronic center [2], which was finally attributed to Ti impurity [3]. Until now the interpretation of Ti-related PL spectrum is controversial. The most comprehensive results on the electronic structure of luminescence center can be obtained with the methods of magnetic resonance, specifically optically detected magnetic resonance

(ODMR). Initial identification of the Ti as isolated impurity atom was performed using ODMR [4]. EPR identification of titanium–nitrogen pairs (Ti–N)⁰ in 6H–SiC was made in Ref. [5]. In these papers, authors found a correlation between excited triplet states [4] or three signals with the spin $\frac{1}{2}$ [5] and A_0 , B_0 , and C_0 lines of luminescence spectrum.

We report on PL, thermally stimulated luminescence (TSL) and photoluminescence excitation (PLE) study in 6H– and 4H–SiC crystals. PLE spectroscopy is applied to reveal details of electronic energy transfer within complex PL center.

2. Experiment

Applying the procedure of a selective photoexcitation, we used two grating spectrometers, one of them coupled with xenon or tungsten lamp was used as an excitation source and the second spectrometer coupled to photomultiplier served for PL spectroscopy. The system recorded PL and PLE spectra with a resolution of 0.015 and 0.04 nm, respectively. Combining polarization of the excitation light and the luminescence, we

*Corresponding author. Tel.: +1-813-974-2031; fax: +1-813-974-3610.

E-mail address: ostapenko@eng.usf.edu (S. Ostapenko).

with the maximum at 2.43 eV (Fig. 2). Spectral distributions of PL and TSL are shown in the insert.

Performed experiments, especially on selective photo-excitation, revealed details of processes of the excitation and luminescence in Ti-related centers in SiC. PL spectra assigned as A and C, can be connected with different hole transitions in the bound exciton state of the same center (A-center) involving an isolated Ti atom. Such excitons are the excited states of the pseudo ion Ti (d^n) if a Colomby coupled hole is formed from Bloch waves of the valence band near the charged Ti (d^{n+1}) ion (an excited state of the type of an ‘acceptor exciton’— $[d^{n+1} \times h]$ in denotation of Ref. [6]).

We established that PLE series showed by dotted line in Fig. 1c as three maxima at 2.911, 2.930, and 2.949 eV is connected with excitation of C-spectra PL. Two other PLE series with identical energy interval of 19 meV have maxima at 2.868, 2.8865, 2.905, 2.9245, 2.944 eV (noted by single arrows) and 2.861, 2.880, 2.900 eV. These lines can be connected with the excitation of A spectrum. The head lines of these series at 2.911, and 2.868, 2.861 eV correspond the excitation of electron from different valence bands- Γ_7 (P_7) and Γ_9 , respectively, into the

Fig. 1. PL spectra of elementary series composing green PL band in 6H-SiC:Ti (left). Low-energy region of PLE spectrum measured of the maximum of these band (right). Polarisation of excitation is $E_E \perp c$, polarisation of luminescence is performed—in two components $E_L \perp c$ and $E_L \parallel c$. c -direction of the crystallographic axis. Maximum in PLE spectra taken for $E_L \parallel c$ turned out to be connected to the excitation of the B spectrum, while the maxima marked by dotted lines in this spectrum taken for $E_L \perp c$ are connected with excitation of C-spectrum.

Fig. 2. Low-temperature parts of TSL glow curves of 6H –(solid and dotted lines) and 4H-(dashed lines) SiC corresponds to (a) n-type and (b) p-type conductivity. Dotted curve represents TSL after emptying of the nitrogen traps. In insert the spectral distribution of PL and TSL (circles).

d-orbitals of Ti (d''). Indeed, these head lines are separated by 43–50 meV which is close to 53 meV $\Gamma_7 - \Gamma_9$ crystal field splitting Δ_{CR} in 6H-SiC. The energy separation of two PLE series 2868–2861 = 7 meV is very close to spin-orbit splitting of the Γ_9 valence band ($\Delta_{so} = 7.1$ meV [4]). Differences in the vibration structure of C and A luminescence spectra can be explained by different coupling of holes [4]. In such interpretation, vibration modes dominating in the PL spectra are determined by the symmetry of the hole wave function in the final state of optical transitions within A-center. Specifically 24.4 meV phonon replica in C spectrum shows a vibration structure of final states of this center with the hole corresponding to the $A_1(P_z)$ valence band symmetry. We suggest that three equally separated at 19 meV maxima in PLE spectrum at 2.947, 2.966, and 2.982 eV correspond to a softer vibration mode of electronic excited state in A center.

The continuous background under the structure of the discussed PLE spectrum is presumably a spectral distribution of the photo-excitation cross section of electrons (d''/d^{n+1}) into d-orbitals of Ti impurity. The long-wavelength cut-off in this background at the energy at about 2.90 eV represents the level of Ti-related deep acceptor A^0/A^- above the valence band. This acceptor level links to the electron trap with energy $E_{trap} \approx 170$ meV estimated from TSL glow peak at the temperature 140 K (Fig. 2b). We suggest that a complex of the ionized $(Ti^0-N^+)^+$ pair is involved in PL and TSL. Indeed, ABC-spectra in 6H-SiC is observed only in p-type crystals, but EPR of $(Ti-N)$ pair-only in n-type. The photo-EPR spectra of a neutral $(Ti-N^+)^0$ were observed in highly compensated n-type SiC under broad band illumination [5]. The energy position of the Ti-related glow peak in 6H-SiC is consistent with the Ref. [5] where the energy level of $(Ti-N)^0$ pairs attributed to the level of nitrogen donor in this polytype.

In our study the glow peak with the maximum near 110 K (Fig. 2a and b) is connected with nitrogen trap with activation energy of 140 meV. A similar model of isoelectronic complex composed of deep acceptor and an electron trap was developed in GaP:N [7].

In 4H-polytype only one glow maximum in the region of 77–120 K is observed both in n-type and p-type Ti-doped crystals. The initial temperature of photo-excitation has to be reduced below than 77 K [8] to correctly estimate a depth of corresponding trap. We noticed the coincidence of PL and TSL spectra, which indicate a difference in the depth of the trap and level of excited state of Ti-related center in 4H-SiC.

Besides the band-to-band excitation, there are two possibilities of the photoexcitation of A-spectrum: (1) direct excitation to the lowest excited state of the A-center and (2) indirect excitation-to the level of deep acceptor, d''/d^{n+1} . We found an efficient PL excitation through the α -maximum in PLE spectra of 6H-SiC (see Fig. 1a). This α -maximum is location in the region of the excitonic band gap, for this polytype $E_{gx} = 3.023$ eV. It is important, that in PLE of 4H-SiC the structure in the region of E_{gx} of this polytype (3.265 eV) is also exhibited however excitation efficiency is much lower. Individual lines in PLE spectra in the region of photon energies corresponding to the values of E_{gx} in both polytypes can be explained as free exciton scattering on titanium atoms. Indeed, substitution Ti, which is an isoelectronic impurity in SiC, can substantially change the exciton quasi-momentum by elastic scattering due to a short-range potential of Ti-center.

The PLE efficiency of A_0 line in 6H-SiC is of the order of magnitude higher in the α -maximum than under band-to-band excitation [9]. This can be explained by coincidence of the free exciton energy ($E_{gx} = 3.023 \pm 0.01$ eV) and the energy of the excited electronic state of the 'A-center' in 6H-SiC polytype

only. A mechanism of the resonance energy transfer from the free excitons to A-center is involved. The high efficiency of non-radiative energy transfer in isoelectronic impurities of rare-earth metals in II–VI compounds was shown in [10]. The spectral structure in PLE spectrum of the A_0 line in the 3.023–3.150 eV region represents electron transitions at the exciton states with the emission of phonons [11] and proved the participation of the free excitons in the excitation process of A-center.

A direct evidence on existence of (Ti–N) pair was presented by EPR in Refs. [5,12]. A strong β maximum at 3.003 eV (see Fig. 1b) in PLE spectra of B_0 line in the region of ZPL of the excitons bounded to the neutral N donors ('D₀X' complexes in terms of Ref. [2]), can be attributed to the (Ti–N) pair. Cross relaxation study between the excited triplet states of titanium and the ground state of nitrogen donors [13], also supports this identification. This study demonstrates an essential role of excitons in the resonance energy transfer to Ti-related centers in silicon carbide.

Abstract

Beryllium has been implanted into both n- and p-type 6H-silicon carbide (SiC) with high and low doses. Upon subsequent annealing at 1600°C, Beryllium implantation induced deep levels have been investigated by deep level transient spectroscopy. Five deep level centers labeled as BE1–BE5 were detected from high dose beryllium implantation produced pn junctions. A comparative study of low dose beryllium implanted n-type 6H-SiC sample proved that the BE1–BE3 centers were electron traps located at 0.34, 0.44, and 0.53 eV, respectively below the conduction band edge. At the same time, the BE4 and BE5 centers were found to be hole traps situated at 0.64 and 0.73 eV, respectively, above the valence band edge. In the case of beryllium implanted p-type 6H-SiC, four hole traps labeled as BEP1, BEP2, BEP3, and BEP4 have been observed. The observed levels of the hole traps BEP1 and BEP2 at 0.41 and 0.60 eV, respectively, above the valence band agree well with those from the Hall effect data from material with beryllium acting as doubly charged acceptor. The other hole traps BEP3 and BEP4 at 0.76 and 0.88 eV, above the valence band, respectively, are thought to be due to beryllium implantation induced defects or complexes. © 2001 Elsevier Science B.V. 1. Introduction

Beryllium (Be) is known as a doubly charged acceptor in silicon carbide (SiC). The acceptor levels, 0.42 and 0.60 eV were determined at the first attempt by Hall measurements on 6H-SiC bulk material [1]. Recently, Be was successfully applied in the fabrication of SiC diodes. A better forward characteristic was obtained in comparison with pn junctions produced by boron (B) and aluminum (Al) implantation [2]. On the other hand, Be may also act as a donor in SiC when residing on the interstitial sites, although, the donor levels are not known [3]. However, the knowledge about the physics of the Be dopant in SiC is still very limited.

2. Experiment and results

The 6H-SiC used in this work was purchased from CREE Research Inc. in the form of 10 µm thick nitrogen doped (0001) oriented epilayers grown on n⁺ type SiC substrates. The nitrogen donor concentrations were 1×10^{16} and $8 \times 10^{17} \text{ cm}^{-3}$ in the epilayer and the substrate, respectively. 50–590 keV Be implantation (termed as high-dose Be implantation hereafter) was carried out to obtain a box-shaped profile with a mean Be concentration of about $1 \times 10^{19} \text{ cm}^{-3}$. To repair the implantation induced damage and to electrically activate the dopant, samples were annealed in flowing argon gas at 1600°C for 1 min using a rapid thermal annealing (RTA) system.

For a comparative study, 6H-SiC samples with a lower Be concentration of about $1 \times 10^{18} \text{ cm}^{-3}$ (termed

Fig. 1. DLTS spectrum recorded on the high-dose Be implanted 6H-SiC pn junction samples.

Fig. 2. DLTS spectrum recorded on the low-dose Be implanted n-type 6H-SiC.

low-dose Be implantation hereafter) were implanted into n- and p-type 6H-SiC samples, respectively. The same multiple energy implantation schedule as for the high-dose implantation was applied. RTA was performed at 1600°C for 30 s under similar conditions as stated above.

A typical majority carrier spectrum is shown in Fig. 1. Five peaks labeled as BE1, BE2, BE3, BE4, and BE5 were observed in the deep level transient spectroscopy (DLTS) measurement temperature range of 100–450 K. To check whether these traps were induced by Be implantation, a control measurement was performed on a schottky contact on unimplanted n-type epilayer. None of the above traps were detected indicating that all the traps described above were induced by the Be implantation process.

It should be pointed out that for the high-dose Be implanted samples, the Hall measurements indicated a weak p-type conduction in the Be implanted layer, the free hole concentration in the p-region and the free electron concentration in the n-region of the pn junction were of the same order of magnitude. Under reverse bias conditions it is thus reasonable to expect that the width of the depletion layer in the p-region is comparable with the one in the n-region. Consequently, the observed DLTS peaks may arise either from hole traps in the p-region or electron traps in the n-region of the pn junction. A definitive assignment is not possible without further information about these traps. Therefore, the n-type low-dose Be implanted samples was additionally prepared. A typical DLTS spectrum of these samples is shown in Fig. 2, all the three levels are attributed to electron traps. Since the energy level and the temperature position of the DLTS peak BE1' (see Fig. 2) are in excellent agreement with those of BE1 (see Fig. 1), BE1'

Fig. 3. DLTS spectrum recorded on the low-dose Be implanted p-type 6H-SiC.

and BE1 are attributed to the same defect center. Likewise BE2' and BE3' are assumed to be related to the overlapping peaks BE2 and BE3 because of their very similar energy levels. Hence, it is unambiguously clear that three (BE1, BE2, and BE3) of the five deep level traps observed in the high-dose Be implanted sample are electron traps arising from the n-region while the other traps (BE4, BE5) are assumed to be hole traps from the p-region of the pn junction.

Fig. 3 shows the DLTS spectrum of Be implanted p-type 6H-SiC. Four deep levels labeled as BEP1, BEP2, BEP3, and BEP4 as hole traps are observed in a

Table 1

Energy levels E_T , capture cross sections σ_T , and concentrations N_T of the deep level traps determined using DLTS data of the high- and low-dose Be implanted 6H-SiC samples

	E_T (eV)	σ_T (cm ²)	N_T (cm ⁻³)
BE1	$E_C - 0.34$	$\sim 10^{13}$	$4\text{--}10 \times 10^{13}$
BE2	$E_C - 0.44$	$\sim 10^{14}$	$1\text{--}6 \times 10^{13}$
BE3	$E_C - 0.53$	$\sim 10^{14}$	$3\text{--}8 \times 10^{13}$
BE4	$E_V + 0.64$	$\sim 10^{16}$	$4\text{--}6 \times 10^{14}$
BE5	$E_V + 0.73$	$\sim 10^{16}$	$2\text{--}7 \times 10^{14}$
BEP1	$E_V + 0.41$	$\sim 10^{13}$	$4\text{--}10 \times 10^{14}$
BEP2	$E_V + 0.60$	$\sim 10^{15}$	$1\text{--}6 \times 10^{13}$
BEP3	$E_V + 0.76$	$\sim 10^{16}$	$1\text{--}3 \times 10^{13}$
BEP4	$E_V + 0.88$	$\sim 10^{17}$	$2\text{--}6 \times 10^{13}$

temperature range of 180–450 K. At temperatures below $T = 180$ K, the DLTS peak shape is strongly affected by the increased series resistance due to the free carrier freeze-out of the shallow Al dopant. The energy levels, capture cross sections, and concentrations of the defect centers determined are summarized in Table 1.

3. Discussion

Recent DLTS studies on electron-irradiated [4–6] and deuterium-implanted [5] n-type 6H-SiC have demonstrated the existence of two overlapping levels at $E_C - 0.33$ and 0.34 eV that were designated as E_1 and E_2 , respectively. Our previous DLTS investigations on electron-irradiated 6H-SiC revealed several deep level traps. Two of them (labeled as ED_3 and ED_4) were attributed to the E_1/E_2 center [6]. The fact that the BE1 peak is so close in energy to those of the E_1/E_2 doublet is suggestive that the two are one and the same defect with the perturbations present on the center close to the pn junction perhaps causing the doublet to smear into a single peak. Such a view, however, meets with some difficulty when it is realized that the peak maximum temperatures of BE1 and ED_3 differ by 50 K and the calculated cross-section by two orders of magnitude. This makes it unlikely that BE1 and E_1/E_2 are the same defect.

An alternative explanation for BE1 is that it is associated with interstitial Be. It is known that Be may act as a donor when residing on interstitial positions [3]. Further, there is strong evidence indicating that Be diffuses via interstitial sites [3,7,8]. Since a deep diffusion tail into the epilayer is observed after RTA, there is definite evidence for fast interstitial diffusion of Be and thus by inference the related donor site [7,8]. It may tentatively be argued that Be is residing on an interstitial site that leads to the BE1 center. Clearly, further theoretical investigations will be necessary to test this possibility.

The trap BE3, the energy level of which has been determined as $E_C - 0.53$ eV, is similar to the defect level was previously found in electron irradiated 6H-SiC by several groups [4,5]. On the other hand, Dalibor et al. observed a trap labeled as ID_7 at $E_C - 0.50$ eV after vanadium as well as titanium implantation followed by an annealing process at 1700°C [9]. This defect level was ascribed to an implantation induced intrinsic defect center. Due to the different annealing behavior, the defect associated with the ID_7 center must be different from the one observed in electron irradiated material. We believe that the BE3 and ID_7 levels originate from the same defect, i.e., an intrinsic defect center induced by the implantation process. The peak BE2 in the DLTS spectrum is very weak and overlapped by the peak BE3, which limits the precision of the calculated parameters. Therefore, the question whether the trap BE2 is to be associated with an implantation induced intrinsic defect or a Be induced defect cannot be answered at present.

In the case of the low-dose Be implanted Al doped p-type 6H-SiC samples, the Fermi-level should mainly be controlled by the acceptor level of Al dopant. Therefore, the doubly charged states of Be may be observed in Be implanted p-type samples by using DLTS technique. The energy levels of BEP1 and BEP2, respectively at $E_V + 0.41$ and 0.60 eV determined from the current experiment are consistent with the Hall effect result determined in Be diffused 6H-SiC samples [1]. Thus, we can conclude that the BEP1 and BEP2 traps are attributed to the doubly charged states of substitutional Be acting as acceptor. On the other hand, the BE4 center located at $E_V + 0.64$ eV from the p-side of Be implanted pn junction may also arise from the second charge state of the Be acceptor. The different measurement techniques and purities of the samples are assumed to be responsible for the small discrepancy between the DLTS and the Hall result ($E_V + 0.60$ eV) reported in the past [1].

Considering the hole trap BEP3, energy level was determined to be 0.76 eV above the valence band. Though comprehensive investigations on intrinsic defects in p-type 6H-SiC are still lacking, a defect level labeled as H2 at a similar energy position was found in electron irradiated material by our group [10]. It was demonstrated that the defect associated with H2 anneals out at about 350°C . As stated earlier, the current Be implanted 6H-SiC samples were annealed at temperature $T = 1600^\circ\text{C}$, the different thermal annealing behaviors seem to argue against the assignment of BEP3 as H2 in the p-type 6H-SiC. However, it should be pointed out that the DLTS signal of BEP3 is very weak (as shown in Fig. 3), and the low-dose Be implanted p-type samples were annealed at 1600°C for 30 s. It does not preclude the possibility that BEP3 may arise from an intrinsic defect due to the very short annealing duration used for the low-dose Be implanted SiC samples.

The BEP4 at $E_V + 0.88$ eV determined from p-type sample and the BE5 at $E_V + 0.73$ eV detected from the p-side of pn junction are determined as hole traps induced by Be implantation. Since there was no similar energy levels observed from electron irradiated or boron and gallium implanted p-type 6H-SiC experiments, we assign the two levels to be beryllium-related defects. Recently, several deep Be related centers were found by electron paramagnetic resonance (EPR) investigation on 6H-SiC crystal doped by diffusion technique [11]. The BEP4 and BE5 centers may be associated with these defects which were found to resemble the deep B center in terms of electronic and magnetic properties [12].

Passivation of p-type dopants in 4H-SiC by hydrogen

B. Aradi^{a,*}, A. Gali^a, P. Deák^a, N.T. Son^b, E. Janzén^b^a Department of Atomic Physics, Budapest University of Technology and Economics, Budafoki út 8, H-1111 Budapest, Hungary^b Department of Physics and Measurement Technology, University of Linköping, Linköping, S-58183 Sweden

Abstract

Experimental investigations showed passivation of the p-type dopants B and Al in 4H-SiC by the formation of B + H and Al + H complexes. The dissociation energies of these complexes differed by 0.9 eV. Ab initio supercell calculations have been performed to investigate the interaction of H with B and Al in hexagonal 4H-SiC. The total energy, geometry and electronic structure of the possible complexes have been determined. Site dependencies have also been investigated. The most stable configurations were found with H at a bond center site next to B at the Si site, and with H at the antibonding site of a carbon atom which is first neighbor to Al at a Si site. Both the $B_{Si} + H_{BC}$ and the $Al_{Si} + H_{ABc}$ complexes turned out to be electrically inactive. The different structure of the passivated complexes explains the observed difference in their dissociation energy: the calculated difference of the binding energies of these complexes is 0.9 eV, which agrees well with the experimental finding. © 2001 Elsevier Science B.V. 1. Introduction

Hydrogen is one of the most common impurities in semiconductors, introduced by both wet and dry etching among other methods. Due to its ability to passivate dopants or to compensate them by forming electrically active centers, its properties have been studied in various semiconductors. Silicon carbide (SiC) is one of the most promising wide band gap semiconductors for building high-power, low-loss electronic devices. Hydrogen has a special importance with regard to the doping of this semiconductor: due to the slow diffusion under 1300°C, doping is very often carried out in growth. This is most often done using chemical vapor deposition (CVD) from precursor molecules (e.g. C_3H_8 , SiH_4 , B_2H_6 or $Al(CH_3)_3$) diluted in H_2 carrier gas, causing an unavoidable hydrogen contamination in the epitaxially grown sample.

The most important p-type dopants of silicon carbide are boron and aluminum. The behavior of aluminum is

relatively predictable, it substitutes a silicon atom in the lattice (Al_{Si}) and produces a shallow acceptor level between $E_V + 0.19$ – 0.25 eV in the different polytypes [1]. Boron has been reported to occupy both the silicon and the carbon site, alas with preference for the Si site [2]. It produces a shallow and a deep acceptor level with (0/–) occupation levels at $\sim E_V + 0.30$ eV and $\sim E_V + 0.55$ eV, respectively, in the 4H polytype [3,4]. Although no conclusive proof has yet been shown, B_{Si} is usually associated with the shallow acceptor.

For boron doped 6H-SiC samples it was shown with SIMS (secondary ion mass spectrometry) and PL (photoluminescence spectroscopy) [5,2] that hydrogen is incorporated during epitaxial growth. Those samples showed strong decrease in the carrier concentration due to hydrogen. Experiments introducing hydrogen by implantation [6] or low-temperature plasma anneal [7] showed a passivation of the p-type doping by the formation of Al + H and B + H complexes. The observed dissociation energies for these complexes (1.61 and 2.51 eV for Al + H and B + H, resp. [8]) differ by 0.9 eV, suggesting that the atomic configurations of the two complexes are significantly different.

2. Method

First-principles calculations using the local density approximation (LDA) to density-functional theory were carried out using a plane wave basis. The Ceperley–Alder exchange-correlation functional was used as parametrized by Perdew and Zunger. Atomic cores were represented through norm conserving Troullier–Martins pseudopotentials. The basis included plane waves with kinetic energy up to 36 Ry. This makes the relative stability of the calculated complexes converge within 0.05 eV. Integration over the Brillouin zone of the supercells was carried out through a summation on the $2 \times 2 \times 2$ Monkhorst–Pack (MP) mesh. The defective solid was modeled with a 96 atom supercell ($2\sqrt{3} \times 2\sqrt{3} \times 1$) enabling symmetry constrained relaxation of the atoms within the first three shells around the defect. The calculation had been carried out with the FHI98MD code [9]. LDA is known to underestimate the width of the gap. To correct that a posteriori, the conduction band has been rigidly shifted to reproduce the experimental gap. Defect levels in the gap had been shifted proportional to their overlap with the conduction band states of the perfect lattice [10]. In the case of occupied defect levels, this gives rise to a correction in the total energy as well. Details and references are given in Ref. [11].

3. Hydrogen in 4H-SiC

To find the stable geometry for the neutral interstitial hydrogen, we started hydrogen from the different antibonding and bond center positions using initial Si–H and C–H distances that we have obtained earlier for interstitial hydrogen in 3C-SiC [11]. The most stable configuration turned out to be hydrogen in an antibonding position behind a silicon atom ($H_{AB_{Si}}$). The geometry of the stable configuration is shown in Fig. 1.

Fig. 1. Geometry of the $H_{AB_{Si}}$ complex.

The stable $H_{AB_{Si}}$ complex causes a single occupied defect level at $E_V + 1.45$ eV.

Calculation of the negatively charged interstitial hydrogen showed hydrogen to be most stable staying behind the silicon atom in an antibonding position. The hydrogen–silicon distance decreases to 1.76 Å, while the silicon–carbon bond gets weakened by the additional electron, and increases to 1.96 Å. In the positively charged state, hydrogen prefers the antibonding site of carbon at a distance of 1.15 Å. The positively charged hydrogen weakens the bond of the carbon atoms to its silicon neighbors: the bond lengths increase to 1.95–1.96 Å.

A Comparison of the total energies of the stable interstitial hydrogen complexes in the different charge states (shown in Fig. 2) predicts a negative U behavior for hydrogen in 4H-SiC, with a (+/–) occupation level at $E_V + 2.3$ eV. Accordingly, interstitial hydrogen is an amphoteric defect in 4H-SiC, being (unlike in 3C-SiC) a deep electron and hole trap as well. It is positively charged in the p-type material and, therefore attracted by the negatively charged acceptors.

4. Passivation of boron and aluminum by hydrogen

We have investigated the complexes of hydrogen with the p-type dopant B_{Si} in 4H-SiC. Among the investigated $B_{Si} + H$ complexes those with hydrogen in a bond center position between the substitutional boron and one of its carbon ($B_{Si} + H_{BC}$) neighbor turned out to be most stable. The geometry for the complex is shown in Fig. 3. As it can be seen, the hydrogen bonds to the carbon atom (having a typical C–H distance of ~ 1.1 Å) and pushed the boron in an almost planar configuration. All of these complexes turned out to be electrically inactive, meaning that the complex has no level in the gap. The next stable complex contains hydrogen at an antibonding position behind one of the carbon neighbors of the substituting boron.

Fig. 2. Stability of the charge states of interstitial atomic H with respect to the neutral state in 4H-SiC as a function of the Fermi level in the gap.

Fig. 3. Geometry of the $B_{Si} + H_{BC}$ complex.Fig. 4. Geometry of the $Al_{Si} + H$ complex.

To investigate the interaction of hydrogen with aluminum in 4H-SiC, we performed a similar calculation for aluminum as for boron. In the energetically most favorable complex, the hydrogen is at an antibonding position to one of the first neighbor carbon atoms of the substituting aluminum ($Al_{Si} + H_{AB_C}$). The geometry of this complex is shown in Fig. 4. The hydrogen bonds here also to the carbon atom, however, from the antibonding site. The $Al_{Si} + H_{BC}$ configuration, containing a bond center hydrogen between the Al and the C atom is less stable, the difference to the $Al_{Si} + H_{AB_C}$ complex is about 0.3 eV. Obviously, hydrogen would prefer to have a bond center position, to have a "normal" bond with carbon as in the case of boron, but since aluminum is too big, this configuration involves too much relaxation, making it energetically less favorable. Similar to boron, the complex forming with hydrogen causes passivation of Al, since all of these complexes turned out to be electrically inactive.

5. Dissociation of the dopant-hydrogen complexes

To calculate the dissociation energy of the passivated complexes, one has to consider that hydrogen is

positively charged in p-type silicon carbide, while the acceptors are negative. Therefore, the reaction for the dissociation would be

where the variable X stands for the different p-type dopants (B and Al in our case). By subtracting from the sum of the total energies of the dopant X in the negative charge state and the hydrogen in the positive charge state the sum of the total energies of a neutral $X + H$ complex and a perfect supercell, one obtains the binding energy which is a lower limit for the dissociation energies. (The dissociation energy is equal to the binding energy *plus* the activation energy of the diffusion.)

By calculating the binding energy for the $B_{Si} + H_{BC}$ and the $Al_{Si} + H_{AB_C}$ complexes in this way we obtain 1.6 and 0.7 eV, respectively. The difference between them can be explained with the bonding configuration of hydrogen: in the case of $B_{Si} + H$, hydrogen is the fourth neighbor of the more or less tetrahedral coordinated carbon atom, giving rise to a strong C-H bond, while in the case of aluminum, hydrogen bonds weakly to the carbon atom from an antibonding position.

The experimental values for the dissociation energy are 2.51 and 1.61 eV for B and Al, respectively. The difference to our binding energies are 0.9 eV in both cases. This value can be interpreted as an approximate activation energy of diffusion. (For neutral H Kaukonen et al. have obtained a migration barrier of 0.7 eV, Ref. [12]). The difference of the binding energies are equal to the observed difference of dissociation energies.

6. Summary

Using ab initio LDA supercell calculations we investigated the interaction of hydrogen with the boron and aluminum dopants in 4H-SiC. We showed that the interstitial hydrogen has a negative U behavior in 4H-SiC and is a deep electron and hole trap. In p-type SiC it is positively charged and, therefore attracted by the negatively charged boron and aluminum dopants. Our calculations showed that these dopants can be passivated by forming complexes with the hydrogen. The difference in the structures of the most stable electrically inactive $B_{Si} + H_{BC}$ and $Al_{Si} + H_{AB_C}$ complexes explain the experimentally observed difference between the dissociation energies of the B + H and Al + H complexes.

First-principles studies of Ti impurities in SiC

K.O. Barbosa, W.V.M. Machado, L.V.C. Assali*

Departamento de Física dos Materiais e Mecânica, Instituto de Física da Universidade de São Paulo, CP 66318, CEP 05315-970, São Paulo, SP, Brazil

Abstract

In this work we perform a theoretical investigation on the atomic structure, atomic geometry, and formation energy of isolated substitutional and interstitial Ti impurities in cubic silicon carbide (3C–SiC), using the spin-polarized full-potential linearized augmented plane wave method. For each configuration, the atoms around the impurity site are allowed to relax without any constraints, following the damped Newton dynamics scheme. The overall structural stability is analyzed in the light of the electronic structure and the bonding features. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Transition metals; Silicon carbide; Ab initio methods

1. Introduction

Silicon carbide (SiC) is a wide band gap semiconductor that is finding a place which is difficult to fill with the presently available Si or GaAs technology. One of the aspects that makes SiC fascinating from a fundamental point of view is that in some sense SiC is not a single semiconductor but a whole class of semiconductors because of its polytypism [1]. The material can crystallize in many different but closely related crystal structures. Since its discovery [2], more than 200 polytypes have been determined [3]. The most extreme polytypes are the zinc-blende 3C–SiC with pure cubic stacking of Si–C bilayers in the [111] direction and the wurtzite 2H–SiC with pure hexagonal stacking in the [0001] direction. The pure crystals indirect band gap varies in the range of 2.4 eV for 3C–SiC to 3.3 eV for 2H–SiC. Due to the existence of these polytypes, a variety of impurity sites exist since there are two different sublattices and no equivalent cubic (k) and hexagonal (h) sites in the sublattices. It is known that not only the electronic properties of SiC crystals are influenced by the different

stacking order but also those of the defects and impurities.

The study of 3dⁿ transition metal (TM) point defects in SiC is very important because they can be incorporated in SiC by doping or can be present in the material as residual impurities [4,5] and, as in Si, they play an important role in the crystal electric and magnetic properties. The TM impurity properties would vary if it is built in C or Si sites or in an interstitial site, and vary also from polytype to polytype.

Theoretically, there are few studies involving TM impurities in SiC. The aim of this work is to describe the electronic and atomic structure, the spin state, and the energetics for the Ti impurity in 3C–SiC. In order to understand the effects of the Ti impurity in the material properties we studied, using a total energy method with atomic relaxation, isolated substitutional Ti impurity in a Si site ($\text{Ti}_{\text{Si}}^{\text{Si}}$) and in a C site ($\text{Ti}_{\text{C}}^{\text{C}}$), as well as tetrahedral interstitial isolated Ti impurity surrounded by four C atoms ($\text{Ti}_{\text{C}}^{\text{C}}$) and surrounded by four Si atoms ($\text{Ti}_{\text{Si}}^{\text{Si}}$) in 3C–SiC. A 54-atom supercell approach is used to describe the impurity located in different atomic and interstitial sites. The calculations are performed within the framework of the density functional theory (DFT) [6,7], using the full-potential linearized augmented plane wave (FP-LAPW) method [8], implemented into the

package WIEN97 [9], using the exchange-correlation potential of Perdew et al. [10].

2. Results

2.1. Perfect crystal 3C–SiC

The properties of the zinc-blende 3C–SiC material parameters are obtained using $RK_{\max} = 8$, the smallest *muffin-tin* radius of the host atoms times the largest reciprocal lattice vector in plane wave expansion ($R_{\text{Si}} = 1.5a_0$ and $R_{\text{C}} = 1.2a_0$), that corresponds to a cutoff energy of 44 Ry. In the atomic regions a spherical harmonic basis set is used with azimuthal quantum number up to $\ell = 10$ and a nonspherical contribution up to $\ell_{\text{ns}} = 4$. The carbon 1s, 2s wave functions and the silicon 1s, 2s wave functions are considered as core states. The k-mesh in the full Brillouin zone (BZ) consists of $6 \times 6 \times 6$ Monkhorst–Pack points, which are reduced to 28 k points in the irreducible edge of the BZ. The self-consistent iterations were considered to be converged when both the total energy and the total charge in the atomic spheres were stable within 10^{-4} eV per unit cell and 10^{-4} electron charges per atom, respectively. Minimizing the total energy with respect to changes in the volume of the unit cell, the computed primitive 3C–SiC unit cell constant is $a = 4.38$ Å. The obtained energy/SiC is -656.304 Ry.

The computed electronic and structural properties of 3C–SiC, using the optimized lattice parameter, are shown in Table 1 and are in good agreement with experiments [11].

For the perfect supercell, convergence with respect to k points was checked. It was used the Γ , L and a $2 \times 2 \times 2$ grid for k-space integrations and no difference in the electronic properties of the material was verified and the total energy was converged within 0.02 eV/atom. We must note that 27 points of the unit cell BZ are sampled in just one point. The points 1Γ , $6 \Delta (\frac{2}{3}, 0, 0)$, $12 \Sigma (\frac{2}{3}, \frac{2}{3}, 0)$, and $8 \Lambda (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ of the unit cell BZ are all equivalent to the Γ point of the 54-atom supercell BZ. All properties displayed in Table 1, for the unit cell, are reproduced by the perfect supercell.

2.2. Electronic structure of Ti impurities

For an impurity supercell with a Ti impurity, the self-consistent iterations were considered to be converged when both the total energy and the total charge in the atomic spheres were stable within 10^{-4} eV and 10^{-5} electron charges per atom, respectively. The atoms were assumed to be in their fully relaxed positions when the forces acting on ions were smaller than 0.05 eV/Å.

Fig. 1 displays, schematically, the impurity-induced energy levels based on Kohn–Sham eigenvalues for the neutral $\text{Ti}_{\text{Si}}^{\text{Si}}$, $\text{Ti}_{\text{Si}}^{\text{C}}$, $\text{Ti}_{\text{C}}^{\text{Si}}$, and $\text{Ti}_{\text{C}}^{\text{C}}$ centers at Γ . The full lines indicate the energy level with ‘up’ spin and the dotted lines with ‘down’ spin. The occupation of the energy levels is represented by the numbers of \uparrow (spin up) and \downarrow (spin down) arrows, respectively. In the crystal field, the Ti 3d-derived states split into twofold degenerate e levels and threefold degenerate t_2 levels, which are displayed in Fig. 1.

The $\text{Ti}_{\text{Si}}^{\text{Si}}$ center (substitutional Ti impurity in the Si site) introduces no energy levels in the band gap region. The energy levels related to Ti impurity are unoccupied resonant levels in the conduction band, where the e energy levels lie below the t_2 energy levels. Therefore, when a Si atom is replaced by a Ti atom, the latter undergoes a p–d hybridization, bonding to the nearest-neighbor C atoms, causing the band structure of the 3C–SiC material to be restored. Furthermore, we can say that the $\text{Ti}_{\text{Si}}^{\text{Si}}$ center reconstructs the Si vacancy dangling bonds, showing little influence in the band structure of the perfect material. On the other hand, one can understand these results on comparing them with the electronic structure of a substitutional Ti impurity in diamond [12] that shows no energy levels in the band gap. As the Ti impurity replacing a Si atom in 3C–SiC has four C atoms as nearest-neighbors, its electronic structure is quite similar to that of the substitutional Ti impurity in diamond. The Ti atom, which has an electronegativity similar to that of a Si atom and smaller than that of a C atom, interacts mainly with the nearest-neighbor C atoms through a p–d hybridization. The neutral $\text{Ti}_{\text{Si}}^{\text{Si}}$ center shows a closed-shell configuration, leading to an effective spin $S=0$. The point structure of the center has a T_d symmetry with a small relaxation where the

Fig. 1. Schematic representation of the Ti 3d-related impurity energy levels, in the band gap region for the neutral $\text{Ti}_\text{Si}^\text{Si}$, $\text{Ti}_\text{Si}^\text{C}$, $\text{Ti}_\text{i}^\text{Si}$, and $\text{Ti}_\text{i}^\text{C}$ centers at Γ ($E_\text{g} = 2.4\text{ eV}$). The full lines indicate the energy levels with 'up' spin and the dotted lines with 'down' spin. The occupation of the energy levels is represented by the numbers of \uparrow (spin up) and \downarrow (spin down) arrows, respectively.

four nearest-neighbor C atoms undergo an outward relaxation of 0.1 Å.

The $\text{Ti}_\text{Si}^\text{C}$ center (substitutional Ti impurity in the C site) introduces totally occupied t_2 energy levels in the band gap region and resonant unoccupied e energy levels in the conduction band. Therefore, when a C atom is replaced by a Ti atom, the latter does not bond to the four nearest-neighbor Si atoms and does not reconstruct the C vacancy dangling bonds. Therefore, different from the substitutional Ti impurity in Si crystal [13], the interactions between Ti and the nearest-neighbor C atoms cause a crystal field splitting so that the t_2 energy levels lie below the e levels. The neutral $\text{Ti}_\text{Si}^\text{C}$ center shows a closed-shell configuration, leading to an effective spin $S = 0$. The point symmetry of the center is T_d where the four nearest-neighbor Si atoms and the 12 near-nearest-neighbor C atoms show an outward relaxation of 0.5 and 0.1 Å, respectively.

The $\text{Ti}_\text{i}^\text{Si}$ center (interstitial Ti impurity tetrahedrally surrounded by four Si atoms) introduces occupied t_2 energy levels, with up spin, and partially occupied t_2 energy level, with down spin, in the band gap region, and resonant unoccupied e energy levels with up and down spins in the conduction band. This center shows a low-spin configuration with an effective spin $S = 1$. The center point symmetry is approximately T_d where the four nearest-neighbor Si atoms and the six near-nearest-neighbor C atoms show an outward relaxation of 0.2 and 0.1 Å, respectively.

The $\text{Ti}_\text{i}^\text{C}$ center (interstitial Ti impurity tetrahedrally surrounded by four C atoms) introduces degenerate energy levels, $t_2 + e$, with spin up, in the band gap region (Ti 3d-related state) and unoccupied energy levels, with down spin, in the conduction band. The crystal field splitting is practically null and the center

shows a high-spin configuration with an effective spin $S = 2$. The center point symmetry is approximately T_d where the four nearest-neighbor C atoms and the six near-nearest-neighbor Si atoms show an outward relaxation of 0.1 and 0.2 Å, respectively.

2.3. Impurity formation energies and chemical potentials

At equilibrium and in the dilute limit, the concentration of an impurity in a crystal depends upon its free energy of formation

$$[D_i] = N_\text{sites} \exp\{-\Delta G_f/k_B T\}, \quad (1)$$

where N_sites is the number of sites, per unit volume, in the crystal where the impurity can occur. k_B is the Boltzmann constant, T is the temperature, and ΔG_f is given by

$$\Delta G_f = \Delta E_f - T\Delta S_f + P\Delta V_f. \quad (2)$$

Here, ΔE_f is the total energy variation, ΔS_f and ΔV_f are the entropy and volume variation when the impurity is introduced into the system under pressure P .

The formation energy of a charged point defect in SiC, ΔE_f^q is computed as

$$\Delta E_f^q = E(n_\text{Si}, n_\text{C}, n_\text{Ti}, q) - n_\text{Si}\mu_\text{Si} - n_\text{C}\mu_\text{C} - n_\text{Ti}\mu_\text{Ti} - q(\mu_\text{e} + E_\text{F}), \quad (3)$$

where $E(n_\text{Si}, n_\text{C}, n_\text{Ti}, q)$ is the total supercell energy with n_Si silicon atoms, n_C carbon atoms, and n_Ti Ti impurity atoms; μ_Si , μ_C , and μ_Ti are the external chemical potentials for Si, C, and Ti, respectively; q is the charge state of the defect. The electron chemical potential μ_e gives the position of the Fermi level in the band gap relative to the top of the valence band E_V . Silicon and carbon chemical potentials are not independent but are under the constraint

$$\mu_\text{Si} + \mu_\text{C} = \mu_\text{SiC(Bulk)} \quad (4)$$

that represents the equilibrium of a pair of atoms in the SiC crystal. $\mu_\text{SiC(Bulk)}$ is the chemical potential of the SiC pair in the bulk SiC compound. The allowed range of μ_Si and μ_C is determined from the heat formation ΔH_f defined as

$$\Delta H_f^{\text{SiC}} = \mu_\text{SiC(Bulk)} - \mu_\text{Si(Bulk)} - \mu_\text{C(Bulk)}, \quad (5)$$

where $\mu_\text{Si(Bulk)}$ and $\mu_\text{C(Bulk)}$ are the total energies per atom for Si and C crystals in the diamond structure, respectively. The calculated heat formation energy for SiC is -0.59 eV/SiC . This value is in good agreement with the experimental -0.68 eV/SiC enthalpy of formation [11]. In accordance with the preparation condition, the Si and C chemical potentials fluctuations vary according to

$$\mu_\text{Si} = \mu_\text{Si(Bulk)} + \lambda\Delta H_f^{\text{SiC}}, \quad (6)$$

$$\mu_\text{C} = \mu_\text{C(Bulk)} + (1 - \lambda)\Delta H_f^{\text{SiC}} \quad (7)$$

Table 2
Formation energies (ΔE_f), in units of eV, of the Ti impurity in 3C–SiC for different sites

Impurity	$\Delta E_f (\mu_{\text{Si}} = \mu_{\text{Si(Bulk)}})$	$\Delta E_f (\mu_{\text{Si}} = \mu_{\text{Si(Bulk)}} + \Delta H^{\text{SiC}})$
$\text{Ti}_{\text{S}}^{\text{Si}}$	6.9	6.9
$\text{Ti}_{\text{S}}^{\text{C}}$	14.1	15.3
$\text{Ti}_{\text{I}}^{\text{Si}}$	15.5	16.1
$\text{Ti}_{\text{I}}^{\text{C}}$	16.0	16.6

λ being a parameter ranging from 0 (Si-rich condition) to 1 (C-rich condition).

Table 2 presents the formation energies (ΔE_f) of the Ti impurity in 3C–SiC, in the limits of the silicon chemical potential, for different sites.

The results indicate that the substitutional sites are more stable than the interstitial ones and that substitutional Ti is more favorable in the Si sublattice than in the C sublattice.

3. Conclusion

We have performed ab initio total energy calculations of isolated Ti impurities in 3C–SiC, using the FP-LAPW method, the damped Newton dynamics scheme, and the supercell approach.

The electronic structure results show that the bonding features are quite different for the substitutional Ti impurity if it is built in Si or C sites. The $\text{Ti}_{\text{S}}^{\text{Si}}$ center reconstructs the Si vacancy dangling bonds and shows no energy levels in the band gap. On the other hand, the $\text{Ti}_{\text{S}}^{\text{C}}$ center does not reconstruct the C vacancy dangling bonds, showing fully occupied t_2 energy levels in the band gap region. For the interstitial Ti impurities the results show that when Ti impurity is surrounded tetrahedrally by Si atoms ($\text{Ti}_{\text{I}}^{\text{Si}}$) the exchange splitting drives the center to a low-spin configuration while for the Ti impurity surrounded tetrahedrally by C atoms ($\text{Ti}_{\text{I}}^{\text{C}}$) the crystal field splitting is practically null and the exchange splitting drives the center to a high-spin configuration. Although the relaxations are small for all centers studied here, our results show that they are important to compute values related to hyperfine parameters.

The formation energy results indicate that the Ti impurity in 3C–SiC in substitutional sites are more stable than in interstitial sites. Moreover, the Si site sublattice is the more stable one.

We can conclude from our results that isolated Ti impurity in 3C–SiC crystal is more stable as a substitutional impurity in the Si sublattice and, in this microscopic structure, it presents no band gap energy levels, in agreement with experimental evidences [14].

Deep level defects in sublimation-grown 6H silicon carbide investigated by DLTS and EPR

Abstract

6H-SiC bulk single crystals grown by physical vapor transport (PVT) were investigated by deep-level transient spectroscopy (DLTS) and electron paramagnetic resonance (EPR). One of the observed deep level defects was identified as isolated tungsten on Si sites by EPR. The electron spin of $\frac{1}{2}$ could be explained by W^{5+} ($5d^1$). This is equivalent to the single positive charge state of a double donor when taking into account the Fermi level position in the n-type samples. The interpretation is also consistent with the DLTS detection of a W related deep level which showed a behavior of the capture of electrons and holes that hints at a double donor. In addition a tantalum related deep level is tentatively discussed. W and Ta were incorporated on electrically active sites in 6H-SiC only in low concentrations ($2\text{--}4 \times 10^{14} \text{ cm}^{-3}$) during crystal growth by PVT. © 2001 Elsevier Science B.V. 1. Introduction

The high temperatures during the PVT growth of 6H-SiC crystals bear the risk of unintentional impurity incorporation and incomplete annihilation of intrinsic point defects. Many of these impurities and defects form deep levels which can alter the electrical properties of the crystal by their action as compensation or recombination centers. Therefore, we investigated our 6H-SiC PVT crystals by DLTS and EPR to find out which deep levels are present, their concentration and electrical parameters as well as their structural and chemical identity. Especially, we were interested if tungsten and tantalum, which are potential impurities in our crystal growth process, were incorporated as deep level defects. Recent investigations of W and Ta implanted SiC by radiotracer DLTS revealed deep levels which could unambiguously assigned to W and Ta related defects, respectively [1,2].

However, such experiments cannot prove whether the chemically identified impurity is incorporated on a substitutional or an interstitial site, and if it is isolated or associated with other defects.

We report about the EPR identification of W substituting for Si in 6H-SiC and its assignation to a deep double donor level for the first time. A tentative correlation of the measurements in the case of Ta is also given.

2. Experimental details

6H-SiC bulk single crystals 30 mm in diameter were grown by physical vapor transport using 6H(0001)-SiC seeds with about 3° off-orientation. The sublimation of the SiC source took place at about 2200°C in an inductively heated crucible made of graphite [3]. For the most investigated crystal of this report 5 wt% of metallic tantalum was added to the source powder without deterioration of the resulting crystal quality. Furthermore, this crystal was only unintentionally doped with nitrogen and we obtained n-type samples in the mid 10^{16} cm^{-3} range.

E-mail address: irmscher@ikz-berlin.de (K. Irmscher).

The DLTS measurements were performed using a commercial digital system in the capacitance detecting mode (DL8000, BioRad) equipped with a liquid nitrogen cryostat for temperature scans from 90 to 550 K. We have extended the system by an ultraviolet laser excitation source (Crystal GmbH) emitting at a wavelength of 355 nm to enable minority carrier pulses. As test structures semitransparent Schottky contacts obtained by Ni evaporation were used.

The EPR spectrometer (ESP300E, Bruker) works at X-band (9.4 GHz). The sample temperature can be varied between 4 and 300 K by means of a helium-flow cryostat (Oxford Instruments).

3. Results and discussion

3.1. EPR

In the EPR spectra the shallow nitrogen donor signals dominated and the known resonances of transition metals (TM's) in SiC [4,5] could not be detected. The latter was not surprising since former studies of the incorporation of selected TM's in our crystals revealed only low chemical concentrations, e.g. for vanadium around 10^{14} cm^{-3} [6].

Fig. 1(a) shows a typical EPR spectrum without illumination of the sample for the direction of the static magnetic induction \mathbf{B} parallel to the c -axis of the crystal. At the measurement temperature of 4 K and the used microwave power (0.2 mW) the N donor signal is strongly suppressed by saturation and an extremely narrow line (peak-to-peak line width of about 0.03 mT) labeled W^{5+} is visible at a resonance field of 335.7 mT. There are further lines, which could not be analysed up to now because of their low intensities for arbitrary directions of the magnetic induction. However the pair

of line groups labeled $\text{Ta}^{3+?}$ at about 320 and 350 mT, respectively, most probably originates from a defect with an electron spin $S = 1$, an axial fine structure and a complicated hyperfine interaction. These characteristics are to be expected for the ^{181}Ta isotope (natural abundance of nearly 100%) with nuclear spin $I = \frac{7}{2}$ and a very large nuclear electric quadrupole moment. The effect of near band gap light on the EPR spectrum is shown in Fig. 1(b). The lines of W^{5+} and $\text{Ta}^{3+?}$ almost disappear whereas new ones arise. This behavior proves that the underlying defects possess energy levels within the band gap. Among the new resonances the ones at about 302 and 368 mT labeled $\text{W}^{4+?}$ can be described by a spin $S = 1$. The identities suggested by the labels with question marks are only working hypotheses and need justification by further investigations.

Fig. 2 shows the spectrum of W^{5+} for \mathbf{B} parallel to c on an expanded scale. The central line exhibits an additional structure, which is assumed to arise from a super hyperfine (shf) interaction with ligand nuclei. The pair of outer lines, on which this shf structure is also present, is thought to be a result of a hyperfine (hf) interaction of the electron spin of an impurity ion with its own nuclear magnetic moment. The ratio of the sum of the two outer line intensities to the total intensity, i.e. central line plus two outer lines, amounts to 14.3%. Among the impurities which are possible candidates for an unintentional incorporation during crystal growth only tungsten has an isotope (^{183}W) with nuclear spin $I = \frac{1}{2}$ and a natural abundance of 14.3% while the other W isotopes (with even numbered atomic masses) have zero nuclear spin. Therefore tungsten is the most probable chemical identification of the impurity in question. Concerning the electron spin, we can conclude from the anisotropy of the spectrum and the missing fine structure that it must be $S = \frac{1}{2}$. The incorporation of W on interstitial sites or on substitutional carbon sites is

Fig. 1. Typical EPR spectrum of an as-grown 6H-SiC crystal for the direction of the static magnetic induction parallel to the c -axis, (a) without illumination and (b) with near band gap light excitation.

Fig. 2. Measured (solid line) and simulated (dashed line) EPR spectrum of W^{5+} on a Si site in 6H-SiC. The calculated stick spectrum (bottom) was convoluted with Lorentzian lines of 0.036 mT peak-to-peak width.

incompatible with the observed shf structure as checked by trial simulations of the spectrum. Hence, W substituting for Si is more obvious. Then four electrons are spent for the bonds and the $5d^1$ electron configuration of W^{5+} can be assumed in agreement with $S = \frac{1}{2}$. This is equivalent to the single positive charge state of a donor. All features of the spectrum can be adequately described by the spin Hamiltonian

$$H = \mu_B \mathbf{B} \mathbf{g} \mathbf{S} + \mathbf{S} \mathbf{A}^W \mathbf{I}^W + \sum_{i=1}^{12} \mathbf{S} \mathbf{A}_i^{\text{Si}} \mathbf{I}_i^{\text{Si}} \left(+ \sum_{i=1}^4 \mathbf{S} \mathbf{A}_i^{\text{C}} \mathbf{I}_i^{\text{C}} \right) \quad (1)$$

and $S = \frac{1}{2}$. The first term describes the electronic Zeeman interaction and determines the anisotropy of the central resonance line. The hf interaction with the ^{183}W nucleus is represented by the second term of Eq. (1) and accounts for that 14.3% of the total line intensity is split into two lines. The third term contains the shf interaction with the nuclear spin possessing isotopes of the 12 next-nearest Si neighbors which gives rise to the substructure of the resonance lines when taking into account that in natural composition only 4.7% of the Si isotopes have a nuclear spin (^{29}Si). The shf interaction with the four nearest C neighbors, included in Eq. (1) by the term in parentheses, could not be detected because of too low intensity compared to the N donor background signal. Only the nuclei of the isotope ^{13}C (natural abundance 1.1%, $I = \frac{1}{2}$) take part in this interaction. The parameters of the spin Hamiltonian are summarized in Table 1. For the simulation of the spectrum (Fig. 2) it was, compatible with $\mathbf{B} \parallel c$, necessary to divide the 12 next-nearest Si neighbors into two groups of 6 magnetically equivalent atoms in each case with shf splitting constants of 0.13 and 0.18 mT, respectively.

3.2. DLTS

In Fig. 3 a typical DLTS spectrum of an as-grown 6H-SiC crystal, the same one as investigated by EPR, is shown for a time window of 20 ms, which corresponds to an emission time constant of about 8 ms at the DLTS peak maximum. Most of the observed deep levels have already been reported by other authors [7,8]. The activation energies and capture cross sections were

Fig. 3. Typical DLTS spectrum of an as-grown 6H-SiC crystal in comparison to a spectrum obtained when UV light pulses were included in the excitation and to simulations.

Table 2

Parameters of the deep levels observed in as-grown, n-type 6H-SiC crystals

Peak	$E_C - E_T$ (eV)	σ_n (10^{-14} cm^2)	N_T (10^{14} cm^{-3})	Related defects
1	0.28	2	2.4	?
2	0.42	1–2	33	E_1/E_2 [7,8]
3	0.49	1–2	4.5	Ta [2]
4	0.69	1–2	5.3	Z_1/Z_2 [7]
5	0.95	1–2	1.6	?
6	1.16	14–18	2.3	W [1,2]
7	1.23	4–6	31	R [7,8]

obtained from an Arrhenius plot analysis. The trap concentrations were corrected for the influence of the so-called transition region. These data are summarized in Table 2 together with possible defect assignments. The deep levels E_1/E_2 , Z_1/Z_2 and R are most probably related to intrinsic defects [7,8], whereas the temperature positions labeled Ta and W in Fig. 3 were proven to be the peak positions of tantalum and tungsten related defects, respectively [1,2]. Since Ta and W related defects could not completely identified by the experimental DLTS spectrum simulations based on the deep level parameters (Table 2) were carried out. In Fig. 3 the simulation, including all deep levels for which a parameter evaluation was possible, shows that the shoulder at about 240 K can be assigned to the Ta related defect with a concentration of about $4 \times 10^{14} \text{ cm}^{-3}$. For the W related defect an additional simulation excluding the level in question was calculated to support that its presence with a concentration of about $2 \times 10^{14} \text{ cm}^{-3}$ much better fits the measurement. Finally, a DLTS spectrum was recorded using an electric (i.e. voltage) pulse followed by an optic one from the UV

Table 1

Spin Hamiltonian parameters of W^{5+} in 6H-SiC

	G	$A(^{183}\text{W})$ (mT)	$A(^{29}\text{Si})$ (mT)
$B \parallel c$	2.0023	0.947	0.13–0.18
$B \perp c$	2.0035	0.91	0.15

laser. All deep electron traps which have a not too low hole capture cross section should be cleared. For two peaks (Fig. 3) this was not the case. Especially, the peak at about 480 K mainly consists of the W related defect with its full concentration. Hence, the hole capture cross section of this level is very low, whereas its electron capture cross section, in accordance with the Arrhenius plot analysis given here (Table 2) and in Ref. [1], should be very large. This behavior suggests a double donor state for the W related deep level.

4. Conclusions

Isolated tungsten on Si sites in 6H-SiC was identified by EPR for the first time. The anisotropy and the splitting pattern of the observed resonance lines could be interpreted by W^{5+} ($5d^1$, $S = \frac{1}{2}$). This is equivalent to a single positively charged donor. By DLTS a W related deep level was detected at about $E_C - 1.16$ eV. Its capture behavior for electrons and holes hints at a double donor level. Since this level is occupied by one electron in our n-type samples the resulting charge state is consistent with the EPR observation. Further support of our interpretation of the W related defect comes from theory [9,10]. Overhof calculated the charge transfer energy levels for several isolated TM's at different high-symmetry positions in 3C-SiC. There are theoretical [9] and experimental [7] arguments that these energies are relatively insensitive to the polytype and that the valence band edge can be used as reference level. Especially for isolated W on a Si site a double donor level at $E_V + 1.94$ eV, a single donor level at $E_V + 2.98$ eV and a single acceptor level at $E_V + 4.15$ eV were obtained [10]. The double donor level fits very well with the energy position determined by DLTS when using a gap

energy of 3.03 eV for 6H-SiC. Furthermore the charge state assigned by EPR and DLTS agrees with theory.

The W related defect detected by radiotracer DLTS in implanted samples [1] is the same one as in our as-grown samples, i.e. it is not a defect complex. However the assignation to a single acceptor given in [1] is incorrect.

The DLTS results for the Ta related deep level in an ion implanted sample [2] agree with ours for Ta in as-grown crystals. Therefore a complex of Ta with residual radiation damage can be excluded for the radiotracer DLTS experiments of [2].

W and Ta were incorporated on electrically active sites in 6H-SiC only in low concentrations of $2.4 \times 10^{14} \text{ cm}^{-3}$ during PVT growth.

Abstract

We have performed diffusion experiments with B-implanted 6H-SiC at temperatures between 1700°C and 2100°C. After diffusion, B concentration profiles were measured by means of secondary ion mass spectrometry. Accurate modeling of B diffusion is achieved on the basis of a kick-out diffusion mechanism which only involves point defects on the Si sublattice. Fitting of our experimental profiles yields data for the B interstitial-controlled B diffusion coefficient which are in good agreement with literature data. Moreover, the analysis of B diffusion provides data for the Si interstitial-controlled B diffusion coefficient which is interrelated with the Si self-interstitial contribution to Si diffusion in SiC. This contribution is found to be two orders of magnitude lower than an extrapolation of Si diffusion data reported in the literature. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

SiC is a promising wide band gap semiconductor for high-temperature, high frequency, and high voltage electronic applications (see e.g. Ref. [1]). B like Al behaves as an acceptor in SiC but diffuses more rapidly in SiC than Al. Implantation of B in SiC is generally used for selective area doping [2]. This implantation process induces native point defects in concentrations exceeding the equilibrium value and can cause transient enhanced diffusion of B towards the surface and into the undamaged region of the SiC substrate during a subsequent high-temperature treatment. A preanneal at 900°C for 2 h has been shown to effectively reduce this transient enhanced B diffusion [3,4].

The fast diffusion of B compared to Al may seem unusual since B like Al is considered to be mainly dissolved on Si lattice sites in SiC. However, assuming that B diffuses via interstitial–substitutional exchange mechanisms

namely the dissociative mechanism and the kick-out mechanism, respectively, the fast diffusion of B is a consequence of a non-neglectable fraction of B in a highly mobile interstitial configuration B_i . V_{Si} , B_{Si} , and Si_i denote a vacancy on a Si lattice site, B dissolved on a Si lattice site, and a Si self-interstitial, respectively.

The B profiles shown in this work are considered to reflect B diffusion under near-equilibrium conditions and provide strong evidence that B diffusion at temperatures between 1700°C and 2000°C is mediated by the kick-out mechanism. Compared to a recent paper on B diffusion in SiC [5], we extend the present measurements to a wider temperature range. Additionally we have found evidence that a substantial fraction of B within the damaged region of the implanted sample may be not electrically active and hence some B atoms are not dissolved as isolated defects on Si lattice sites.

2. Experimental

A SiC wafer with a 10 μm thick Al-doped ($4.8 \times 10^{15} \text{ cm}^{-3}$) epitaxial SiC layer grown on an Al-doped

substrate with a resistivity of $2.10 \Omega \text{ cm}$ was cut into stripes of 5 mm width with various length. These stripes were subsequently subjected to a five-fold B implantation at energies ranging from 20 to 200 keV and doses between 2.7×10^{13} and $7.3 \times 10^{13} \text{ cm}^{-2}$. The implantation results in a box-shaped as-implanted B profile with a B concentration of about $5 \times 10^{18} \text{ cm}^{-3}$. After implantation the sample stripes were preannealed at 900°C for 2 h to reduce the implantation damage and thus the transient enhanced diffusion of B during the high-temperature diffusion anneal. After the implantation and the preanneal, SiC samples, $5 \times 5 \text{ mm}^2$ in size, were cut and rinsed in organic solvents and placed in a high-temperature furnace for annealing at temperatures between 1700°C and 2100°C . This furnace was specially designed by Gero Hochtemperaturöfen GmbH for annealing of small samples at temperatures up to 2500°C . Various temperature programs are possible which include heating to a single set point and more sophisticated temperature profiles with different temperature ramps. It takes about 1 h to reach a fixed temperature of e.g. 2000°C . The water cooled double-wall vacuum chamber is purged with argon during annealing.

For our diffusion experiments the sample holder is driven into the region of maximum temperature after the set point is reached. The diffusion process is terminated by pulling the sample holder out of the high-temperature area. The distribution of B in the as-grown and annealed samples were measured with secondary ion mass spectrometry (SIMS). The recorded secondary ion counts were converted to concentrations by using B-implanted SiC calibration samples. The depths of the craters left from the analysis were determined with a surface profilometer.

3. Results and discussion

Fig. 1 shows concentration profiles of B after diffusion at 1700°C , 1800°C and 2100°C . Similar B profiles after diffusion at 1900°C and 2000°C are illustrated in Fig. 2. All profiles measured after diffusion at temperatures between 1700°C and 2000°C show a B concentration near the surface which is lower than 10^{18} cm^{-3} , a maximum concentration of $2\text{--}3 \times 10^{18} \text{ cm}^{-3}$ at about 300 nm within the damaged region of the implanted layer, and a pronounced B profile tail which extends several microns into the undamaged SiC substrate. Contrary to these findings annealing at 2100°C causes B to diffuse out of the sample and to accumulate near the surface. Moreover, B diffusion into the undamaged SiC substrate is not observed. This sample reveals an interesting pattern under an optical microscope which could originate from B segregation. We currently analyze this sample and the other B-diffused SiC crystals

Fig. 1. Concentration depth profiles of B measured with SIMS (thin solid line) before (as-implanted) and after diffusion at 1700°C (120 min), 1800°C (120 min), and 2100°C (20 min) in Al-doped 6H-SiC. The thick solid lines represent the simulations on the basis of the kick-out mechanism.

Fig. 2. Concentration depth profiles of B measured with SIMS (thin solid lines) before (as-implanted) and after diffusion at 1900°C (30 min) and 2000°C (30 min) in Al-doped 6H-SiC. The thick solid lines represent the simulations on the basis of the kick-out mechanism.

with transmission electron microscope (TEM) to detect the possible existence of B precipitates within the B-implanted layer. Taking the B profile at 2100°C as indication that B segregation very likely takes place within the damaged region, we believe that the corresponding B profile measured with SIMS does not reflect the actual distribution of isolated B on Si lattice sites. Hence for modeling the B distribution in the undamaged SiC substrate we neglected the first 500 nm of the B profiles. Furthermore we assumed that the B-implanted near-surface layer serves as an infinite source for B diffusion into the SiC substrate as long as the B concentration in this region is sufficiently high. All B diffusion profiles in 6H-SiC are accurately described on the basis of the kick-out reaction (2) (see thick solid lines in Figs. 1 and 2) whereas the dissociative mechanism

expressed by reaction (1) does not provide an accurate fit to the experimental profiles as demonstrated recently [5]. It is noted that the shape of the B diffusion profile slightly changes from convex to concave with increasing temperature. This observation is consistent with the kick-out diffusion model and reveals that B diffusion at temperatures below 2000°C is controlled by Si self-interstitials Si_i whereas B interstitials B_i control B diffusion at 2000°C.

Modeling of the B diffusion profiles yields data for the effective B and Si diffusion coefficients D_{B}^* and D_{Si}^* , respectively, which are interrelated with the products $C_X^{\text{eq}} D_X$, $X \in \{\text{B}_i, \text{Si}_i\}$ between the equilibrium concentration and diffusivity of the respective point defects according to

$$D_{\text{B}}^* = \frac{C_{\text{B}_i}^{\text{eq}} D_{\text{B}_i}}{C_{\text{B}_i}^{\text{eq}}}, \quad (3)$$

$$D_{\text{Si}}^* = \frac{C_{\text{Si}_i}^{\text{eq}} D_{\text{Si}_i}}{C_{\text{B}_i}^{\text{eq}}}, \quad (4)$$

where $C_{\text{B}_i}^{\text{eq}}$ represents the solubility of B on the Si sublattice. We assume that this solubility is given by the B concentration measured with SIMS at the interface between the damaged and the undamaged region of the SiC epilayer. Data deduced for D_{B}^* and shown in Fig. 3 are in good agreement with earlier results given by Mokhov et al. [6] which are thus considered to represent the B_i -controlled B diffusion characterized by D_{B}^* . The data extracted for D_{Si}^* and $C_{\text{B}_i}^{\text{eq}}$ enables us to calculate

the Si self-interstitial contribution $C_{\text{Si}_i}^{\text{eq}} D_{\text{Si}_i} / C_{\text{B}_i}^{\text{eq}}$ of Si diffusion in SiC. This contribution is shown in Fig. 3 in comparison to the directly measured Si diffusion coefficient in 6H-SiC [7]. The Si self-interstitial contribution to Si diffusion in SiC is about two orders of magnitude lower than an extrapolation of the Si diffusion data to lower temperatures. This may suggest that Si diffusion is mainly mediated by vacancies on the Si sublattice. Consequently the vacancy contribution to Si diffusion should be two orders of magnitude higher than the Si self-interstitial contribution. In this case, one would expect that the interstitial–substitutional exchange via Si vacancies, that is, the dissociative mechanism mediates B diffusion in SiC. This, however, is in contrast with the shape of the B profiles which clearly points to B diffusion mediated by the kick-out mechanism. This conflict leaves some doubt about the accuracy of the earlier measured Si diffusion coefficients and may be solved by novel Si tracer-diffusion experiments that are currently in progress at our laboratory.

For modeling B diffusion in SiC, we recently assumed that B is completely electrically activated even within the ion-implanted region of the SiC layer [5]. Since this appears to be questionable now, we have considered in this paper that a substantial fraction of B within the damaged region is clustered and that actually the B concentration at the interface between the B implanted layer and the undamaged region equals the equilibrium concentration of B on Si lattice sites for the pertaining experimental conditions. Taking this approach for modeling B diffusion in SiC, all conclusions given in Ref. [5] remain valid. Only the values extracted for D_{B}^* and $C_{\text{Si}_i}^{\text{eq}} D_{\text{Si}_i} / C_{\text{B}_i}^{\text{eq}}$ are slightly lower (by about a factor of 3) than the values earlier reported [5]. Moreover, B diffusion in N-doped 4H-SiC is also accurately described on the basis of this approach as demonstrated by Fig. 4.

Fig. 3. Temperature dependence of B and Si diffusion coefficients D_{B} and D_{Si} (solid lines) in 6H-SiC reported in the literature [6,7] in comparison to our results. B diffusion data indicated by the upper solid bars were obtained from fitting the experimental B profiles shown in Figs. 1, 2 and 4. The lower solid bars represent the Si self-interstitial contribution to Si self-diffusion which is compared to Si tracer data extrapolated from high-temperatures (dashed line).

Fig. 4. Concentration depth profiles of B measured with SIMS (thin solid lines) before (as-implanted) and after diffusion at 1700°C and 1775°C for 60 and 180 min, respectively, in N-doped 4H-SiC. The thick solid lines represent simulations on the basis of the kick-out mechanism.

Modeling of these profiles yields data for the B and Si related diffusion coefficients which are equal to the results obtained from B diffusion in Al-doped 6H-SiC. This shows that the diffusion of B and Si in 6H-SiC and 4H-SiC is similar and does not depend very strongly on the conduction type of the SiC material, at least for the moderate doping concentrations under consideration.

4. Conclusions

The diffusion of B in 6H-SiC at temperatures between 1700°C and 2000°C is accurately described on the basis of the kick-out diffusion mechanism (see Eq. (2)). Values obtained for the B_i-controlled diffusion coefficient $D_{B_i}^*$ are in good agreement with literature data. The deduced Si self-interstitial contribution to Si self-diffusion is lower than data reported for Si diffusion in SiC which leaves some doubt about the accuracy of the Si diffusion data given in the literature. In order to investigate the interrelation between B and Si diffusion in more detail Si tracer-diffusion experiments exploring the temperature range between 1700°C and 2200°C should be performed. Annealing of B-implanted SiC at 2100°C seems to result in a pronounced outdiffusion of B and a segregation of B near the surface. TEM analyses of all samples are in

progress to characterize the precipitates which may exist after B-implantation and subsequent annealing.

Identification of arsenic antisite defects with EL2 by nanospectroscopic studies of individual centers

Akira Hida*, Yutaka Mera, Koji Maeda

Department of Applied Physics, School of Engineering, The University of Tokyo, Tokyo, Japan

Abstract

The bistable behavior of point defects, presumably considered to be arsenic antisite defects, in low-temperature-grown GaAs crystals was studied experimentally by using scanning tunneling microscopy (STM) coupled with spectroscopic measurements in the nanometer scale (nanospectroscopy). At room temperature, the photoabsorption detected at the individual defects by measuring the reduction of the tunneling current flowing out of the filled gap states associated with them exhibits spectroscopic features quite similar to those observed in bulk GaAs crystals containing EL2 centers. At 90 K, optical excitation causes transformation of the individual defects from the normal state to a metastable state devoid of gap states. The metastable state is recovered to the normal state by injecting electrons from the STM tip into the defects. The excitation spectrum of the defect transformation was very close to that observed in photoquenching of the EL2 centers. These facts strongly indicate that, if the present defects are isolated arsenic antisite defects (As_{Ga}), the EL2 centers in bulk GaAs crystals are truly As_{Ga} . © 2001 Published by Elsevier Science B.V.

Keywords: As antisite defect; EL2; Scanning tunneling microscopy; GaAs

The midgap deep level center EL2 in GaAs has long been a well-known defect drawing great attention [1] not only of the technological importance as a center responsible for obtaining semi-insulating GaAs bulk crystals, but also of the academic concern on the peculiar behaviors of the bistable transformation, one of the most remarkable features of EL2. Particularly the so-called photoquenching effect, the reduction of photoabsorption induced by light illumination at low temperatures, stimulated intensive studies on the microscopic mechanism. Phenomenologically, the photoquenching effect has been interpreted by the configuration coordinate diagram as illustrated in Fig. 1(a) proposed by Vincent et al. [2]: the intracenter optical excitation from the normal state (neutral EL2) to an excited state being resonant with the conduction band relaxes along the adiabatic potential of a

metastable state (neutral EL2*) with a large atomic displacement. The problem that remained was on the atomistic structures of the defect in the bistable states.

Many experimental facts and some theoretical calculations [3,4] strongly suggested that the EL2 centers are isolated arsenic antisite defect (As_{Ga}). In this framework, the photoquenching effect could be interpreted in terms of the Jahn–Teller distortion that breaks the on-center symmetry of the antisite As atom to a lower symmetry by displacing the As along the $[111]$ direction to an interstitial site (off-center site) as illustrated in Fig. 1(b). However, the microscopic identification of EL2 as isolated As antisites remained somewhat controversial since there has been no direct experimental evidence for the atomistic structure of EL2.

In this report, we present a direct proof for the identity of EL2 with isolated As antisites by showing the photoabsorption property and the bistable behavior of individual point defects, presumably isolated As antisites, abundantly observed by cross-sectional STM in low-temperature-grown (LT-) GaAs [5]. The present STM instrumentation coupled with optical spectroscopic

Fig. 1. (a) The configuration coordinate diagram suggested for EL2 [2] and (b) an isolated arsenic antisite (As_{Ga}) model [3,4] for EL2 suggested to explain, especially, the photoquenching effect.

measurements with nano-scale resolution (nanospectroscopy [6–8]) allowed us to show that individual single defects exhibit an infrared photoabsorption spectrum quite similar to that of EL2, and a photo-induced transformation with an excitation spectrum very close to that obtained for the photoquenching effect.

The LT-GaAs undoped film of 200 nm in thickness was grown homoepitaxially on a Si-doped n-type GaAs (001) substrate ($n \sim 10^{18} \text{ cm}^{-3}$) at 250°C in a VG-SEMICON VG80H molecular beam epitaxy (MBE) system. A clean (110) surface was prepared by cleaving a wafer piece in the ultra-high vacuum (UHV) STM chamber (UNISOKU, a custom model, base pressure $< 2 \times 10^{-8} \text{ Pa}$) and probed with a Pt–Ir tip.

Other than the instrumentation for the conventional scanning tunneling spectroscopic (STS) measurements [9], the present experimental set-up, schematically shown in Fig. 2, contained implements for photo-spectroscopic measurements as well. The monochromatic light from a monochromator was used to illuminate the sample surface at various photon energies.

For photoabsorption measurements, the light was chopped and the induced change of the tunneling current that occurs anyhow reflecting the photoabsorption of the sample were detected by a lock-in amplifier tuned at the chopping frequency. The photoabsorption

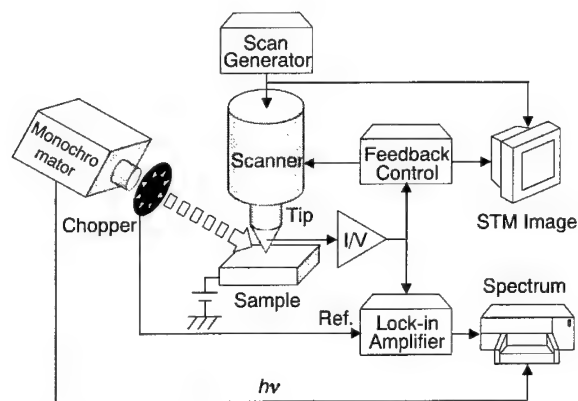

Fig. 2. The schematic diagram of the experimental setup for photoabsorption nanospectroscopy. A change in the tunneling current induced by photoabsorption of a defect is detected by a lock-in amplifier as a modulation signal synchronizing with the chopped light from a monochromator. The photoabsorption spectrum can be obtained by measuring the output of the lock-in amplifier as a function of the photon energy of the light.

signals could be generated by various mechanisms. Here we consider a case in which the STM tip positioned above a defect site is biased to extract electrons from the electronic level associated with the defect. When the electron occupying the defect level is optically pumped to an unoccupied upper level, the tunneling current will be reduced since the electron occupancy is decreased. Therefore, the photon energy dependence of the modulated signal of the tunneling current (ΔI) detected by the lock-in amplifier represents the photoabsorption spectrum of the defect. In the present experiments, the chopping frequency was chosen to be 1 kHz, high enough for the thermal expansion effect [7] to be suppressed and for the current modulation to be undamped by the STM feedback control. The photoabsorption measurements were performed at room temperature.

For inducing photoreactions that are to be detected in STM images, the sample was illuminated continuously in order to avoid thermal disturbance caused by light chopping. The spectroscopic measurements of the photoreaction rate were conducted at 90 K, low enough for the photoquenching effect to be observed. Excitation spectra of the photoreaction were obtained by measuring the mean rate of the atomic reaction that was detected in the repetitively acquired STM images of the same surface that was continuously subject to illumination with various photon energies.

Fig. 3(a) shows an STM image of the representative defects observed at room temperature in the cross-section of the LT-GaAs samples. The defects have characteristic contrasts appearing the same as those first reported by Feenstra et al. [10] and later cited by Jaeger

Fig. 3. (a) A typical STM image of a defect observed in an LT-GaAs epi-layer at room temperature and (b) the STS spectrum obtained at the defect site exhibiting a distinct midgap donor level. (c) The photoabsorption spectrum obtained with a tip fixed above one of the defects and setting the sample bias voltage at -0.5 V with respect to the tip so that the tunneling current is supplied from the midgap level if occupied. Note the spectrum is quite similar to the infrared absorption spectra observed in bulk GaAs crystals containing EL2 centers [1].

and Weber [11]. The STS spectra (Fig. 3(b)) obtained at these defects show that they commonly possess a deep donor level around the midgap energy, consistent with the previous report by Feenstra et al. [10].

The photoabsorption spectrum obtained by positioning the tip at the defect site and fixing the sample bias voltage at -0.5 V to extract electrons from the midgap level is shown in Fig. 3(c). The optical spectrum is characterized by the threshold around 1.05 eV followed by the gradually increasing infrared absorption background up to 1.4 eV, and a clear hump around 1.2 eV.

At 90 K, we found that prolonged light illumination causes a transformation of the majority of the point defects from the normal state (Fig. 4(a)) to a state quite different in the STM image (Fig. 4(b)). The STS spectra in the transformed state exhibited no gap levels in contrast to the initial normal state (Fig. 4(c)) as shown in Fig. 4(d). Though the transformed state persisted for long time if kept intact other than illumination, we found that the defect contrasts and the STS spectrum are recovered to the normal state immediately when we injected tunneling electrons to the defect at an appro-

Fig. 4. (a) A typical STM image in the normal state and (b) the STM image in the metastable state transformed from the normal one by light illumination at 90 K (The images were taken at $V_s = -2.3$ V and $I_t = 100$ pA). The metastable state is recovered by injection of electrons from the tip to the defect. The STS spectrum at the defect site in the normal state (c) and in the metastable state (d). In the metastable state the midgap level disappears. Such bistable behaviors were not observed at room temperature.

prate positive sample bias. Taking full advantage of this effect of electron injection allowing 'initialization' of the defect state, we could conduct such experiments that after 'initialized' the defect state by the electron injection, we repeated STM observations under a 'non-destructive' imaging condition ($V_s = -2.3$ V, $I_t = 100$ pA) and as a function of the number of scans (time) we counted the number of the defects that changed the contrasts by the effect of the continuous light illumination. We repeated such experiments for various photon energies and obtained an excitation spectrum of such transformation as shown in Fig. 5.

The infrared absorption spectrum shown in Fig. 3(c) is quite similar to that obtained by macroscopic photoabsorption measurements on GaAs crystals containing EL2 centers. However, we should not hastily conclude that the defects probed with the STM tip are the EL2 centers, because the tunneling current flowing through the defect level probed directly by the STM tip must be supplied by hopping conduction via other centers densely populated in the crystals as pointed out by Grandidier et al. [14]. In other words the spectrum might simply reflect the photoabsorption of the centers along the conduction path rather than the defect at the surface observed by STM.

Nevertheless, the photo-induced transformation of the defects observed at 90 K is quite consistent with the

Fig. 5. The Excitation spectrum of the photo-induced transformation from the normal state to the metastable state. The spectrum is very close to that (broken line) measured by Fisher et al [15] for the macroscopic photoquenching effect of EL2 centers, indicating that the defects observed in the present experiments are EL2.

photoquenching behavior of EL2. The absence of the photo-transformation at room temperature and the long lifetime of the transformed state at the low temperature indicate that the transformed state is metastable. The excitation spectrum of this transformation is very close to that reported by Fisher [15] for the normal to metastable transition of EL2 centers that was studied by macroscopic measurements. The ambiguity discussed above in the interpretation of the local photoabsorption detected by the present method does not exist in the photo-transformation experiments because the transformation does not need the presence of other defects. Also the electron-injection-induced recovery of the metastable state to the normal state is consistent with another feature observed in EL2 [3,16,17]. Therefore, we can safely conclude that the defects observed are EL2 centers.

The defects in LT-GaAs giving the characteristic contrasts were identified by ab-initio calculations of STM images [12,13] to isolated As_{Ga} embedded in the first few layers beneath the (110) surface. The isolated arsenic antisites (As_{Ga}) model of EL2 has achieved successful interpretation for the bistable behaviors of EL2 including the photoabsorption, the photo-transformation and the electron-injection-induced recovery (the

process being illustrated in the coordination diagram in Fig. 1(a) [3]). The STM image of an isolated As_{Ga} in the metastable state was calculated by Zhang [13], but the bias polarity is different from that used in the present study (Note imaging with positive sample biases causes the structural recovery). Although the defect image shown in Fig. 4(b) is one obtained for the first time for the EL2 centers at the metastable state, the direct verification of the validity of the isolated As_{Ga} model was not possible at present from the image comparison. If reasonably we can assume that the present defects are isolated As_{Ga} , we can conclude that the atomic structure of EL2 is isolated As_{Ga} .

Abstract

The diffusion of sulfur was investigated in order to study arsenic self-diffusion. From in-diffusion experiments the effective diffusion coefficients of sulfur and arsenic were determined in the temperature range between 750°C and 1100°C. For this purpose, different surface concentrations of sulfur were provided to establish the diffusion model. The simulations show that As self-interstitials are responsible for the diffusion of sulfur under thermal non-equilibrium of native point defects. The self-diffusion coefficient and the solubility of As self-interstitials were determined. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Dopant diffusion on the group-III sublattice of GaAs was extensively studied in the past, because most of the common dopants are dissolved on this sublattice. In the last few years, the diffusion on the group-V sublattice has become more and more important. Carbon as an acceptor for base doping of HBTs is dissolved on the As sublattice as well as nitrogen for active layer doping of VCSELs. Therefore, reliable diffusion data for this sublattice are necessary. Sulfur, which is a donor, can be used as a vehicle to study dopant diffusion and additionally As self-diffusion on the group-V sublattice of GaAs. Therefore, several experiments and simulations were performed to investigate diffusion depth profiles. It is known that the diffusion behavior of S in GaAs can be described within the kick-out diffusion model [1],

where i_S^+ denotes interstitially dissolved S, S_{As}^+ substitutionally dissolved S and I_{As}^0 an As self-interstitial. k_{KO}^+ and k_{KO}^- are the reaction constants in forward and backward direction. The backward reaction constant is given according to [2] as a diffusion controlled value,

$$k_{KO}^- = 4\pi r_c D_{I_{As}}. \quad (2)$$

In Eq. (2) r_c is the capture radius and $D_{I_{As}}$ the diffusion constant of As self-interstitials. The shape of the diffusion profile and the depth distribution can be controlled by the amount of S at the sample surface. At low concentrations the diffusion is governed by the kick-out diffusion under thermal equilibrium of native point defects. For a high S concentration at the surface the diffusion of S is mainly determined by the diffusion of the As self-interstitials. Based on this thermal non-equilibrium of native point defects self-diffusion of As can be described by simulations.

2. Experiments

For the experiments, undoped semi-insulating Bridge-man-grown GaAs with a low dislocation density was

*Corresponding author.

E-mail address: engler@mpi-halle.mpg.de (N. Engler).

used. After cleaning the samples were added into pre-cleaned quartz tubes. In order to establish an arsenic vapor pressure during the annealing procedure metallic arsenic was added to the ampoule in an amount needed for a 1 bar partial vapor pressure. Sulfur was dissolved in benzene to provide a small concentration and filled into the ampoule before evacuating down to 2×10^{-6} Torr and sealing. The experiments were performed in the temperature range between 750°C and 1100°C with different concentrations of S provided during the annealing procedure. After annealing the samples were quenched to room temperature. The depth profiles of sulfur were recorded by secondary ion mass spectrometry (SIMS) and analyzed by simulating the diffusion according to the 2nd Fickian Law and the kick-out model with the process simulator Zombie [3].

3. Results and discussion

Fig. 1 shows the depth profiles after in-diffusion at 850°C for 4 h. Providing a low S surface concentration of $c_{\text{S}}^{\text{surf}} = 2 \times 10^{18}$, represented by circles, the diffusion occurs under conditions closed to thermal equilibrium of native point defects. This can be described by the relation of the transport capacities, given by the product of the diffusion coefficient and the solubility of the mobile species,

$$D_{\text{IS}} c_{\text{IS}}^{\text{eq}} \approx D_{\text{IAS}} c_{\text{IAS}}^{\text{eq}}. \quad (3)$$

In this case, only a slight supersaturation of As self-interstitials has been established. The second profile with a surface concentration of $c_{\text{S}}^{\text{surf}} = 2.2 \times 10^{20}$ shows a non-equilibrium behavior of native point defects. The relation of the transport capacities is given by

$$D_{\text{IS}} c_{\text{IS}}^{\text{eq}} \gg D_{\text{IAS}} c_{\text{IAS}}^{\text{eq}}. \quad (4)$$

Fig. 1. In-diffusion profiles of sulfur after annealing at 850°C for 4 h. The surface concentration of S was varied between 2×10^{18} and $2.2 \times 10^{20} \text{ cm}^{-3}$. The symbols represent the total concentration measured by SIMS and the lines are the simulated concentration of substitutionally dissolved sulfur.

Under thermal non-equilibrium of native point defects the diffusion progress is controlled by the slower diffusing point defect. These experiments and simulations have shown that As self-interstitials are the diffusion controlling point defects. From the simulations, we were able to extract the diffusion coefficient and the solubility of the IAS according to the relation

$$D_{\text{AS}}^{\text{eff}} = \frac{D_{\text{IAS}} c_{\text{IAS}}^{\text{eq}}}{c_{\text{SAS}}^{\text{eq}}}. \quad (5)$$

For the simulations $D_{\text{AS}}^{\text{eff}}$ was kept constant and the solubility $c_{\text{SAS}}^{\text{eq}}$ is given by the surface concentration of sulfur.

Fig. 2 represents the effective diffusion coefficients of As and S. The As self-diffusion coefficient was determined as

$$D_{\text{AS}}^{\text{eff}} = (8.54 \pm 1.88) \times 10^{-1} \times \exp\left(-\frac{4.01 \pm 0.19 \text{ eV}}{k_{\text{B}} T}\right) \text{ cm}^2 \text{ s}^{-1} \quad (6)$$

and the effective diffusion coefficient of sulfur as

$$D_{\text{S}}^{\text{eff}} = (8.95 \pm 1.08) \times 10^{-4} \times \exp\left(-\frac{2.29 \pm 0.11 \text{ eV}}{k_{\text{B}} T}\right) \text{ cm}^2 \text{ s}^{-1}. \quad (7)$$

The value for As is in a good agreement with the effective As self-diffusion coefficient determined by Stolwijk et al. [4] and the value for sulfur with that reported by Young and Pearson [5]. For all simulations, the conditions

$$c_{\text{S}}^{\text{eq}} \gg c_{\text{IS}}^{\text{eq}} \quad \text{and} \quad c_{\text{IAS}}^{\text{eq}}; c_{\text{IS}}^{\text{eq}} \leq n_{\text{i}} \quad (8)$$

Fig. 2. Effective diffusion coefficients of As from S in-diffusion experiments [1], As tracer diffusion [7,8], N inter-diffusion [9,4] and this work. Additionally, the effective S diffusion coefficient is shown as symbols (this work) in comparison with literature data [5].

Fig. 3. Solubility of As self-interstitials. The values were determined from experiments under non-equilibrium conditions. The dashed line represents the intrinsic carrier concentration [6].

were established to calculate the diffusion parameters. n_i represents the intrinsic carrier concentration and is given in Ref. [6]. To determine the diffusion coefficients the set of partial differential equations for every point defect in Eq. (1) was solved numerically by the simulation program Zombie [3]. In all simulations, the As self-interstitials are assumed to be neutral. For these conditions, the solubility of the As self-interstitials as a function of the inverse temperature is shown in Fig. 3. Additionally, the intrinsic carrier concentration according to [6] is shown in this figure. The solubility of As self-interstitials was determined as

$$c_{I_{As}}^{eq} = (1.2 \pm 1.31) \times 10^{24} \times \exp\left(-\frac{1.95 \pm 0.13 \text{ eV}}{k_B T}\right) \text{ cm}^{-3}. \quad (9)$$

The values calculated in Eq. (9) are in agreement with the condition described in Eq. (8).

4. Conclusion

After sulfur in-diffusion experiments we investigated depth profiles of sulfur using SIMS and theoretically by simulations. Based on these investigations we determined the effective diffusion coefficients of S and As. Additionally, from non-equilibrium profiles we extracted the diffusion coefficient as well as the solubility of As self-interstitials.

On the microscopic structure of the EL6 defect in GaAs

Th. Steinegger^a, B. Gründig-Wendrock^c, M. Jurisch^b, J.R. Niklas^{c,*}

Abstract

Among the intrinsic defects in GaAs the EL6 gains more attention due to its properties as a non-radiative recombination centre. Also, for an efficient defect engineering its atomistic structure becomes an important question. There are many suggestions for this structure in the literature, however, nothing definite is known so far. From a combination of results from PICTS experiments to measure the EL6 concentration, positron annihilation, infrared absorption and laser scattering tomography arguments are put forward which point to a structure $\text{As}_{\text{Ga}}\text{-V}_{\text{As}}$ for the EL6. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaAs; Defects; PICTS

1. Introduction

Among the intrinsic defects in GaAs, the midgap double donor EL2 is the most prominent and the most important one since it enables the GaAs to become semi-insulating (SI) by overcompensating shallow acceptors which, in turn, compensate shallow or medium deep donors. Progress in GaAs technology made it more and more possible to reduce the concentrations of extrinsic impurities and at the same time other, so far, less considered intrinsic defects like the EL6 gain attention. Moreover, it turned out that the EL6 plays an important role as a recombination centre determining the lifetime of excess carriers [1,2]. For these reasons, also the atomistic structure of this defect becomes an increasingly important factor from a basic point of view and also for the optimisation of defect engineering. However, so far, almost nothing is known definitely about the structure of the EL6. Since no spin resonance experiments are available for the EL6 there are only cumbersome indirect ways to first ideas of its structure. Many suggestions are found in the literature: $\text{V}_{\text{Ga}}\text{-V}_{\text{As}}$ [3–6]; $\text{V}_{\text{Ga}}\text{-As}_i$ or $\text{V}_{\text{Ga}}\text{-X}$ [7,8]; $\text{As}_{\text{Ga}}\text{-X}$ [9]; $\text{As}_{\text{Ga}}\text{-As}_i$ or

$\text{As}_i\text{-X}$ [10,11] and finally $\text{V}_{\text{As}}\text{-X}$, $\text{As}_{\text{Ga}}\text{-V}_{\text{As}}$ or $\text{V}_{\text{Ga}}\text{-As}_i\text{-V}_{\text{As}}$ [12–16]. The aim of this work is to find arguments for or against of some of these models using results of IR-absorption experiments [17], laser scattering tomography (LST) [18], positron annihilation (PA) [19], and finally, photo-induced current transient spectroscopy (PICTS) [20]. It is well known for GaAs that different annealing procedures greatly influence the concentration of Ga and As interstitials or vacancies and various intrinsic defects. This is reflected by the results of the above mentioned experiments giving rise to arguments for falsification or verification of structural models of the EL6.

2. Annealing procedures

Special annealing procedures with different temperature–time regimes were used for the GaAs samples investigated. These procedures are usually characterised by the following four steps: (a) A homogenisation at 1453 K resolves As precipitates and atmospheres of structural defects. (b) In the following regime of cooling down, an As supersaturation takes place with the formation of As nuclei. (c) During the subsequent temperature–time regime precipitates grow, additional

*Corresponding author. Tel.: +49-3731-39-2860; Fax: +49-3731-39-4314.

E-mail address: niklas@physik.tu-freiberg.de (J.R. Niklas).

As nuclei are formed and excess As interacts with other defects. (d) Finally, quenching to room temperature stabilises the defect structures thus obtained.

For the following experiments, a more special annealing regime was used. After the homogenisation at 1453 K for 20 h (warm-up rate 1 K/min) and subsequent quenching to room temperature, a second heating with 52 K/min to 1073 K was performed. Each sample was kept at this temperature for a well defined time ranging from 10 to 7200 min before recycling to room temperature again. All measurements took place at room temperature or below and therefore each measurement point in the following figures corresponds to a new sample. The samples treated this way differ clearly also by their EL6 content.

3. Experimental results

The relative concentrations of the EL6 defect were measured by PICTS. This type of spectroscopy delivers results similar to those of DLTS. However, in contrast to DLTS, no capacitance transients of a junction are evaluated but only photoconductivity transients due to a thermal re-emission of carriers out of levels which were filled by a preceding light pulse. This spectroscopy requires no co-doping with shallow levels and is therefore applicable also to high resistive SI material. However, as a drawback, PICTS furnishes no precise information about absolute concentrations of defects but only good values for relative defect concentrations for the same defect as a function of different preparations. Results of PICTS experiments are shown in Fig. 1, where the concentration of the EL6 is plotted versus annealing time, t , at 1073 K. The data indicate a drop of the EL6 concentration by about one order of magnitude

Fig. 1. Concentration of EL6 as measured by PICTS as a function of annealing time. Each dot corresponds to a new sample. Full squares, medium pressure GaAs (inert gas pressure during LEC crystal growth); open squares, low pressure GaAs.

Fig. 2. Concentration of $EL2^0$ as a function of annealing time. Upper curve, medium pressure GaAs; lower curve, low pressure GaAs.

with annealing. It should be stressed that the EL6 concentration is no longer diminished for annealing times longer than 60 min. After this time it remains constant at a value of about 10% of its starting value right after quenching. Fig. 2 reflects the annealing behaviour of the $EL2^0$ as measured by IR-absorption. With increasing annealing time the concentration of the $EL2^0$ increases by roughly a factor of 2 until a maximum at 60 min and then it decreases again. Fig. 3 shows the concentration of V_{Ga} by PA. These data must be taken with some care. There is a detection limit due to background signals as indicated by the horizontal line. The actual V_{Ga} concentrations for the higher annealing times might be well below this line. The concentration of precipitates was measured by LST. The data indicate a continuous increase with annealing time.

4. Interpretation of results and discussion

It is generally accepted that the structure of the EL2 is basically As_{Ga} . Based on ODENDOR-experiments an additional As_i in [1 1 1] direction was put forward [21], it was, however, also shown that the ODENDOR results published do not necessarily require the assumption of this As_i and that this assumption is moreover in contradiction to the corresponding ODEPR spectrum [22]. This controversy, however, does not substantially affect the following arguments. For the interpretation of the results, it is most important that the concentration of the EL2 exhibits a maximum at an annealing time of about 60 min and that exactly after this time the concentration of the EL6 does no longer change. It would be hard to believe that this behaviour could occur if the structures of the EL2 and EL6 were completely unrelated to each other. This is one argument to assume that the structure of the EL6 contains a unit As_{Ga} like in

Fig. 3. Concentration of Ga-vacancies as obtained by positron annihilation as a function of annealing time (medium pressure GaAs).

$\text{As}_{\text{Ga}}\text{-V}_{\text{As}}$ or $\text{As}_{\text{Ga}}\text{-As}_i$ rather than a unit V_{Ga} . The structure As_{Ga} is apparently very stable as indicated by the relatively high concentration in the order $10^{16}/\text{cm}^3$ of the EL2 right after quenching from 1453 K (so-called as-grown state). Under the same conditions the concentration of the EL6 is estimated to be in the order $10^{15}/\text{cm}^3$ [23] indicating a likewise lower stability for this defect. The increase of the EL2 concentration with annealing time by roughly a factor of 2 corresponds well to the decrease of the V_{Ga} from about $10^{16}/\text{cm}^3$ to 'zero' (note PA detection limit): 'All' V_{Ga} are occupied by former As_i to form EL2 at an annealing time where the EL2 concentration reaches its maximum. Due to the high stability of the EL2 the concentration of still existing V_{Ga} in the equilibrium between EL2 and V_{Ga} together with As_i should be, therefore, extremely small, much smaller than the observed concentration of the EL6. This is taken as a further argument not to assume V_{Ga} as an integral part of the EL6.

Assuming now $\text{As}_{\text{Ga}}\text{-V}_{\text{As}}$ for the EL6 gives a much more consistent picture. EL6 is converted to EL2 which contributes to the increase of the EL2 for the lower annealing times. Later the EL6 concentration is stabilised by the equilibrium between $\text{As}_{\text{Ga}}\text{-V}_{\text{As}}$ (EL6) together with As_i and As_{Ga} (EL2). At the higher annealing times the EL2 may be destroyed by more and more accumulation of further As converting EL2 defects to As precipitates. At least in the beginning of this process the EL6 equilibrium is not affected too much since both the EL2 and the As_i concentrations are diminished when forming As precipitates.

The above arguments are indeed not yet able to really establish the structure $\text{As}_{\text{Ga}}\text{-V}_{\text{As}}$ for the EL6. However, there are clear hints towards this assumption to motivate further more specific experiments like spatially resolved defect analyses to account for the cellular structure of

the GaAs. Such special PICTS experiments are underway.

Abstract

As-grown substrate-free LT-GaAs (200°C) and annealed samples (up to 660°C) have been investigated with magnetic circular dichroism of absorption (MCDA) and optically detected electron paramagnetic resonance (MCDA-EPR) in K- and W-bands. MCDA-EPR spectra of all samples reveal several As_{Ga}-related defects with different excitation spectra, that indicate their different structures in as-grown and annealed material. A strong change occurs in samples annealed above 400°C. The ODEPR spectra show another yet unknown defect which we attribute to a Ga vacancy-related defect. Samples annealed at 500°C exhibit EL2-like MCDA spectra. From the above band gap MCDA spectra of the EL2-like defects evidence is found for their low symmetry. The bleaching properties and spin-lattice relaxation times of the different As_{Ga}-related defects were investigated and compared with the properties of the EL2 defect in bulk semi-insulating GaAs. © 2001 Elsevier Science B.V. Keywords: LT-GaAs; As_{Ga}-related defect; Lift-off; MCDA-EPR

1. Introduction

The non-stoichiometry of LT-GaAs (As-rich) is a reason of really unique properties which have found many applications. The ultra short lifetimes of photo-generated carriers (< 1 ps), semi-insulating (SI) behavior after annealing and other useful properties influenced the development of different devices working in THz region [1]. Most of these features are caused by native point defects, mainly As_{Ga}-related defects, in extremely high concentrations (10^{18} – 10^{20} cm⁻³) which control the optical and electrical properties [2].

In general, in As-rich LT-GaAs three native point defects (or complexes between them) are favored: As antisite (As_{Ga})-like defects, Ga-vacancies (V_{Ga}) and As interstitials (As_i). Evidence was found for all of them [3–5], but their role and identification is still questioned, especially in connection with dramatic changes of the properties after annealing. The concentration and probably also the microscopic structure of the native

defects are influenced by annealing, which is often required in device processing. The question arises whether the defects are only modified by the annealing with respect to strain or charge states or whether different defects exist in as-grown and annealed material.

The dominant deep donor in LT-GaAs is regarded to be an As_{Ga}-related defect, a defect similar to the well-known EL2 defect which is responsible for the compensation of SI bulk GaAs. The optical and electrical properties of the EL2 defect are well known and have been extensively investigated. However, the mechanism of its metastability as well as its microscopic structure have still remained controversial issues. Similar bleaching behavior was observed for As_{Ga}-related defects in LT-GaAs, although less effective, and together with the SI properties supported somehow the suggestion that native defects in LT-GaAs are EL2-like defects [6,7].

In this paper we present and discuss experimental results which were obtained with magnetic circular dichroism of the optical absorption (MCDA) and MCDA detected electron paramagnetic resonance (MCDA-EPR) of substrate-free GaAs layers grown by

MBE at low substrate temperature ($\sim 200^\circ\text{C}$) and annealed after growth at different temperatures. Investigations were performed within a wide range of photon energies (0.7–1.8 eV) and MCDA-EPR in K- and W-microwave frequency bands (~ 24 and ~ 94 GHz, respectively) has been measured. Furthermore, the bleaching properties of As_{Ga} -related defects in LT-GaAs and of EL2 defects in SI bulk GaAs have been investigated for comparison. Experimental details can be found elsewhere [8].

The LT-MBE GaAs samples were grown in the University of California (Santa Barbara, USA) and in the University of Erlangen, Germany (Institut für Technische Physik). The temperature of the GaAs substrate was about 200°C . The thickness of the layers varied from 0.5 to $1\ \mu\text{m}$. After growth the samples were annealed in N_2 atmosphere at different temperatures from 200°C up to 660°C with minimal temperature steps of 50°C . To suppress the As evaporation, the surface of the samples was laid face down onto a GaAs substrate during annealing. After annealing the samples were prepared with a lift-off technique where the MBE films were separated from the GaAs substrate and glued onto glass plates [9]. This procedure was performed in the University of Erlangen.

2. Experimental results and discussion

ODEPR spectra of as-grown (200°C) and annealed (500°C) LT-GaAs measured via the MCDA at 0.93 and 1.12 eV are shown in Figs. 1a and b, respectively. The spectra are detectable in four different series of samples in different MCDA bands with exception of the samples annealed above 600°C , in which the MCDA-EPR

spectra of the LT-GaAs disappear. The MCDA-EPR spectra show mainly the four line hyperfine (hf)-split spectra due to As_{Ga} -related defects (nuclear spin of ^{75}As is $I = \frac{3}{2}$) [10]. The spectra are isotropic. Important to note are the large line widths ($W_{1/2}$) of about 40–50 mT of each hf line consistent with conventional EPR measurements of such samples [11]. The hf lines are broader than those measured for the EL2 defects in SI bulk GaAs (~ 38 mT). The g -values range from 2.030 to 2.041 for samples annealed at different temperatures. The central ^{75}As hf interaction of 2630 MHz is nearly constant.

The difference in intensity of the four hf lines does not disappear even at lowest microwave power levels ($\sim \mu\text{W}$), where forbidden transitions are suppressed definitely [15]. Therefore, one has to assume that a superimposed MCDA-EPR spectrum with a large line width and g factor of about 2.04 is also measured. It has the typical line shape (dashed curve 1 in Fig. 1) as was observed for different intrinsic acceptors in bulk GaAs [12]. It should be noted that the new spectrum was detected both in the as-grown and the annealed samples. We attribute the new MCDA-EPR line to V_{Ga} -related defects for the following reasons: (i) V_{Ga} is very probable in As-rich high non-stoichiometric LT-GaAs and (ii) positron annihilation experiments detect high concentrations of V_{Ga} defects in the same material [5]. V_{Ga} is a multiple acceptor with a T_2 ground state in the band gap of GaAs and is compensated by As_{Ga} -related donors. V_{Ga} -related defects with trigonal symmetry were detected and identified earlier in electron-irradiated GaAs [13,14]. The measured spectrum is compatible with the V_{Ga} (trigonal) for B [100] with a g -value of about 2.04 and a shf interaction with one ^{75}As neighbor of about 540 MHz.

In addition to the V_{Ga} -related defects another MCDA-EPR spectrum was observed for samples annealed above 450°C exposing the material to light with a photon energy above 1.12 eV (dashed curve 2 in Figs. 1b and c). It has a g -factor of about 1.98. Unfortunately, the large line widths and high intensity of the As_{Ga} -related spectra prevent the reliable identification of the defect. Neither the tagged MCDA technique nor high-frequency (91 GHz) MCDA-EPR (Fig. 1c) measurements could separate the different spectra.

The small differences in the MCDA-EPR parameters of the As_{Ga} -related defects could be an indication that different As_{Ga} -related defects exist in as-grown and annealed material. Rather strong evidence for that was obtained with the tagged MCDA technique, where when setting the EPR resonance conditions to a particular ODEPR line and varying the optical wavelength the EPR line of the defect can be correlated with its optical properties [8]. Fig. 2 shows such excitation spectra for the as-grown sample (Fig. 2a) and for the 500°C

Fig. 1. (a) MCDA-EPR spectrum of as-grown (200°C) LT-GaAs measured at 24.0 GHz with photon energy of 0.92 eV at 1.5 K. (b) MCDA-EPR of annealed (500°C) LT-GaAs measured with light energy of 1.12 eV at 23.5 GHz and temperature of 1.5 K and (c) the same spectrum measured at 91 GHz (W-band).

annealed sample (Fig. 2b). Clearly the spectra are different. From earlier investigations of several different As_{Ga} -related defects in electron-irradiated GaAs it is known that most of them have nearly indistinguishable MCDA-EPR spectra, but different tagged MCDA spectra which serve as their fingerprints [15]. MCDA-detected electron nuclear double resonance experiments confirmed evidently the difference in the microscopic structure of the defects [15,16]. We conclude therefore that we deal with different As_{Ga} -related defects in as-grown and annealed LT-GaAs. Furthermore, one can notice the similarity of the MCDA spectrum of the annealed (500°C) LT-GaAs sample and the MCDA spectrum of the EL2 defect (dashed line), which appears in SI bulk GaAs (Fig. 2b). The critical annealing temperature lies near 400°C, where the MCDA and MCDA-EPR spectra nearly disappear. This behavior has been observed in different series of samples. It may indicate that the Fermi level position is shifted because of the recombination of defects or reconstruction of the microscopic structure of defects, which affect their electronic levels in the band gap.

Of particular interest are also the MCDA transitions at photon energies above the band gap of GaAs (Fig. 2). The preparation of the LT-GaAs films with the lift-off technique enabled us to perform MCDA and MCDA-EPR measurements without the influence of the GaAs substrate and very importantly, to measure above the band gap. For example, in as-grown LT-GaAs, a MCDA-EPR signal was detected using the photon energy of 1.69 eV (730 nm). For the isolated As_{Ga} defect the MCDA spectrum, which shows a single derivative-like shape, has been interpreted as belonging to a transition from the A_1 ground state to a localized excited T_2 state in the conduction band [17]. For the EL2 defect and also for the EL2-like defects in LT-GaAs more

transitions are observed, which are probably explained by a symmetry reduction which splits the excited state T_2 confirming previous MCDA-EPR/ENDOR results that EL2 is not the isolated As_{Ga} defect [18].

Of interest are also the different spin-lattice relaxation times T_1 measured for the different As_{Ga} -related defects. The MCDA depends only on the longitudinal magnetization, therefore only on T_1 [8]. From such measurements a difference between the As_{Ga} -related defects in as-grown and annealed material was found. T_1 of the defects in as-grown material was measured to be ~ 0.7 – 1 s at 1.5 K, while in annealed samples at 500°C it is ~ 3.5 – 4 s. The latter value is almost the same as that measured for EL2 defects in SI bulk GaAs. Interesting to note is that As_{Ga} -related defects in LT-GaAs (200°C) on substrate studied earlier showed T_1 times of < 100 ms [10]. It seems that the lattice mismatch between substrate and layer induce additional strains which reduce the T_1 times similarly to observations in plastically deformed GaAs.

For comparison of EL2 defects in bulk GaAs and As_{Ga} -related defects in annealed LT-GaAs the metastable properties have also been investigated under light illumination at low temperatures. It has been argued that the As_{Ga} -related defects in LT material are modified EL2 defects because of the lattice strain caused by the As excess. Inspecting the bleaching behavior of the native defects in as-grown and annealed LT-GaAs we have observed rather complicated bleaching dynamics which depend strongly on annealing. Our investigations confirm that the bleaching efficiency for the As_{Ga} -related defects in LT GaAs is shifted to higher photon energies, what has been observed previously also by different techniques [6]. The shift in photon energy depends on the annealing temperature and seems to be maximal for as-grown samples with lowest bleaching efficiency. When exposing the samples to light which was usually used to bleach the EL2 defect ($h\nu \sim 1.2$ eV), we have observed the opposite effect, namely enhancement of the MCDA-EPR spectra. This can be related to recharging from the diamagnetic (As_{Ga}^0) to the paramagnetic (As_{Ga}^+) charge states. The maximal enhancement was detected for as-grown LT-GaAs. Exposing the material to white light during 4 h only $\sim 32\%$ of the total MCDA of the defects in samples annealed at 500°C could be bleached. For as-grown material this value is even less (near 10%), which indicates that most of the As_{Ga} -related defects are unbleachable. It seems likely that we deal with As_{Ga} -related defects in different local environments and structures.

Fig. 2. Tagged MCDA spectra of As_{Ga} -related defects in (a) as-grown (200°C); (b) annealed at 500°C LT-GaAs. Measurement temperature 1.5 K, microwave frequency 24.8 GHz, resonance field B of 700 mT.

3. Summary

MCDA and MCDA-EPR spectra of different As_{Ga} -related defects in as-grown and annealed LT-GaAs have

been observed. A critical annealing temperature has been determined to be about 400°C. In samples annealed near 500°C EL2-like defects were detected, whereas for annealing at 600°C and above As_{Ga} -related MCDA-EPR spectra disappeared. The MCDA-EPR spectra superimposed on the spectra of the As_{Ga} -related defects were attributed to V_{Ga} -related defects, consistent with positron annihilation experiments. The lift-off sample preparation technique allowed the observation of the MCDA bands of the As_{Ga} -related defects with photon energies exceeding the band gap energy of GaAs. These transitions were attributed to localized excited states in the conduction band, which are indicative of low symmetry defects where the T_2 excited state of the isolated As_{Ga} is split. The EL2-like defects observed in 500°C annealed LT-GaAs show nearly the same tagged MCDA spectra as those of EL2 defects in SI bulk GaAs and a maximum bleaching efficiency. Therefore, their structure should be similar. The large MCDA-EPR line widths of these defects are explained by local disorder and strain in the samples.

Abstract

For almost two decades the structure model of the EL2 defect in semi-insulating (SI) GaAs has been controversially discussed. Neither the isolated As_{Ga} with T_d symmetry, nor the $\text{As}_{\text{Ga}}\text{--As}_i$ pair model nor any other As_{Ga} -related defect model could be unambiguously established. The reason was that the analysis of previous optically detected electron nuclear double resonance (ODENDOR) and optically detected electron paramagnetic resonance (ODEPR) spectra measured at 24 GHz was difficult and not unambiguous because of forbidden transitions, pseudo-dipolar couplings and higher order effects. However, the ODEPR spectra of the EL2 defect measured in W-band (93 GHz) can be fitted by first order perturbation calculation of the spin Hamiltonian thus allowing a much simpler analysis compared to X- or K-band. From ODEPR measurements in different SI GaAs samples both in K- and W-band we show that the ODEPR spectra of the EL2 defect together with the K-band ODENDOR data are not consistent with the $\text{As}_{\text{Ga}}\text{--As}_i$ pair model, but the highly symmetric isolated As_{Ga} model has to be excluded as well. First ODENDOR measurements in W-band are also reported. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaAs; EL2; EPR; ENDOR

1. Introduction

The microscopic structure of the dominant deep donor EL2 in semi-insulating (SI) GaAs with its fascinating metastable properties is still not fully understood. Two microscopic models are mainly discussed (i) the isolated As_{Ga} model having T_d symmetry and the (ii) $\text{As}_{\text{Ga}}\text{--As}_i$ pair defect. The first model was based on piezospectroscopic studies of optical transitions of the EL2 defect [1] and favored by theory to explain the metastable state [2,3]. The second model was proposed from a combined study of electron paramagnetic resonance (EPR) and deep level transient spectroscopy (DLTS) [4] and supported by optically detected electron nuclear double resonance (ODENDOR) [5]. In 1992, ODENDOR studies of electron irradiation-induced

As_{Ga} -related defects revealed an As antisite defect which was attributed to the isolated As_{Ga} defect with higher symmetry (T_d) compared with EL2 [6]. In 1997, the model of the EL2 defect as an $\text{As}_{\text{Ga}}\text{--As}_i$ pair defect was questioned by a calculation of the width of the EPR lines measured in X- and K-band [7].

In principle, for each defect model derived by ENDOR, which allows the determination of the hyperfine (hf), super-hyperfine (shf) and quadrupole interaction tensors for many neighboring nuclei, the EPR line width has to be explained by a calculation using these ENDOR parameters. This is necessary because ENDOR permits only the determination of the ‘chemical’ nature and the symmetry and principal values of the interaction tensors of the neighboring nuclei, but not their numbers, i.e. how many members are in a shell [8]. The calculation of the EPR spectrum from the ENDOR parameters is necessary to confirm a proposed defect model. The analysis of previous

E-mail address: sp-it@physik.uni-paderborn.de (I. Tkach).

optically detected electron paramagnetic resonance (ODEPR) and ODENDOR spectra in K-band was very difficult because of forbidden transitions, pseudo-dipolar couplings and higher order effects in the spectra. The same holds for conventional X-band (10 GHz) EPR measurements. The EPR (and ENDOR) spectra would have to be calculated using exact diagonalization of the appropriate spin Hamiltonian with prohibitive large spin matrices preventing a satisfactory calculation.

We present the results of W-band (93–95 GHz) high-field/high-frequency ODEPR investigations of the EL2 defect in SI GaAs samples grown either by the liquid encapsulated Czochralski (LEC) or the horizontal Bridgman (HB) technique. The samples were cut to dimensions of $1.5 \times 1.5 \times 3.0 \text{ mm}^3$ and orientated by X-ray Laue analysis along the [001], [110] and [111] crystallographic axes. It is shown that the high-field ODEPR spectra can be described by first order perturbation calculation of the spin Hamiltonian thus allowing a much simpler analysis compared to X- or K-band spectra. First results of very recent ODENDOR measurements in W-band are also reported. The results are discussed with respect to the proposed EL2 structure models.

2. Experimental results

Fig. 1 shows the typical four-line hf-split ODEPR spectra of the EL2 defect in SI GaAs measured for $B_0 \parallel [001]$ in K-band (a) and W-band (b), respectively. The spectra were monitored with the magnetic circular dichroism of the absorption (MCDA) at 1.5 K in MCDA band centered at 0.94 eV. The observed hf splitting is due to the central ^{75}As nucleus of the antisite

Fig. 1. ODEPR spectra of the EL2 defect in GaAs measured in (a) K-band (24 GHz) and (b) W-band (93 GHz) for $B \parallel [001]$ at 1.5 K.

($I = 3/2$, 100% abundance) and is described by an isotropic hf constant of $2656 \pm 30 \text{ MHz}$ in agreement with the previously determined one from K-band. However, the four hf lines measured in W-band are equidistant (93 mT separation) in contrast to the K-band spectra where the hf line separation increases with increasing magnetic field.

The angular dependence of the ODEPR line widths measured in W-band is shown in Fig. 2. The center line positions of the hf ODEPR lines are isotropic. But the ODEPR line width varies by about 2.5 mT with the orientation of the samples. It is smallest for $B_0 \parallel [001]$ and largest for $B_0 \parallel [111]$, both in K- and W-band spectra. The ODEPR line widths in W-band are smaller by about 2 mT compared to K-band measurements. This result is expected because of reduced contributions of forbidden transitions in W-band. For example, ODEPR line widths measured very carefully with the lowest microwave power levels for $B_0 \parallel [001]$ are $38.0 \pm 0.8 \text{ mT}$ and $35.7 \pm 0.8 \text{ mT}$, in K- and W-band, respectively.

Fig. 3 shows the very first ODENDOR measurements in W-band for $B_0 \parallel [110] + 20^\circ$ (20° off $[110]$ in a (001) plane) setting B_0 into the flanks of two of the ^{75}As hf lines. Compared to the many ENDOR lines in K-band [5] due to higher order effects there are less lines. All lines are due to ^{75}As and $m_s = -1/2$ ('sum' frequencies) as seen from the lines shifts when varying B_0 . No further sample orientations could yet be measured. Further work is in progress.

3. Discussion

Wirbeleit et al. [7] have performed calculations of the EPR/ODEPR line width of the EL2 defect using an exact diagonalization of the spin Hamiltonian and

Fig. 2. Angular dependence of the ODEPR line widths of the EL2 defect in SI GaAs measured in W-band for rotation of the magnetic field in the (011) plane. 0° corresponds to $B \parallel [001]$ and 90° to $B \parallel [110]$.

Fig. 3. ODENDOR spectra measured in W-band (93 GHz) for $B_0 \parallel [1\ 1\ 0] + 20^\circ$ (20° in $(0\ 0\ 1)$ plane) for two B_0 values. All lines are due to ^{75}As nuclei.

compared the results with experimental spectra. Unfortunately, Wirbeleit et al. did not publish absolute values for the line widths. They concluded, that the $\text{As}_{\text{Ga}}\text{--As}_i$ pair model for the EL2 defect was wrong and that the half width calculated with the ENDOR parameters without the As interstitial is consistent with the EPR line width, i.e. they favored the isolated As_{Ga} antisite model. However in their calculations Wirbeleit et al. used some approximations: (i) they considered only off-diagonal elements of the spin matrices near the diagonal and (ii) they neglected the central ^{75}As hf interaction. Unfortunately, a calculation of the EPR spectra never appeared using their full diagonalization procedure.

The equidistance of the four-line hf-split ODEPR spectrum measured in W-band indicates that the spectrum can be calculated in the first order perturbation theory approximation, i.e. the Zeeman interaction is much stronger than the hf interaction of the central ^{75}As nucleus. Thus, the W-band ODEPR spectra are much simpler to analyze in comparison with X- or K-band spectra because forbidden transitions of type $\Delta m_I = \pm 1$ are less probable. The transition probability of the forbidden transitions is proportional to $(1/B_0)^2$. Therefore, their intensities in W-band are reduced by more than one order of magnitude compared to K-band measurements (see also Ref. [9]).

In W-band in first order perturbation theory all nuclei can be treated independently. One needs only to know their shf interaction constants and their nuclear spin quantum numbers. With the knowledge of the ODENDOR line width which is about 1 MHz as measured for the EL2 defect in K-band, all allowed EPR transitions can be summed up to give the total ODEPR spectrum in first order.

For the line width calculations the ODENDOR parameters of Ref. [5] have been used, i.e. $g = 2.04$, $a = 2656\text{ MHz}$ (central ^{75}As nucleus), and the shf parameters: $a = 167.8\text{ MHz}$, $b = 53.9\text{ MHz}$ (4 next nearest As neighbors); $a = 35.2\text{ MHz}$, $b = -1.3\text{ MHz}$ (3 second nearest As neighbors); $a = 19.5\text{ MHz}$, $b = 3.2\text{ MHz}$ (9 second nearest As neighbors). In order to examine of the two structure models, isolated As_{Ga} versus $\text{As}_{\text{Ga}}\text{--As}_i$ pair defect, for the latter the As interstitial was considered with its shf parameters $a = 215\text{ MHz}$ and $b = 44\text{ MHz}$ [5]. Anisotropic shf interaction parameters b have been included in the calculations for orientations different from $[0\ 0\ 1]$. The quadrupole interactions of the neighboring nuclei can be neglected in first order [8].

Calculating the full half width ($W_{1/2}$) of the ODEPR spectra for the isolated As_{Ga} model we obtain 33.7, 36.0 and 39.1 mT for the $[0\ 0\ 1]$, $[1\ 1\ 0]$ and $[1\ 1\ 1]$ orientations, respectively. Considering the interaction with an additional As interstitial in the $\text{As}_{\text{Ga}}\text{--As}_i$ model we obtain 39.5, 41.3 and 42.8 mT. The measured line widths in W-band are 35.7, 36.8 and 38.0 mT, respectively, with an error of $\pm 0.8\text{ mT}$. In the literature a value of 33.0 mT has been published for the peak-to-peak line width (W_{pp}) of the conventional EPR spectrum of the EL2 defect for $B_0 \parallel [0\ 0\ 1]$ in X-band [10], which corresponds to 38.0 mT for $W_{1/2}$ in agreement with K-band ODEPR measurements.

The result can be summarized as follows: (i) the experimental (W-band) ODEPR line widths lie between the calculated ones for the isolated and the $\text{As}_{\text{Ga}}\text{--As}_i$ pair model; (ii) the measured variation of the line width with orientation of the samples is smaller than the calculated one both for the isolated and for the pair model; (iii) the ODEPR line width in W-band is smaller by 2 mT compared to the K-band line width and (iv) the ODEPR line width measured in K-band is in agreement with X-band conventional EPR measurements. The first result can be explained if we assume that the high shf values determined for the As interstitial from the ODENDOR measurements [5] are not correct. The corresponding ODENDOR lines with very low intensity may have been due to forbidden transitions and were wrongly interpreted. From the second result a lower symmetry than C_{3v} could be suggested because in that case the measured line width variation ΔW is smaller as the calculated one for both the isolated as well as for the pair defect. The third result is consistent with a predicted reduction of forbidden transition probabilities at higher magnetic fields B_0 . The last point means that conventional EPR and ODEPR detect the same defect.

Thus, when calculating the ODEPR spectra of the EL2 defect in first order perturbation theory with the ODENDOR parameters of Ref. [5] and comparing the results with the new W-band experimental results we can exclude the $\text{As}_{\text{Ga}}\text{--As}_i$ model as the model for EL2. An

additional As_i with $a = 215 \text{ MHz}$ and $b = 44 \text{ MHz}$, respectively, leads to larger line widths compared to the isolated As_{Ga} model. However, when comparing the measured and calculated line shapes the EL2 defect can not be the isolated As_{Ga} antisite defect with T_d symmetry either. The resulting line width would be too small. This conclusion is supported by other experimental information such as its MCDA line shape in comparison with other As_{Ga} -related defects [11], the ODENDOR spectra of the higher As neighbor shells and the observation that the isolated As_{Ga} defect is produced in SI GaAs by low temperature electron irradiation and not stable at room temperature [6].

The first W-band ODENDOR spectra for $B_0 \parallel [110] + 20^\circ$ show at least 8 lines belonging to ^{75}As and $m_s = -1/2$, all in a frequency range where nearest neighbors are measured (further neighbors would be at much lower frequencies). For an isolated As_{Ga} -defect with T_d -symmetry including a quadrupole interaction ($I = 3/2$) at most 2 triplets, that is only 6 lines would be measured for B_0 in a $\{001\}$ plane. There are, however, more lines. The observed pattern can not be due to a tilt of the sample either. Thus, with all precaution, because an angular dependence has not yet been measured, it looks as if the EL2 defect is a perturbed As_{Ga} defect in which not all nearest As neighbors are equivalent.

4. Conclusions

From ODEPR measurements of the EL2 defect in W-band and calculations of the ODEPR spectra we can conclude that the $\text{As}_{\text{Ga}}\text{--As}_i$ model assuming an additional As interstitial is not consistent with the observed ODEPR line widths. However, the EL2 cannot be the

highly symmetric isolated As_{Ga} defect either. Thus, EL2 must be an As_{Ga} -related defect with lower than T_d symmetry. The cause for the symmetry lowering, however, should only contribute a very small shf interaction. For example, a vacancy as suggested in Ref. [11] could cause a nonequivalence in nearest neighbor shf interactions and thus explain the experimental line width in W-band. The first W-band ENDOR measurements seem to support this.

Abstract

Two deep-level traps associated with lattice-mismatch induced defects in GaAs/InGaAs heterostructures have been revealed by means of deep-level transient spectroscopy (DLTS). An electron trap, at $E_c - 0.64$ eV, has been attributed to electron states associated with threading dislocations in the ternary compound while a hole trap, at $E_v + 0.67$ eV, has been ascribed to misfit dislocations at the heterostructure interface. Detailed investigation of the dependence of DLTS-line amplitude and its shape on the filling time of the traps with charge carriers allowed us to specify the type of electronic states related to both traps. In terms of the model of electronic states associated with extended defects, which takes into account the rate at which the states reach their internal electron equilibrium, we relate the electron trap to “localized” states and the hole trap to “bandlike” ones. © 2001 Elsevier Science B.V. 1. Introduction

Lattice-mismatched GaAs-based heterostructures are of continual interest because of their application in high-speed and optoelectronic devices. Epitaxial growth of those heterostructures is accompanied by a strain in the epitaxial layer that results from a difference in lattice parameters between the substrate and the layer. If the thickness of the layer exceeds its critical value the strain is relieved by the formation of misfit dislocations. In heteroepitaxial semiconductor systems with zinc-blende structure and small lattice mismatch, grown on (001)-oriented substrates, orthogonal arrays of regular 60° misfit dislocations are formed at the interface [1]. The misfit dislocations are accompanied by threading dislocations which propagate into the epitaxial layer. Both kinds of dislocations can give rise to energy levels in the band gap which act as recombination centres or traps for free carriers. Due to translational symmetry along dislocation lines, one-dimensional energy bands rather

than isolated localized electron states are expected to be associated with the dislocation cores.

In our recent paper [2], we revealed, by means of deep-level transient spectroscopy (DLTS), three deep-level traps associated with lattice-mismatch induced defects in two types of GaAs-based heterostructures: GaAs/GaAsSb and GaAs/InGaAs. In this communication we report new results of systematic investigation of kinetics for capture of charge carriers into the trap states. They give a new insight into the nature of the electronic states associated with two of the traps, which have been related to lattice-mismatch induced dislocations.

2. Samples

We investigated GaAs/InGaAs heterostructures, with the In content of 2%, grown by molecular beam epitaxy (MBE). The InGaAs layer of 1 μm thickness was grown on n^+ -type GaAs buffer layer doped with Si. The InGaAs layer was Si doped to a thickness of 0.3 μm and its upper part was Be doped to p-type at the concentration of 10^{16} cm^{-3} , so that an n^+ –p junction was formed in the layer of the ternary compound. The junction

Fig. 1. Distribution of misfit dislocations at the interface of $n^+ - p$ GaAs/In_{0.02}Ga_{0.98}As heterojunction revealed by means of EBIC technique in a scanning electron microscope.

position was shifted from the heterointerface towards the InGaAs side by 0.3 μm .

A difference in lattice constant between GaAs and the ternary compound, of about 0.2%, resulted in the generation of a two-dimensional network of misfit dislocations lying along two orthogonal $\langle 110 \rangle$ directions at the (001) interface. Such a dislocation network which has been revealed by means of an electron-beam induced current (EBIC) technique in a scanning electron microscope is shown in Fig. 1. Here, the misfit dislocations are visible as dark lines owing to enhanced recombination rate of electron-hole pairs generated by an electron beam.

3. DLTS results

The spectrum of lattice-mismatch induced defects has been studied by means of DLTS using $p - n$ junctions formed in the epilayers. This allowed for investigation of both electron traps in the upper half of the band gap and hole traps in the lower half.

One electron trap, called ED1, has been revealed in the DLTS spectrum measured under typical bias conditions, i.e. under reverse quiescent bias, which was decreased to zero during the filling pulse, Fig. 2. This trap, with a deep level at $E_c - 0.64 \text{ eV}$ as determined from the slope of the Arrhenius plot shown in Fig. 3, has been attributed to threading dislocations in the layer of ternary compound close to the plane of $p - n$ junction [2]. The ED1 trap had been, for the first time, revealed by means of DLTS in plastically deformed bulk GaAs at $E_c - 0.68 \text{ eV}$ and related to electron states associated with 60° dislocations [3]. The same trap was then found in several MOVPE-grown GaAs/InGaAs heterostructures by Watson et al. [4] and by Panepinto et al. [5], who ascribed the trap to misfit dislocations generated either at the interface [4] or in GaAs buffer layer close to the interface [5].

Fig. 2. DLTS spectra measured at a rate window of 48 s^{-1} for the $n^+ - p$ GaAs/InGaAs heterojunction. The upper spectrum was recorded under reverse-bias conditions while the lower one was detected under forward-bias injection. Note the scale expansion for the upper spectrum.

Fig. 3. Temperature dependence of the thermal emission rates (Arrhenius plots) for the traps revealed in the GaAs/InGaAs heterojunction. Energy positions of the trap levels, evaluated from the Arrhenius plots, are written in the figure. The inset shows DLTS peak amplitudes of ED1 and HD3 traps versus filling-pulse duration.

We have also identified the ED1 trap in GaAs/GaAsSb heterostructures with different Sb content (0–3%) and attributed it to threading dislocations present in the GaAsSb epilayer [2,6]. The activation energies for the electron emission from the ED1 traps, obtained for various heterostructures, decrease with an increase of the Sb or In content in the epitaxial layer similar to the manner in which the band-gap energy in the ternary compound decreases [2]. This relation implies that the energy level position of the trap with respect to the top of the valence band remains the same in each material, suggesting that the defect state is composed primarily of the valence band states. A similar dependence of the trap activation energy on the band gap energy has recently been found by Pal et al. [7] for the electron trap, attributed to threading dislocations in MBE-grown InGaAs layers with higher (10–30%) In mole fractions.

On the other hand, our DLTS measurements performed under injection conditions, i.e. under zero quiescent voltage and forward-bias filling pulse, revealed one hole trap (Fig. 2), called HD3, with a deep level at $E_v + 0.67$ eV (Fig. 3). We relate the trap, which has been detected only when the DLTS-active region comprises the interface, to defects associated with the lattice-mismatched interface, most probably to misfit dislocations lying at the interface. We revealed the same hole trap in the DLTS spectra of lattice-mismatched GaAs/GaAsSb heterostructures; however, the precise evaluation of its activation energy was strongly disturbed owing to the position of its DLTS line on the high-temperature slope of another line in those heterostructures [2]. Probably the hole trap recently found by Du et al. [8] in lattice-mismatched GaAs/InGaAs heterostructures with various In mole fractions and layer thicknesses is the same as HD3. That trap, labelled H4 by the authors, with the DLTS activation energy between 0.67 and 0.73 eV, has been related to misfit dislocations at the interface by comparing the DLTS spectra in various heterostructures with the distribution of dislocations revealed by means of transmission electron microscopy (TEM).

4. Capture kinetics

The principal argument for the assignment of the traps to dislocations was logarithmic kinetics for capture of charge carriers into the trap states. Such kinetics results from the Coulomb interaction between a charge carrier just being captured and other charges already captured at the dislocation line [9]. This interaction manifests itself in DLTS measurements in a linear dependence of the signal amplitude on the logarithm of the filling-pulse duration [3], as shown for the ED1 and HD3 traps over several orders of magnitude of that duration; see the inset of Fig. 3. In contrast, isolated point defects or impurities exhibit exponential capture kinetics.

Recently, Schröter et al. [10,11] proposed that electronic states associated with extended defects in semiconductors can be classified as *localized* or *bandlike* by taking into account the rate R_i , at which the states reach their internal electron equilibrium. The internal equilibration rate, when compared to the carrier emission rate from the defect R_e and the capture rate R_c , allows us to distinguish between *localized* states ($R_i \ll R_e, R_c$) and *bandlike* ones ($R_i \gg R_e, R_c$). The authors demonstrated, by computer simulation of DLTS spectra induced by the two types of states, that can be distinguished on the grounds of dependence of their DLTS-line shape on the filling time.

For *localized* states the DLTS-line maximum stays constant while changing the filling-pulse duration,

Fig. 4. DLTS line for the ED1 trap and its dependence on filling-pulse duration, whose values are written in the figure, measured at a rate window of 2 s^{-1} . In the inset, the line amplitude is normalized to the same height.

Fig. 5. DLTS line for the HD3 trap and its dependence on filling-pulse duration, written in the figure, measured at a rate window of 2 s^{-1} .

whereas the line amplitude exhibits a linear dependence on the logarithm of the filling time. Such behaviour has been found for the ED1 trap as shown in Fig. 4. This finding is in agreement with the results of Panepinto et al. [5] for the same electron trap, labelled EG4 in Ref. [5]. It has also been shown that the DLTS signal associated with 60° dislocations in plastically deformed Si can be described by this type of electronic states [10].

On the contrary, in the case of *bandlike* states, variation of filling-pulse duration results in broadened DLTS lines whose maximum shifts towards lower temperature on increasing that duration and whose high-temperature sides coincide. This is the case of the HD3 trap as demonstrated in Fig. 5. Possibly, the electronic states associated with misfit dislocations belong to *bandlike* states because of a higher regularity of those dislocations as compared with the threading ones. To this category of states belong also electronic states associated with dislocation rings bounding nanoscale NiSi_2 precipitates in silicon [11].

5. Conclusions

One electron trap and one hole trap have been found with the DLTS technique in lattice-mismatched GaAs/InGaAs heterostructures. The electron trap, called ED1, has been attributed to threading dislocations in the layer of ternary compound, whereas the hole trap, HD3, has been related to misfit dislocations lying at the heterostructure interface. A thorough analysis of the dependence of DLTS-line shape of the traps on the filling time allowed us to specify the type of electronic states related to both traps. We relate the ED1 electron trap to *localized* states and the HD3 hole trap to *bandlike* ones.

Abstract

The effect of low-energy plasma treatment on GaAs/AlGaAs multiple quantum wells structures has been studied by CW and time-resolved photoluminescence. An increase of the photoluminescence intensity of quantum wells below the plasma damaged region is observed. The concentration of nonradiative centers in these QWs is reduced by a factor of 30 after a 40 s exposure to a CF₄ plasma. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Plasma treatment; Defect passivation; Photoluminescence

Low-energy fluoride-based plasmas are widely used in III–V semiconductor device fabrication for selective removal of dielectric films from the surface of the structures. During this reactive ion etching (RIE) process, overetching is a common practice to ensure complete removal of the dielectric films. Inevitably, semiconductor materials below the dielectric films have to be exposed to the plasma leading to damage of the near-surface region and as a result both the electrical and the optical properties of the materials deteriorate significantly [1–7]. In order to exploit the full potential of the plasma treatment and to develop new processes for future applications it is necessary to understand the cause and effect of this damage. Wang et al. [8] have proposed to detect the RIE induced effects utilizing the photoluminescence (PL) properties of AlGaAs/GaAs multiple quantum well (MQW) structures. To increase the detection sensitivity of point defects generated by RIE, Ooi et al. [9] have used a quantum well intermixing technique. Both publications report on a reduction of the PL intensity generated by near-surface QWs which are damaged by the RIE process. In our investigations

not only a reduction of the near-surface PL is observed, in addition we also detected an increase of the PL intensity from QWs lying below the damaged region after the structure is treated using a CF₄ plasma.

The AlGaAs/GaAs MQW structures used in this study were grown by molecular beam epitaxy. A 1.0 μm undoped GaAs layer was grown on a (100) semi-insulating GaAs substrate, followed by a 0.5 μm undoped Al_{0.3}Ga_{0.7}As layer, and GaAs QWs of different widths were grown on top of this layer. In particular the region contains six QWs with 2.2, 2.8, 3.4, 4.2, 5.6 and 8.5 nm wide wells, which are separated by 24 nm Al_{0.3}Ga_{0.7}As barriers. The sample was capped by a 10 nm GaAs layer. Furthermore a short-period AlAs/GaAs superlattice was introduced within the 0.5 μm Al_{0.3}Ga_{0.7}As layer to trap impurities which are segregated during growth on the AlGaAs surface [10–13] and point defects originating from the substrate [14]. For the plasma treatments CF₄ gas was used. The plasma power density was kept at 0.5 W cm^{−2} with an operating pressure of 0.07 Torr and direct current self-bias of approximately −300 V. The exposure time was varied from 5 to 600 s. In order to avoid sample heating during extended plasma treatment the plasma was extinguished after 120 s exposure and the sample was cooled. A 632.8 nm He–Ne laser with a power density of

E-mail address: timur@thermo.isp.nsc.ru
(T.S. Shamirzaev).

20 W cm^{-2} was used to perform continuous wave PL measurements. Since the absorption coefficient at 632.8 nm is about $3 \times 10^4 \text{ cm}^{-1}$ and $1 \times 10^4 \text{ cm}^{-1}$ in GaAs and $\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}$ ($T = 77 \text{ K}$), respectively, approximately 3% of the illuminated light is absorbed in each QW. The details of the equipment used for time resolved PL measurements were described elsewhere [15].

Fig. 1 presents 77 K PL spectra of the structure obtained before and after an exposure to CF_4 plasma. The PL peak at 822 nm (1.507 eV) originates from band to band recombination in the GaAs layer and the other peaks are due to $1\text{e}hh$ transitions in the quantum wells. The 2.2, 2.8, 3.4, 4.2 and 5.6 nm QWs in the as-grown sample reveal a high PL intensity, only the 8.5 nm QW (which is nearest to the substrate) shows a low PL intensity. Note that at liquid helium temperature all the QWs show the same PL intensities, therefore, the amount of the excitation light absorbed by the 8.5 nm QW is approximately the same as in the others. After 60 s exposure to the CF_4 plasma the PL signal originating from the surface near QW completely disappears, while the PL signal generated in the 3.4, 4.2 and 5.6 nm QWs remains unchanged. Unexpectedly the PL signal arising from the 8.5 nm QW is increased by more than one order of magnitude and lines up with the intensities of the 3.4, 4.2 and 5.6 nm QWs. No shift in the PL peaks of the QWs is observed.

Fig. 2 shows the PL peak intensities of all QWs after CF_4 plasma exposure. The PL intensities were normalized relative to the intensities obtained from as-grown QWs. Since the GaAs layer is far enough away from the sample surface to remain undamaged under the plasma

Fig. 1. PL spectra of the GaAs/GaAlAs MQW structures obtained before (solid line) and after (dashed line) a 60 s CF_4 plasma exposure. Numbers label the PL originating from the following QWs: 1–2.2, 2–2.8, 3–3.4, 4–4.2, 5–5.6, and 6–8.5 nm.

Fig. 2. Normalized QW PL intensity vs depth in the structures exposed for 60 s in the CF_4 and Ar plasmas.

treatment its PL was used as a reference. Fig. 2 clearly shows that the CF_4 plasma causes PL degradation in the near surface region and also induces an increase of the PL intensity of deeper lying QWs below this region. A clear PL enhancement is observed in the QW, which reveals a low initial PL intensity in as-grown samples. The low PL intensity is thereby attributed to the segregation of impurity atoms and point defects at QW interfaces during growth, which act as traps or nonradiative recombination centers. Possible reasons for the plasma-induced increase of the PL intensity would be an annihilation or significant transformation of the nonradiative centers due to interaction with some plasma-induced highly mobile defects.

During plasma exposure an implantation of incident species (ions of plasma, elements from walls of the reactor) and a generation of point defects, such as vacancies and interstitial atoms, occurs in the near-surface region of the structures. It is well known that fluoride and hydrogen can passivate the dangling or defective bonds acting as traps or nonradiative recombination centers in amorphous silicon [16]. Moreover, it was shown [17–19] that the incorporation of hydrogen in III–V semiconductor structures leads to the passivation of deep nonradiative centers and to enhancement of PL efficiency. Therefore we first assumed that implanted fluoride could penetrate into the GaAs/AlGaAs MQW structures and passivate the growth defects. In order to prove this assumption we compared the influence of Ar and Kr plasmas on the PL intensity obtained from the MQW structures. The normalized PL intensities of QWs, which are treated by an Ar plasma are shown in Fig. 2 as full triangles. From comparison it becomes

evident that the nature of the PL enhancement is independent from the plasma gas used. We therefore conclude that the observed PL increase is caused by plasma-induced, highly mobile point defects and not by a fluoride passivation. After low-temperature annealing (400°C in Ar atmosphere for 60 s) a depassivation occurs, and the PL intensity of the deeper lying QW drops again. However, a second plasma treatment once more leads to the passivation of the growth defects.

Fig. 3 shows the normalized PL intensity as a function of CF₄ exposure time. This figure demonstrates that the PL intensity arising from the 8.5 nm QW significantly increases after only a $\tau_0 = 20$ s exposure to the plasma, a further prolongation of the exposure time hardly increases the PL intensity. Moreover, Fig. 3 shows that the prolongation of the exposure time up to 10 min enlarges the near-surface damaged region. In order to estimate a diffusion coefficient (D) of the plasma-induced point defects, which cause the increase in the PL intensity in the deepest QW we use the diffusion length relationship $d = (Dt)^{1/2}$, where t is the exposure time and $d = 17$ nm is the distance of 8.5 nm QW from the surface. We took t equal to τ_0 and obtained the D value of about 10^{-11} cm² s⁻¹. It should be noted that the measured values of the defect diffusion coefficient are too high, particularly taking into account that during the plasma treatment the temperature of the samples did not exceed 50°C. It seems likely that an excitation of the crystal by ultraviolet, X-rays, and energetic electrons generated in the plasma enhances diffusion of the defects in MQW structures. Investigations of these effects are in progress now.

In order to estimate the change of the growth defect concentration in the 8.5 nm QW we measured the PL lifetime in this QW before and after a 40 s exposure to plasma as a function of the temperature. Jin et al. [20] obtained the following equation that connect the PL decay lifetime (τ) with the bath temperature (T) and the

nonradiative recombination probability (R_{nr}).

$$\tau(T) = (p_0 + n_c(T)) / (p_0 R_r(T) + n_c(T) R_{nr}(T)), \quad (1)$$

$$R_r(T) = B n_c(T) + R_x,$$

$$R_{nr}(T) = R_0 + R_s \exp[-E_A/kT],$$

$$n_c(T) = [m_e m_h / (m_e + m_h)] [kT / \pi \hbar^2] \exp[-E_x/kT],$$

where $1/R_x$ is the intrinsic exciton radiative lifetime, B is the rate of the band-to-band radiative recombination of the free carriers, R_0 is the nonradiative recombination probability, which is proportional to the concentration of nonradiative centers, $n_c = np/n_x$, where n , p , n_x are the electron, hole, and exciton concentration, respectively, E_x is the exciton binding energy, E_A is the activation energy of nonradiative recombination, p_0 is the concentration of the free holes, $m_e = 0.065m_0$ and $m_h = 0.5m_0$ are respectively electron and hole effective masses, which are taken as equal to bulk GaAs masses independently of the QW size.

The experimental values of the PL decay lifetime measured at different temperatures in the 8.5 nm QW and the calculated lifetime dependence using Eq. (1) are shown in Fig. 4. The best coincidence between the experiment and calculation has been obtained for the following parameters which were fixed for both as-grown and exposed structures: $E_x = 8$ meV, $E_A = 90$ meV, $B = 10^{-10}$ cm² c⁻¹, $p_0 = 5 \times 10^9$ cm⁻², $R_s = 1.2 \times 10^{10}$ c⁻¹, $R_x = 1.8 \times 10^9$ c⁻¹. The factor R_0 , proportional to the concentration of nonradiative centers, changes from 1.17×10^9 c⁻¹ in the as-grown structure to 4.2×10^7 c⁻¹ in the plasma treated structure. Therefore,

Fig. 3. Variation of the normalized PL intensities originating from the QWs in the structure as a function of CF₄ plasma exposure time.

Fig. 4. PL decay lifetime of the 8.5 nm QW as a function of the bath temperature. Symbols mark (1) as-grown structure, (2) the same structure after 40 s exposure in CF₄ plasma. Dashed lines show the calculated dependence according to Eq. (1).

the defect concentration is decreased by a factor of about 30 after exposure to CF_4 plasma.

In conclusion we have examined the effect of a CF_4 plasma exposure on the PL properties of GaAs/AlGaAs MQW structures and observed a plasma induced quenching of the QW PL in the near surface region. Unexpectedly, the CF_4 plasma causes a remarkable increase of the PL intensity in the QW below this region. We explain this PL enhancement by a passivation of nonradiative growth defects which is induced by plasma generated highly mobile point defects.

Exciton localization dynamics due to intrinsic interface defects within growth island terraces of all-binary GaAs/AlAs quantum wells

Abstract

The localization dynamics of excitons within growth island terraces of a narrow GaAs single quantum well confined by all-binary GaAs/AlAs short-period superlattices is investigated by time-resolved photoluminescence (PL) spectroscopy. Under resonant photoexcitation into the ground light-hole exciton state of the dominant terrace, as confirmed by PL excitation spectra, we clearly observe an enhancement of the fundamental free heavy-hole exciton emission as well as the localized excitons associated with the terrace. The time evolution of the split PL line-shape indicates the coexistence of distinct free and localized excitons in the ps time domain, revealing transfer from the free to localized excitons within the terrace in addition to the transfer between the island terraces. These results directly evidence that the binary–binary heterointerface contains intrinsic interface defects within the terraces and that the split PL line-shape dynamically evolves due to confinement potential fluctuations on the island terraces in agreement with the bimodal interface nano-roughness model. © 2001 Elsevier Science B.V. Keywords: GaAs quantum well; Interface defects; Photoluminescence; Exciton

1. Introduction

In narrow quantum wells prepared by growth interrupted molecular beam epitaxy, split two-dimensional exciton lines are observed in photoluminescence (PL) spectra, which reflect the formation of uniform and flat monolayer (ML) growth islands whose lateral terrace size is larger than the exciton Bohr radius [1–6]. However, recent analyses [7–13] of the detailed PL line-shape and atomic-scale characteristics indicate that the interface heterostructure within the terraces is not always perfectly abrupt but contains a number of intrinsic defects due to atomic displacement in the group III sublattice. Therefore, a microscopic roughness, called nano-roughness exists on the macroscopically flat island terraces. In this paper, the localization dynamics of excitons within growth islands of a narrow GaAs single quantum well (SQW) confined by all-binary GaAs/AlAs

short-period superlattices is investigated by time-resolved PL spectroscopy to provide further evidences for the nano-roughness. Under resonant photoexcitation into the ground light-hole exciton state of the dominant terrace, we clearly observe an enhancement of the fundamental free heavy-hole exciton emission associated with the terrace by measuring the time evolution of the split PL line-shape. The PL line-shape thus shows the coexistence of distinct free and localized excitons in the ps time domain, revealing the transfer from free to localized excitons within the terrace. These results under resonant photoexcitation conditions directly evidence that the binary–binary heterointerface contains intrinsic interface defects within the SQW island terraces.

2. Experimental

The GaAs SQW sample was grown by a molecular beam epitaxy (MBE) with growth interruption for 2 min

*Corresponding author. Fax: +81-93-884-3221.

E-mail address: fujiwara@ele.kyutech.ac.jp (K. Fujiwara).

at 670 °C under arsenic exposure at each interface. The well width (L_z) of the different SQW growth islands approximately range from 22 (6.2 nm), 21 (5.9 nm), 20 (5.7 nm) and 19 (5.4 nm) MLs, named A, B, C and D, respectively. The SQW layer is separated by all-binary GaAs/AlAs superlattice layers ($L_z/L_B = 3.4/1.2$ nm, 40 periods). The detailed sample heterostructure has been described previously [5,6]. The low intensity cw PL and PL excitation (PLE) measurements were carried out at 6 K using monochromatized radiation from a halogen lamp, for excitation, and a photon counting system, for detection. Spectrally and temporally resolved PL experiments were performed at 15 K by using a streak-camera based system for detection, and a pyridine 2 dye laser synchronously pumped by a mode-locked Ar⁺ laser for excitation. The narrow GaAs SQW sample was mounted in a temperature variable cryostat and directly excited by 10 ps optical pulses with a wavelength of 755 nm (1.642 eV) at which the light-hole exciton is resonantly excited in the dominant terrace C. The average excitation power was 34 mW which corresponds to an excitation power density of a few W/cm².

3. Results and discussion

The PL and PLE spectra from the GaAs SQW sample are shown in Fig. 1. The PL spectrum was measured using an excitation wavelength of 600 nm, while the PLE spectrum was obtained by setting the PL detection wavelength at 777 nm. Three PL structures are observed, which are associated with terraces A, B and C. The PLE spectrum reveals three distinct resonances associated with the 1s heavy-hole (1hh) excitons (as well as the light-hole (1lh) excitons) for terraces B, C and D. The strongest PL peak B is red-shifted by 9.8 meV from the main exciton resonance peak C (Stokes-shift) with a narrow, but finite line-width of about 2 meV (FWHM). We note that a doublet PL structure with about 3 meV splitting is seen for the dominating terrace C, while additional shoulders or tails are also observed on the longer wavelength (lower energy) side. The higher energy PL structure of terrace C coincides with the PLE peak position. The energy separations between the PLE peaks, B and C and C and D, are found to be 6.0 and 6.9 meV, respectively. These values correspond to well-width changes of 0.75 and 0.80 ML and are smaller than the calculated energy gap changes (8.0 meV/8.9 meV) by one ML. In addition, the PL peak position of terrace B is also red-shifted by 3.8 meV from the corresponding PLE peak as assigned in Fig. 1. This PL red-shift, which is also valid for terrace C, is due to the exciton center-of-mass motion (exciton intra-terrace transfer) from the free to localized excitons in terraces B and C in addition to the inter-terrace transfer (from C to B) during the radiative recombination processes. The

Fig. 1. cw PL (dashed) and PLE (solid) spectra of the 19–22 ML GaAs single quantum well. The excitation wavelength for PL is 600 nm while for PLE the PL detection is set at 777 nm. The inset figures schematically show the spatial configuration of the well and the areal density distribution of the SQW growth islands.

PL emission from terrace D was not observed in the cw PL spectrum of Fig. 1.

Fig. 2 shows the time evolution of transient PL spectra for the GaAs SQW as a function of delay time under 1lh exciton resonant photoexcitation of the main terrace C. In Fig. 2, the PL spectra (a)–(g) were measured at 14, 94, 174, 254, 414, 574 and 814 ps, respectively, after the excitation pulse averaged over 80 ps each. The PL intensity is vertically shifted for clear comparison and normalized to the highest peak intensity in each spectrum. In spectrum (a), the PL intensity distribution is dominated by emissions from terrace C over those from other terraces. In addition, a small PL signal from terrace D is observed on the higher energy side in the early stage. Within the emission band C, a doublet structure similar to the one seen in Fig. 1 is now more clearly observed in Fig. 2(a), and the short wavelength (high energy) peak is drastically enhanced in intensity. This is obviously due to the resonance enhancement effects on the photoexcitation in terrace C, i.e., more excitons are selectively generated in the spatial region of terrace C. With increasing delay time, the relative PL intensity from terrace C decreases generally, while the PL intensity from terrace B increases. For example, in the spectrum (c) after 174 ps, the strongest emission is already shifted to the lower energy peak B,

Fig. 2. Normalized PL spectra of the GaAs single quantum well as a function of time after pulsed excitation. The transient spectra (a)–(g) are detected at 14 (a), 94 (b), 174 (c), 254 (d), 414 (e), 574 (f) and 814 ps (g) after the 10 ps excitation pulse averaged over 80 ps each. The peak positions, F_i (L_i) ($i = A, B, C$ and D) of the free (localized) excitons are indicated by vertical solid (dashed) lines.

revealing the exciton transfer from terrace C to B. In the lowest spectrum (g), the PL intensity of terrace B dominates, while the emission intensity from terrace A is higher than terrace C. We also note that the emission band B has a doublet structure in Fig. 2, although the spectral separation is not so clear like the one for terrace C. Considering this doublet the dominating PL peak (B) in (g) is sharper than the one in (a), which indicates that the free excitons with the high energy emission component are significantly transferred to the localized states after 814 ps. These dynamical changes of the PL intensity in Fig. 2 indeed reflect the fact that during radiative recombination the excitons are moving in real space from terrace C to B, as schematically illustrated in Fig. 3.

The most important point we would like to stress here is, however, that the PL emission lines in the transient spectra clearly exhibit an additional doublet structure within the terraces, while their relative intensities of the different peaks evolve due to changes in the exciton population (see Fig. 3). In order to compare the cw PL and PLE peak positions, the measured peak wavelengths are indicated by solid (dashed) vertical lines for the free

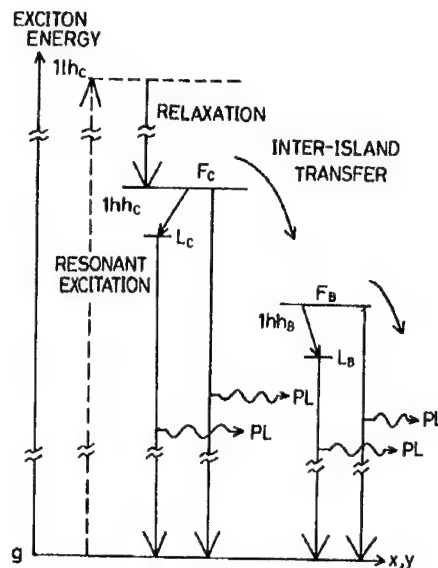

Fig. 3. Schematic model for the exciton energy distribution of the free and localized exciton states under resonant excitation into the ground light-hole exciton of the dominant terrace C.

(localized) excitons in Fig. 2 for the terraces A, B, C and D. A clear correlation is seen between the cw PL/PLE peak energies and those from the transient PL spectra, although the free exciton peak A cannot be resolved for PLE. This allows one to assign the transient PL fine structures to the free and localized $1hh$ excitons in the terraces.

Here we use excitons as a probe to examine the interface potential fluctuations whose lateral length scale is less than the exciton Bohr radius. Hence, the energy splitting of the doublet structure is naturally explained by the interface nano-roughness, which causes the confinement energy changes by a fractional ML (0.3 ML/3.8 meV). This is also valid for the case between the terraces, since the energy splitting is only partial, equivalent to 0.75–0.8 ML. The reduction of the probe size by increasing the quantum confinements thus makes it possible to visualize miniature-size intrinsic defects by a discrete exciton level, i.e., isoelectric trap sites for localized excitons. The experimental results presented here directly show the existence of nano-roughness within the macroscopically flat island terraces, which supports the bimodal interface roughness model [8].

4. Conclusion

In summary, PL transients in a narrow GaAs single quantum well with growth islands confined by all-binary GaAs/AlAs short-period superlattices have been inves-

tigated using resonant photoexcitation at the ground light-hole exciton level to the dominant island terrace. The transient PL spectra reveal two types of dynamical Stokes shifts due to intra- and inter-terrace exciton transfers. The finely split line-shape of the PL doublet structure directly evidences the existence of localized excitons formed within the terraces due to the confinement potential fluctuations. This reflects the existence of intrinsic interface defects caused by atomic displacements with respect to the sublattice. The discrete change of the PL peak energy with increasing delay time indicates the existence of a small-scale nano-roughness within the macroscopically flat quantum well island terraces.

Abstract

It has been shown that He^{++} ions irradiation introduces in Be doped $\text{Al}_{0.5}\text{Ga}_{0.5}\text{As}$ MBE layers some metastable defects. After sample illumination at liquid nitrogen ambient with photons of energy below the band gap energy persistent photocapacitance was observed. DLTS measurements performed in darkness after such illumination revealed the presence of additional deep level with energy activation equal to 0.24 eV. © 2001 Elsevier Science B.V. Keywords: Deep levels; AlGaAs; α -irradiation

1. Introduction

Defects in semiconductors play important role as they control operation of semiconducting devices. It is well-known that irradiation introduces or increases the number of defects in semiconductors. This impact is of premium importance for the devices exposed to irradiation, as in the case of those applied in extraterrestrial space. On the other hand studying defects introduced by irradiation gets insight into physics of defects.

Some defects introduced during light-ion irradiation of semiconductors can be metastable. Metastability refers to the reversible transformation of defects from one structural configuration to another. Their formation can strongly depend on heat treatment or biasing condition during heating or cooling of the sample. Metastable defects are important for both fundamental physics and device applications as they can affect semiconductor properties. In some cases the metastability follows a large lattice relaxation and is

explained with the help of configuration coordinate diagram.

Whereas metastable defects introduced in n-type GaAs during α irradiation have been widely investigated [1] there is very little information about irradiation induced metastable defects in p-type GaAs and related $\text{Al}_x\text{Ga}_{1-x}\text{As}$ mixed crystals. Recently, observation of metastability in p-type GaAs has been reported [2].

In the present paper the influence of He^{++} ion radiation on defects in beryllium doped p-type MBE layers has been studied by DLTS and photocapacitance method. It was found that irradiation introduced a metastable defect which manifests itself after light illumination in nitrogen temperatures. Metastability due to this defect is similar to the metastability observed in many II–VI and III–V semiconducting crystals. The “signature” of the defect has been determined.

2. Experiment

The samples under study were Be doped to obtain p-type $\text{Al}_{0.5}\text{Ga}_{0.5}\text{As}$. Their net acceptor concentration was equal to $1 \times 10^{16} \text{ cm}^{-3}$. The wafer from which the samples were made was grown on a semi-insulating

[001] GaAs substrate in a Varian Gen II MBE-machine. Metal-semiconductor structures were realised in order to perform DLTS studies. Detailed description of the sample and contact processing is given in Ref. [3]. The samples with contacts processed were exposed to He ion bombardment. The irradiation was performed at Copenhagen University's accelerator laboratory with 0.3 MeV He^{++} ions of fluences equal to 10^{11} and 10^{12} cm^{-2} . Capacitance and DLTS measurements were collected with 1 MHz capacitance bridge and a lock-in system. Applied temperature range was equal to 77–350 K.

3. Results and discussion

In Fig. 1 the DLTS signal temperature scans are shown for reference sample and irradiated with two different doses of He^{++} ion fluences: 10^{11} and 10^{12} cm^{-2} . The data for non-irradiated sample had to be multiplied 10 times and for the sample irradiated with lower fluence—5 times so that it was possible put the data together in one figure with those for higher dose.

DLTS signal peaks labeled as H1 and H3 are visible on each of the curves. Increasing ion fluence however magnifies more the second one. Level H2 remains unaffected by radiation, as it disappears gradually with increasing fluence, hidden inside the signal related to the trap H3. The peak labeled as H4 becomes barely distinguishable with increasing fluence due to the new giant peak H5. Another new peak appeared, the one which is partly included on the high temperature side of the scan. Properties of the traps determined for both non-irradiated and irradiated samples by fitting theoretical DLTS signal to experimental data have been presented elsewhere [4].

It was found, that irradiation introduced also some metastable defects. The presence of a metastable defect in a semiconductor manifests itself in persistent photo-

conductivity or persistent photocapacitance effects. These effects are observed when the sample is exposed to illumination at sufficiently low temperature. For metastable defects, illumination increases conductivity or capacitance and this state persists for a long time period after turning off the light. Both conductivity and capacitance return to their 'dark' values after warming up the samples above certain temperature. In order to explain the effect it is assumed that after illumination the metastable defect undergoes transformation and return to its initial state is not possible due to energetic barrier for carrier recapture. Warming the sample allows overcoming of the barrier and return to the ground state. Persistent photocapacitance was observed for the He^{++} irradiated samples of Be doped $\text{Al}_{0.5}\text{Ga}_{0.5}\text{As}$ studied here. After applying for several minutes at liquid nitrogen 'below band gap' illumination, increase in capacitance has been observed. After turning off the light, the capacitance remained unchanged for many hours. The quenching of the effect might be achieved by warming the sample above 200 K. The optical threshold for the persistent photoeffect was found to be equal to 1 eV, approximately. The effect of persistent photocapacitance is shown in Fig. 2. Both curves representing (i) capacitance measured without illumination, and (ii) after illumination at 77 K coincide at 200 K, approximately.

Besides the persistent photocapacitance, another metastable effect has been observed for the irradiated samples. It was found that for the samples exposed for several minutes to illumination at 77 K additional minimum appeared on DLTS temperature scan run in darkness. Above minimum was observed after sample illumination with photons energy higher than 1 eV. In Fig. 3. DLTS signal vs. temperature dependence is shown with wavelength taken as a parameter. It is clearly seen that for wavelengths lower than $1.3 \mu\text{m}$ a new minimum appears within 150–200 K temperature range i.e. new deep level is created by photons.

Fig. 1. DLTS signal temperature scans for beryllium doped $\text{Al}_{0.5}\text{Ga}_{0.5}\text{As}$ MBE layers. Lock-in frequency was equal to 69 Hz.

Fig. 2. Curve (i) capacitance measured without illumination, and curve (ii) capacitance measured also in darkness but after initial illumination at 77 K for several minutes.

Fig. 3. “Dark” DLTS temperature scans taken after exposing the sample for several minutes at 77 K to monochromatic illumination of different wavelengths.

Fig. 4. Arrhenius plot of the DLTS trap appearing after illumination of the irradiated samples with photons of energy higher than 1 eV.

Arrhenius plot related to the new level is shown in Fig. 4. Solid line is the best square fit to the experimental data. The plot results in activation energy equal to 0.24 eV and apparent capture cross section $\sigma = 7 \times 10^{-17} \text{ cm}^2$.

As optical thresholds for persistent photoeffect and appearance of a new DLTS minimum were equal to 1 eV, it was tempting to propose, that both effects are related to the same origin. Let us assume therefore, that illumination changes charge state of some metastable defect by light induced emission of holes and in effect transformation of the defect into another defect takes place. At low temperature, say close to 77 K, return to the initial state is not possible and persistent photocapacitance is observed. It should be pointed out here,

that emission of holes to the valence band is considered here, as for a metal—p-type semiconductor junction this process is accompanied by increase of a negative charge within depletion region of the junction and increase of its capacitance. This new defect accompanies creation of additional deep level within band gap which can be visible in DLTS. It is clear now, that the DLTS signal is observed only after illumination by photons of energy higher than energetic distance of the ground state of the defect.

Physical origin of such a defect can be different. One of the possibilities is creation of a complex composed of a mobile (due to irradiation) host atom, attracting (after hole emission) some element. Another, transformation of the same defect accompanied by lattice relaxation, like in the case of DX centers in III–V and II–VI compounds.

4. Conclusions

In present paper the results of DLTS studies and photocapacitance measurements are given for He^{++} irradiated Be doped $\text{Al}_{0.5}\text{Ga}_{0.5}\text{As}$ MBE layers. Comparison of DLTS studies with those made for unirradiated samples let us assume, that irradiation introduced metastable centers. In effect, persistent photocapacitance was observed and additional DLTS minimum on DLTS temperature scan related to new deep level emerged after exposing the samples to illumination at 77 K. As optical thresholds for persistent photoeffect and creation of the new deep level were equal we assumed that new level is related to metastable defect created by irradiation.

Abstract

The spatial extents of the wave functions of the collective plasmon–LO phonon excitations were studied as a function of the doping concentration and the temperature in the AlGaAs alloy. A strong increase of the localization length was found with the increase of doping, while a decrease of the localization length was detected with the increase of the doping level at higher electron densities. A theoretical analysis based on the variational principle showed that the ionized impurities are responsible for the observed decrease of the localization length. © 2001 Elsevier Science B.V. Keywords: AlGaAs alloys; Plasmons; Localization

1. Introduction

The problem of the interaction of the carriers with the crystal imperfections such as impurity centers, native defects, phonons, etc., is of great importance in solid state physics. In the case of a weak interaction, this problem is usually treated in a semiclassical approach, when an electron can be represented by a point particle in a well-defined Bloch state $\Psi(\mathbf{q})$. The Born approximation is then used to determine the scattering rate $W(\mathbf{q}, \mathbf{q}')$, which defines the probability of the electron in a state \mathbf{q} to be scattered into a state \mathbf{q}' [1]. This approximation is basically valid when the potential energy of the interaction is small in comparison with the particle kinetic energy. An additional consequence of the scattering is the decay of the wave function of the scattered particle. This decay is negligible when the interaction is weak; however, for a strong interaction the uncertainty in the determination of the particle wave number δq —associated with the spatial localization of the particle $L_c(\delta q \propto L_c^{-1})$ —can be large enough, being a

significant part of the Brillouin zone. In this case, the Born approximation fails and a more general approach to treat the scattering process, which would take into account the modification of the wave function, should be used.

In recent papers, we have already shown that in disordered solids, where the Raman selection rules are relaxed, Raman scattering serves as a tool to study the spatial extent of the collective excitations involved, such as phonons, plasmons and coupled plasmon–phonon modes [2,3]. In many aspects, the dynamic properties of the single particle excitations and of the collective excitations are similar. In particular, as the single electron, the plasmons reveal a localization when undergoing a random potential [4]. Therefore, the investigation of the spatial extent of the localized plasmon can shed some light on the behavior of the wave function of the localized electrons.

In this paper, we present a systematic study of the influence of imperfections on the propagation and localization of collective plasmon-like excitations in the AlGaAs alloys. We show that already at rather moderate doping levels the impurities strongly modify the wave functions of the plasmons, giving rise to their

E-mail address: pusep@ifsc.usp.br (Y.A. Pusep).

localization. A simple theoretical model was developed to account for the interaction of the plasmons with the impurities. In addition, a significant increase of the plasmon localization caused by the interaction with phonons was found with the increase of the temperature.

2. Experimental

$\text{Al}_{0.11}\text{Ga}_{0.89}\text{As}$ alloys doped with Si were grown by molecular beam epitaxy on (100) oriented GaAs substrates. The electron concentrations were obtained both by Hall and capacitance measurements. Unpolarized back-scattered Raman spectra were performed at $T = 10\text{ K}$ with a “Instruments S.A. T64000” triple grating spectrometer supplied with a CCD detector cooled by nitrogen; the 5145 Å line of an Ar^+ laser was used for excitation.

Some selected Raman spectra of the $\text{Al}_{0.11}\text{Ga}_{0.89}\text{As}$ alloy are demonstrated in Fig. 1 where the data concerning the AlAs-like mode are presented. The values of the parameters characterizing the AlAs-like coupled

Fig. 1. Raman spectra of the $\text{Al}_{0.11}\text{Ga}_{0.89}\text{As}$ alloys with different electron concentrations measured at $T = 10\text{ K}$ in the frequency range of the AlAs optical phonons (solid lines). The dotted lines show the full calculated spectra, while the separate contributions of the collective plasmon-LO phonon excitations are plotted by dashed lines.

modes (the mode frequencies, the damping constants and the localization lengths) were determined by the fitting of the experimental Raman spectra as in [3].

The parameters of the collective excitations of interest measured in the alloys with different electron concentrations are shown in Fig. 2. The whole interval of the electron densities studied here can be divided into the following three ranges, where different behaviors of the collective excitations were found:

- (i) Low electron densities range. Here, with the increase of the doping level, the LO phonons are transformed in to the coupled plasmon-LO phonon excitations. This process is accompanied by the increase of the intensities of the relevant Raman lines which takes place because the active volume of the excitations contributing to the Raman process rapidly increases when changing from phonons to plasmons. This increase of the active volume of the excitations contributing to Raman scattering is

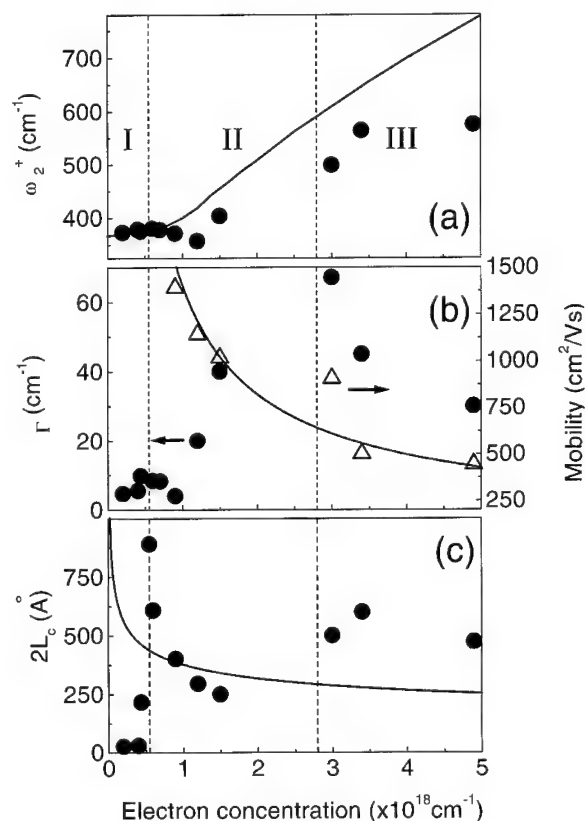

Fig. 2. Dependencies of the frequency ω_2 , the damping constant (Γ) and the localization length ($2L_c$) of the AlAs-like collective plasmon-LO phonon excitations on the electron density measured in the $\text{Al}_{0.11}\text{Ga}_{0.89}\text{As}$ alloy at $T = 10\text{ K}$. The values of the Hall mobilities (μ) are shown in (b) by triangles. The solid lines are the calculated dependencies $\omega_2(N)$ (a) $\mu(N)$ (b) and $2L_c(N)$ (c) as explained in the text.

directly seen in the increase of the localization length (L_c) presented in Fig. 2(c).

- (ii) Intermediate electron densities range. In this range, the collective modes mostly acquire a plasmon character, which is revealed in the corresponding asymmetry of the Raman lines [2] and in the blue shift of the mode frequency. The dependence of the frequency ω_2^+ on the electron density calculated in the $\text{Al}_{0.11}\text{Ga}_{0.89}\text{As}$ alloy is shown in Fig. 2(a) by a solid line. At such doping levels, the scattering of the plasmons by the impurity silicon atoms dominates, resulting in the increase of the damping constant (Γ) and in the decrease of the localization length (L_c) of the studied collective excitations.
- (iii) High electron densities range, where the effects of the correlation caused by the electron-electron interaction—which have already been found in the disordered GaAs/AlGaAs superlattices—become significant, resulting in the formation of the coherent spatial clusters [5,6] and, as a consequence, in the narrowing of the Raman lines (the decrease of the damping constant Γ) and in the increase of the localization length with the increase of the doping levels.

It ought to be pointed out that the relatively small values of the localization lengths of the collective coupled plasmon-LO phonon excitations (comparable with the interelectron distances) obtained in the highly doped samples mean that in this case, the collective excitations are mostly represented by the LO phonon-like vibrations, probably strongly coupled only with the neighboring electrons.

3. Theoretical analysis and discussion

In the range of the intermediate electron densities (range II in Fig. 2), where the scattering dominates in the origin of the spatial extents of the coupled plasmon-like excitations and the above discussed electron-electron correlations are still not significant, the modification of the wave function of the plasmons can be calculated taking into account the interaction of the plasmons with the impurities.

As it was mentioned in the introduction, in the presence of disorder collective excitations can be represented as a superposition of plane waves with the wave vectors distributed in a finite interval δq . In this case, according to the model successfully used for the optical phonons in microcrystalline silicon [7] one can present the wave function in the form of a Gaussian:

$$\varphi(r) = \frac{2\sqrt{2}}{\pi^{3/4}L_c^{3/2}} \exp\left(-\frac{2\pi^2}{L_c^2}\right), \quad (1)$$

which means the effective localization at $|r| < L_c$.

In order to calculate the variation of the localization length caused by the interaction with the scattering potential of the ionized impurities, we developed the following approach. We start with the wave function written in the form of a Gaussian (1), which is equivalent to the representation of the collective excitations as noninteracting quasiparticles with an effective charge e^* and a mass M^* , spatially localized in a sphere of radius L_c . This wave function, coinciding with a spherically symmetric ground state wave function of a 3D harmonic oscillator allows us to write the effective Hamiltonian of the collective excitations as

$$\hat{H}_{\text{eff}} = -\frac{\hbar^2}{2M^*} \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial}{\partial r} \right) + \frac{8\hbar^2}{M^*L_c^4} r^2, \quad (2)$$

where the wave function $\varphi(r)$ is the eigenfunction H_{eff} for $L_c = L_0 = 2\sqrt{\hbar/M^*\omega_0}$, which is the localization length of the harmonic oscillator with a resonance frequency ω_0 . In our case, L_0 has a meaning of the localization length of the plasmon-like excitations in the absence of impurities (in an undoped alloy). The interaction of the plasmon with impurities transforms H_{eff} into

$$\hat{H}_{\text{pl}} = \hat{H}_{\text{eff}} + U_{\text{imp}}(r), \quad (3)$$

$$U_{\text{imp}}(r) = \frac{Ze^*}{\epsilon} \sum_j \frac{e^{-q_0|r-r_j|}}{|r-r_j|}. \quad (4)$$

Here, Ze is the effective charge of the ionized impurities, e is the electron charge, ϵ is the medium dielectric constant. The exponential dependence of $U_{\text{imp}}(r)$ is associated with the screening action of the electrons located between the plasmon and the charge center interacting with it. The screening parameter is q_0 .

The wave function given by Eq. (1) is not the eigenfunction of the operator H_{pl} . We can, however, treat it as a trial function of the Schrödinger equation for the plasmon depending on the Hamiltonian H_{pl} and containing L_c as a variational parameter. Using the interaction in the form presented by Eq. (4) we calculated the ground state energy:

$$E_0 = \frac{N_i e^2 L_c^3}{4\epsilon} \left[\exp\left(-\frac{q_0 L_c - 1}{4}\right) \text{erfc}\left(-\frac{q_0 L_c - 1}{4}\right) - \exp\left(-\frac{q_0 L_c + 1}{4}\right) \text{erfc}\left(-\frac{q_0 L_c + 1}{4}\right) \right], \quad (5)$$

where N_i is the concentration of the ionized impurities correspondingly.

The value L_c of interest can be found from the condition of the minimum of the E_0 as a function of L_c :

$$\frac{\partial E_0}{\partial L_c} = 0. \quad (6)$$

As it is seen from Eq. (5) the value E_0 depends on the impurity and on the electron concentrations causing the corresponding dependence of the localization length

calculated from Eq. (6). The results of the numerical calculations of L_c fulfilled by Eq. (6) are presented in Fig. 2(c) by a solid line. A reasonable agreement between our calculations and the experimental data obtained for the $\text{Al}_{0.11}\text{Ga}_{0.89}\text{As}$ alloys was observed. It should be emphasized that no fitting parameters except the localization length of the plasmon-like excitation in the undoped alloy (L_0) were used in the calculation of the localization lengths presented in Fig. 2(c); the best correspondence with the experimental data was obtained with $L_0 = 4000 \text{ \AA}$.

4. Conclusions

The localization dynamic properties of the collective coupled plasmon-LO phonon excitations were studied in the doped AlGaAs alloys. It was shown that the plasmon-like excitations in the doped AlGaAs alloy are strongly influenced by the ionized impurities

revealing a decrease of the localization length with the increase of the doping level.

Abstract

Three dominant electron traps S1 ($E_c - 0.23$ eV), S2* ($E_c - 0.53$ eV), and S4 ($E_c - 0.74$ eV) are introduced in SiO₂/n-GaAs after rapid thermal annealing (RTA). A defect S3 ($E_c - 0.72$ eV) is observed in uncapped and annealed samples only. The S2* arises from the superposition of two defects, of which S2 ($E_c - 0.46$ eV) can be resolved using filling pulse widths < 1 ms. The intensities of S1, S2*, and S4 show Arrhenius-like dependencies on the RTA temperature. We argue that the defects are formed as a result of an increase in the ratio of As : Ga in the near-surface region of the GaAs layers. The electronic and annealing properties of S4 show that it is a member of the EL2 family of defects. The removal of S1 and S2*, as well as the introduction of secondary defects, during isochronal annealing experiments is also discussed. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Impurity-free Disordering (IFD) using SiO₂ capping layers has recently been used to engineer the bandgap of GaAs-based heterostructures for the monolithic integration of optoelectronic devices (for a comprehensive review of impurity-free disordering see, Ref. [1]). IFD proceeds via the diffusion of point defects, namely the vacancies, on the group III sublattice in the GaAs-based system [1,2]. Excess vacancies (V_{Ga}) are generated at the SiO₂/GaAs interface by the out-diffusion of Ga atoms into the dielectric layer. The controlled modification of semiconductor properties using such defect engineering

can be better understood and improved by investigating the defects created during capped annealing. In this paper, we report on the electronic and annealing properties of electron traps introduced in rapid thermally annealed (RTA) SiO₂-capped n-GaAs epilayers using deep level transient spectroscopy (DLTS).

2. Experimental procedure

Epitaxial GaAs layers of (1 0 0) orientation and doped with 1×10^{16} Si cm⁻³ were used. The 4 μm thick epitaxial layers were grown by MOCVD on n⁺-GaAs substrates. The epitaxial side of the samples were capped with 200 nm SiO₂ by plasma-enhanced chemical vapor deposition. RTA was performed on both SiO₂-capped and uncapped GaAs samples at 800 °C, 850 °C or 900 °C for 30 s under Ar flow. After removing the SiO₂ layer,

selected samples were annealed for 20 min at various temperatures. Annealing up to 400°C was carried out in an Ar atmosphere, while annealing above 400°C was performed under an arsine ambient. DLTS measurements were made on Au Schottky barrier diodes deposited by resistive evaporation on the chemically cleaned layers. Reverse bias and filling pulse conditions were adjusted so that the depth region between 0.35 and 0.60 μm of each sample was probed during the DLTS measurements.

3. Results and discussion

The as-grown n-GaAs epilayers used in this study contained only the EL2 ($E_c - 0.79\text{ eV}$) with concentrations $\sim 1 \times 10^{13}\text{ cm}^{-3}$ [spectrum (a) in Fig. 1]. IFD created electron traps S1 ($E_c - 0.23\text{ eV}$), S2* ($E_c - 0.53\text{ eV}$), and S4 ($E_c - 0.74\text{ eV}$) as shown in spectrum (c) of Fig. 1. In addition to S1, S2*, and EL2, a defect S3 ($E_c - 0.72\text{ eV}$) is only observed in samples annealed without SiO_2 capping. It should, however, be noted that the presence of S3 in IFD samples could be masked by the much larger defect peak S4. Defect S4 is observed only in SiO_2 -capped and annealed samples, and its shallower peak position suggests that it is not the EL2. A comparison of spectra (b) and (c) reveals that although S1 and S2* are generated thermally (i.e. without SiO_2 capping), their concentrations are much increased by IFD. Spectra (d) and (e) were taken from samples annealed at 400°C and

500°C, respectively, following initial IFD at 900°C for 30 s. These spectra show the creation of secondary defects during post-IFD annealing, which will be further discussed later.

We have performed variable-filling-pulse-width (t_p) measurements on S2* ($\sim 221\text{ K}$). Defect peak S2* is, in fact, a superposition of two discrete defects with different capture cross-sections, as evidenced by the two thresholds and the plateau in Fig. 2. In the present study, we detect the superposition of both defects, i.e. S2*, since we have used $t_p = 150\text{ ms}$. In a previous study, we used $t_p = 0.2\text{ ms}$ and determined an activation energy ($E_c = 0.46\text{ eV}$) for S2 [3]. We showed that S2 had an electronic “signature” similar to Si-related defects observed in n-GaAs epilayers grown on Si substrates. Furthermore, S2 was created with an activation energy $\sim 4.4\text{ eV}$, which is in the range 4.02–4.91 eV reported in the literature for the activation energy of group III interdiffusion coefficients in GaAs/AlGaAs and GaAs/InGaAs quantum well heterostructures [3]. Following these observations, S2 has been speculated to be the $V_{\text{Ga}}\text{--Si}_{\text{Ga}}$ complex [3]. The results shown in Fig. 2 indicate that the individual depth profiles of the two overlapping electron traps comprising S2* can be separated using different pulse widths, in a fashion similar to the recently reported deconvolution of overlapping vacancy (VO) and interstitial-related ($C_i\text{--}C_s$) defects in ion implanted n-type Si [4].

We now turn to the influence of RTA temperature on the creation of electron traps in SiO_2 -capped n-type GaAs epilayers. RTA was performed at 800°C, 850°C, or 900°C for 30 s under Ar flow. The peak intensities of S1, S2*, and S4 exhibit Arrhenius-like dependencies on the RTA temperature, $1000/T_{\text{RTA}}$, as depicted in Fig. 3. There is the consensus that defects created in

Fig. 1. DLTS spectra from uncapped (b) and (c) SiO_2 -capped and annealed n-GaAs. RTA was performed for 30 s at 900°C using proximity capping. Only defect EL2 (a) was present in the as-grown epilayers. Spectra (d) and (e) were taken from samples annealed at 400°C and 500°C for 20 min following impurity-free disordering at 900°C.

Fig. 2. Intensity of defect peak at $\sim 221\text{ K}$ (S2*) as a function of the filling pulse width, t_p .

Fig. 3. Arrhenius-type dependence of defects creation on RTA temperature, T_{RTA} .

SiO₂-capped GaAs during annealing relate to the outdiffusion of Ga atoms into the capping layer [1,2]. It is pointed out here that the diffusivity of Ga atoms in SiO₂ also shows an Arrhenius-like relationship with the inverse of temperature [5]. The results shown in Fig. 3, therefore, provide the conclusive evidence that the introduction of S1, S2*, and S4 in our n-type GaAs epitaxial layers is directly related to the outdiffusion of Ga atoms into the SiO₂ capping layer during RTA. An exponential increase in the outdiffusion of Ga atoms into the SiO₂ layer with the RTA temperature results in an exponential increase in the concentration of V_{Ga} . The consequent increase in the ratio of As:Ga in the near-surface region of n-GaAs gives rise to the exponential increase in both As_{Ga} and As_i . We, therefore, propose that defects S1, S2*, and S4 are related to V_{Ga} , As_i , As_{Ga} , or complexes thereof. Similar to the results in Fig. 2, variable-filling-pulse-width measurements have shown that S2* was ~3 times larger than S2 in samples annealed at 800°C or 850°C.

Although defects are necessary to engineer the bandgap in GaAs-based heterostructures, they may also have detrimental effects on device performance. For instance, deep levels, especially those close to the middle of the bandgap, may act as efficient recombination centres [6]. In addition to increasing the leakage current of devices (due to free carrier compensation and increased generation/recombination of carriers), non-radiative recombination centres may also decrease the excitonic behaviour of optical devices [7]. Hence, it is desirable to study the removal kinetics of deep levels for the optimisation of device performance. DLTS spectra (d) and (e) in Fig. 1 show that the removal of defects S1 and S2* are accompanied by the creation of secondary defects. Fig. 4 summarises the isochronal annealing behaviour of defects S1 and S2*, together with the

Fig. 4. Isochronal annealing behaviour of defects.

creation of secondary defects. The change in the intensity of S4 is not shown, but it remained unchanged up to 600°C [spectra (c), (d), and (e) in Fig. 1]. We have previously proposed that S4 was a member of the EL2 family of defects [8]. The intensities of S1 and S2* remained unchanged up to 350°C. Their dramatic removal above 350°C is accompanied by the introduction of a host of secondary defects, including SA2, SA3, SA4, and SB1. The defect SA3 could be detected only at 350°C and 400°C, because it is completely masked by the defect peak SA4 at the higher annealing temperatures. Defect SA5 could be resolved at 450°C after a significant reduction in S2*. It is worth noting here that SA5 may well not be a secondary defect, but one of the constituents of S2*. A defect peak, SB1, which increases with the increasing annealing temperature > 500°C, can also be observed when S2* has been removed. Although the secondary defects may be related to complexes involving V_{Ga} and As_i , when S1 and S2 dissociate, their identities remain unknown. Table 1 summarises the electronic signatures of all electron traps observed in this study (capture cross-sections obtained from extrapolation of the Arrhenius plots).

4. Conclusions

In summary, we have investigated the electronic and isochronal annealing properties of defects created in n-GaAs epilayers by impurity-free disordering. The creation of defects S1, S2*, and S4 is related to the outdiffusion of Ga atoms into the SiO₂ layer during RTA at 800–900°C. We have provided the evidence that S2* arises from the superposition of two discrete traps, including S2. The generation of excess V_{Ga} in the near-surface region of n-GaAs epilayers during RTA also

Table 1
Summary of the electronic properties of defects detected in this study

Defect	Activation energy (eV)	Capture cross-section (cm ²)	Remarks
S1	0.23 ± 0.02	7 × 10 ⁻¹⁵	Electric field dependent [8]
S2*	0.53 ± 0.03	4 × 10 ⁻¹³	Composed of 2 defects, including S2 [3]
S4	0.74 ± 0.04	6 × 10 ⁻¹³	Member of EL2 family of defects [8]
SA2	0.16 ± 0.02	6 × 10 ⁻¹³	
SA3	0.39 ± 0.02	2 × 10 ⁻¹³	
SA4	0.37 ± 0.02	7 × 10 ⁻¹⁴	
SA5	0.51 ± 0.02	6 × 10 ⁻¹⁵	Could be a component of S2*?
SB1	0.51 ± 0.02	2 × 10 ⁻¹³	

creates an excess of As_i and As_{Ga}. We have, therefore, proposed that S1, S2*, and S4 are related to either V_{Ga}, As_i, As_{Ga}, or complexes thereof. S1 and S2* are thermally stable up to 350°C, and their dissociation at higher annealing temperatures gives rise to several secondary defects. S4 is stable up to 600°C, which is typical of the annealing behaviour of a member of the EL2 family of defects.

Acceptor–hydrogen complexes in semiconductors under pressure

Abstract

The structure of acceptor–hydrogen complexes is a subject of fundamental and technological interest. To probe the interactions between hydrogen, the acceptor, and the surrounding host atoms, hydrostatic pressure may be applied over a wide range. Using infrared spectroscopy at liquid-helium temperatures, we have observed carbon and carbon–hydrogen local vibrational mode (LVMs) in InP at hydrostatic pressures as high as 5.5 GPa. For pressures beyond 4.5 GPa, the carbon–hydrogen mode was not observed, perhaps as a result of a transformation of the complex into a different configuration. The LVM arising from carbon substitutional impurities varies linearly with pressure, whereas the shift of the carbon–hydrogen mode has a positive curvature. Both of these observations are in qualitative agreement with the pressure dependence of LVMs in GaAs. While the substitutional carbon impurities show very similar pressure shifts in the two materials, the linear pressure coefficient of the carbon–hydrogen stretch mode in InP is nearly three times that in GaAs. © 2001 Elsevier Science B.V. Keywords: Hydrogen; Local vibrational modes; Infrared; Pressure

Hydrostatic pressure is an important experimental parameter that can be tuned over a wide range in order to obtain insight into the properties of solids [1]. The development of high-pressure diamond anvil cells (DACs) has led to extensive experimental research on the properties of high-density molecular solids [2] and semiconductors [3]. In a DAC, a sample is placed in a pressure-transmitting ambient, such as liquid nitrogen or alcohol mixtures. Pressures up to several hundred GPa (1 GPa = 10 kbar = 10^{-2} Mbar = 9870 atm) have been achieved.

DACs are well suited to infrared (IR) spectroscopy. Diamonds are transparent over a wide spectral range, although type I diamonds contain nitrogen impurities that strongly absorb from 1000 to 1500 cm^{-1} . Type II-A diamonds does not contain this absorption band. In addition, all diamonds contain a two-photon absorption band around 2100 cm^{-1} . N_2 , Ar, or He are typically used

as the ambient, since, unlike alcohol mixtures, they are transparent to IR light. In N_2 , a vibrational mode of CO_2 impurities is sensitive to pressure and is used as a precise in situ pressure calibration for IR absorption experiments [4]. This calibration has been established up to a pressure of 7 GPa.

To measure the IR spectra of semiconductors under pressure, a custom diamond anvil cell has been designed and fabricated (Fig. 1). In this cell, force is applied by six Allen screws, which squeeze together a piston and cylinder [5]. The diamonds are supported by flat and hemispherical backing plates made from tungsten carbide. An off-axis parabolic mirror efficiently focuses the collimated IR beam onto the sample. A photoconducting Ge:Cu detector is placed in close proximity to the sample, so that a large fraction of the transmitted IR light is collected. The entire assembly is placed in a Janis STVP-100 liquid-helium cryostat and kept at a temperature of 6–12 K. The low temperatures are advantageous for two reasons. First, the local vibrational mode (LVM) lines sharpen with decreasing

Fig. 1. Cross section of DACs used for IR spectroscopy. The diamonds, gasket, and sample are shown in the inset.

temperature. Second, the sensitive, low-noise Ge:Cu detector operates at liquid-helium temperatures.

LVM spectroscopy is a useful technique for determining the microscopic structure of impurities and defects in semiconductors [6–8]. LVMs of impurities are localized in real and frequency space [9], giving rise to sharp IR absorption peaks at liquid-helium temperatures [8]. Hydrogen, for example, typically has LVM frequencies 5–10 times the maximum phonon frequency and has narrow IR absorption peaks [10–12]. After the discoveries that hydrogen passivates donors [13] and acceptors [14] in GaAs, numerous hydrogen-related complexes have been observed in compound semiconductors [10,15]. In this paper, we review measurements of the dependence of carbon and carbon–hydrogen LVMs in GaAs and InP under large hydrostatic pressures.

The effect of pressure on LVMs in semiconductors has only recently been studied and has shown interesting results. Pressure has been applied, in conjunction with LVM spectroscopy, to probe DX centers in GaAs [16], resonant interactions in AlSb [17], hydrogen-related complexes in GaAs [18] and InP [19] and interstitial oxygen in silicon [20]. It is hoped that hydrostatic pressure may be used to differentiate between different hydrogen configurations that have the same symmetry (e.g., bond-centered vs. antibonding).

Samples discussed in this paper were carbon-doped and grown by metalorganic chemical vapor deposition on semi-insulating substrates. For the case of InP:C, it has been shown [21] that approximately half of the carbon impurities are paired with hydrogen (C_P-H) while the other half are substitutional carbon acceptors (C_P) that are compensated by donors. At liquid-helium temperatures, the C_P-H stretch mode and C_P mode have frequencies of 2703 and 547 cm^{-1} , respectively. It was proposed [21] that the hydrogen attaches directly to the

Fig. 2. Schematic diagrams of (a) substitutional carbon acceptor (C_P) and (b) carbon–hydrogen pair (C_P-H), in InP.

Fig. 3. IR spectra of InP:C, H for three different pressures, at a temperature of 9 K. The arrow indicates where the $^{12}\text{C}_P-H$ peak should be at 5.2 GPa, by extrapolation from the lower pressure data.

carbon acceptor, in a $[111]$ bond-centered orientation, adjacent to a host indium atom (Fig. 2). This bond-centered model is believed to apply for all known C_V-H pairs in III–V semiconductors [22].

IR spectra for several different pressures are shown in Fig. 3. In this figure, the spectra were taken during a decrease in pressure. The pressure was increased and decreased several times, and no evidence of hysteresis was observed. Both the C_P and C_P-H peak frequencies increase with increasing pressure. For pressures beyond approximately 4.5 GPa, the C_P-H peak was not observed. The arrow in Fig. 3 indicates where the peak should be, by extrapolation from the lower pressure data. The disappearance of this peak may be due to nonhydrostatic stresses that cause significant line broadening. It is not clear, however, why the carbon LVM would not be affected to the same degree. A second possibility is that the C_P-H complex transforms into a different configuration at high pressures, since there is no associated change in the C_P LVM. However, no new peak is observed, so that the location of the “missing hydrogen” is currently an unsolved mystery.

The pressure-dependent shifts of InP two-phonon modes and C_P LVM were measured. The two-phonon modes have been identified previously as 2 TO and LO+TO modes [23]. In the range of pressures studied,

Fig. 4. InP: $^{12}\text{C}_\text{p}$ -H stretch-mode frequency as a function of pressure. The solid line is a polynomial least-squares fit to the data [Eq. (5)].

the frequencies of the phonon modes and C_p LVM vary linearly with pressure. Least-squares linear fits yield the following expressions:

$$\nu(\text{InP}:^{12}\text{C}_\text{p}) = 546.9 + 9.5P, \quad (1)$$

$$\nu(\text{InP}, 2\text{TO}) = 631.6 + 10.7P, \quad (2)$$

$$\nu(\text{InP}, \text{LO} + \text{TO}) = 659.0 + 10.8P, \quad (3)$$

where the frequencies ν are in cm^{-1} and pressures P are in GPa. The similarity between the phonon and LVM shifts is consistent with a mass-defect model, in which the properties of the bonds are not affected by the substitution of an impurity. The pressure dependence of the carbon LVM is similar to that in GaAs (Ref. [18]):

$$\nu(\text{GaAs}:^{12}\text{C}_\text{As}) = 582.7 + 9.3P, \quad (4)$$

The C_p -H stretch-mode frequency is plotted as a function of pressure in Fig. 4. The plot shows a slight positive curvature. A least-squares quadratic fit yields

$$\nu(\text{InP}:^{12}\text{C}_\text{p}-\text{H}) = 2703.4 + 16.4P + 0.9P^2. \quad (5)$$

A positive curvature was also observed in GaAs: C, H stretch modes [18]:

$$\nu(\text{GaAs}:^{12}\text{C}_\text{As}-\text{H}) = 2635.2 + 6.0P + 1.1P^2. \quad (6)$$

While the quadratic terms are similar, the linear term for InP: C_p -H is nearly three times that for GaAs: C_As -H. The reason for this significant difference is not obvious. One contributing factor may be the weaker C_p -In bond compared with the C_As -Ga bond [24,25]. The weaker bond would allow for a larger displacement of the C_p -H pair toward the plane of the three neighboring In atoms, allowing us to speculate that this could lead to a larger rate of change of the LVM frequency with increasing pressure.

In summary, we have measured the pressure dependence of LVM frequencies in InP. As in the case of AlSb: ^{12}C [4], GaAs: ^{28}Si [16], GaAs: ^{12}C , and GaAs: ^{13}C [18], we find that the InP: $^{12}\text{C}_\text{p}$ LVM

frequency varies linearly with pressure. The pressure-dependent shift of the InP: $^{12}\text{C}_\text{p}$ -H stretch mode has a positive curvature, as in the case of GaAs. This result supports the hypothesis that bond-centered hydrogen complexes generally exhibit positive curvatures in their frequency vs. pressure plots. In the future, hydrostatic pressure may prove to be a useful technique for differentiating between bond-centered and antibonding configurations. For instance, the different theoretical models proposed for Mg-H complexes in GaN should predict different pressure-dependent LVM shifts, allowing us to test the models experimentally.

The authors wish to acknowledge E.E. Haller and J. Beeman (Lawrence Berkeley National Laboratory) for providing the Ge:Cu detector and S. Watson (Washington State University) for construction of the diamond-anvil cells. Abstract

The results of a study of peculiarities of donor–acceptor recombination in δ -doped type II GaAs/AlAs superlattices are presented. The binding energies of donors and acceptors in the superlattices have been determined. The possibility of donor–acceptor recombination in superlattices with impurities separated by several undoped layers has been demonstrated. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Superlattice; Photoluminescence; Impurity

Recently type II quantum wells (QWs) and superlattices (SLs), the characteristics of which strongly differ from those of type I QWs and SLs, were investigated both theoretically and experimentally. The investigation of recombination mechanisms in superlattices with type-II band alignment is gaining not only a fundamental, but also an applied importance today. It was shown recently that Auger recombination, which is the major channel of nonradiative recombination at high temperatures and excitation densities, can be suppressed in type II structures [1], which could promote creation of low-threshold lasers [2] on the basis of such structures. The fundamental excitonic recombination has been investigated in type II SLs in detail, while radiative recombination through impurity levels has been studied only scarcely. In this work we report the results of a study of donor–acceptor recombination (DAR) in δ -doped type II GaAs/AlAs superlattices.

The study was performed on δ -doped short-period GaAs/AlAs superlattices grown by molecular beam epitaxy on (100) GaAs substrates at a substrate temperature of 600°C. The SLs consisted of 40 periods of GaAs and AlAs layer pairs grown on top of a 0.5 μ m GaAs buffer layer. The SL layer thicknesses ranged from 5 to 11 monolayers. The doping of the SLs was

performed with δ -layers of acceptors (beryllium) placed in the GaAs layers and δ -layers of donors (silicon) in the AlAs layers. The δ -layers were formed either symmetrically in the center of SL layers, or two monolayers apart from the direct heterointerface (AlAs on GaAs), and could be separated one from another with several undoped layers of the SL.

Steady-state photoluminescence (PL) was excited by an Ar⁺ laser with a wavelength of 488 nm. The excitation intensity was varied in the range 2–100 W/cm². Nonstationary PL was excited by a nitrogen laser with a pulse duration of 10 ns and a repetition frequency 1 kHz. Spectra and PL kinetics were recorded by a double grating spectrometer equipped with a cooled S-20 cathode photomultiplier operated in the photon counting mode.

The low-temperature steady-state PL spectra of non-center-doped (GaAs)₇(AlAs)₉ SLs (7 monolayers of GaAs and 9 monolayers of AlAs per period) with different doping concentrations are shown in Fig. 1. The line of X₂ excitons consisting from electrons in the X₂ valley of the conduction band of AlAs and holes in the Γ valley of the valence band of GaAs dominates in the spectrum of the structure with the lowest doping level of 5×10^{10} cm⁻² (upper spectrum), accompanied by its phonon replicas Y1 and Y2. The line Y1 is separated by 27 meV from the X₂ line, which corresponds to the energy of LA phonons in GaAs and AlAs, and the line

Fig. 1. Steady-state PL spectra of δ -doped type II $(\text{GaAs})_7(\text{AlAs})_9$ superlattices. Doping levels: 1— 5.5×10^{10} , 2— 2×10^{11} , and 3— $7.5 \times 10^{11} \text{ cm}^{-2}$. Measurement temperature $T = 4.2 \text{ K}$.

Y_2 is separated by 49 meV, which corresponds to the LO phonon energy in AlAs.

When the impurity concentration reaches 10^{11} cm^{-2} , a new broad line emerges in the spectrum 50–100 meV below the X_z exciton line, similar to the line which was earlier identified in the spectra of uniformly doped SLs as a line of interimpurity transitions between donors located in the AlAs layers and acceptors in the GaAs layers of an SL [3]. When the impurity concentration is greater than $2 \times 10^{11} \text{ cm}^{-2}$, this line becomes dominating in the spectrum. The increase of the intensity of the new line with doping concentration increase confirms its assignment to the donor–acceptor recombination mechanism.

To reveal the peculiarities of donor–acceptor recombination in δ -doped type II SLs and to determine the carrier binding energies the steady state and nonstationary PL spectra of samples with different layer thicknesses were measured at different temperatures and excitation intensities.

The new line displayed a red shift in the spectrum with a decrease in the excitation intensity, as is the case for DAR in bulk semiconductors. Fig. 2 shows the dependence of the position of the new line on excitation intensity for samples with different layer thicknesses. The magnitude of the red shift is larger than in bulk material and depends on the SL layer thicknesses: in the $(\text{GaAs})_7(\text{AlAs})_7$ SL the shift reaches 20 meV when the excitation intensity is changed by 10 times, while in the $(\text{GaAs})_{11}(\text{AlAs})_{11}$ SL the shift amounts to 15 meV. In comparison, in bulk AlAs a 10-fold excitation intensity increase results in a 10 meV shift of the DAR line [4].

Fig. 2. Dependence of the donor-acceptor PL line position on excitation intensity for the $(\text{GaAs})_7(\text{AlAs})_7$ SL (curve 1) and $(\text{GaAs})_{11}(\text{AlAs})_{11}$ SL (curve 2) at $T = 4.2 \text{ K}$.

Fig. 3. Decay curves of the donor-acceptor PL line for the $(\text{GaAs})_{11}(\text{AlAs})_{11}$ SL (curve 1) and $(\text{GaAs})_7(\text{AlAs})_7$ SL (curve 2) and their power-law fits (curves 3 and 4, respectively). Measurement temperature $T = 6 \text{ K}$.

After a transient excitation the integrated intensity I of the new line exhibits a microsecond-scale decay which follows a power-law $I(t) \sim 1/t^\gamma$ (Fig. 3). The value of the exponent γ depends on the SL layer thicknesses: it was found to be smaller in the $(\text{GaAs})_7(\text{AlAs})_7$ SL ($\gamma = 0.73$) than in the $(\text{GaAs})_{11}(\text{AlAs})_{11}$ sample ($\gamma = 0.93$). It is necessary to note that γ does not change with the sample temperature increased in the range up to $\approx 50 \text{ K}$. The line displays a red shift in the time-resolved spectrum with delay time.

Fig. 4 shows a typical dependence of the integrated intensity and position of the DAR line on temperature

Fig. 4. Temperature dependencies of the donor-acceptor line intensity and position taken on the $(\text{GaAs})_{11}(\text{AlAs})_{11}$ SL sample.

(T). It is seen that the DAR line is red-shifting with temperature faster than the band gap is decreasing. The intensity of the DAR line decreases exponentially with temperature increase. The decrease of the DAR line intensity is apparently connected with ionization of the smaller binding energy impurity in a pair (in bulk AlAs the binding energy of the silicon donors is equal to 80 meV [4,5] and the binding energy of the beryllium acceptors in bulk GaAs is 30 meV [6]). To determine the acceptor binding energy the temperature dependence of the integrated intensity of the DAR line was approximated with the relationship $I(T) = I_0/[1 + A \exp(-E_A/kT)]$, where I_0 is the intensity at 4.2 K, A is a constant, E_A is the acceptor activation energy, and k is the Boltzmann's constant. The activation energy value obtained from the fit equals to 12.5 ± 0.5 meV independently on the layer thickness and position of impurity δ -layers. This value disagrees with the results obtained in experiments with beryllium in quantum wells of similar thickness, where its activation energy is equal to 40 meV [6]. The smaller value of the thermal activation energy in δ -doped SLs may be caused by Coulomb interaction between the acceptor and donor in a pair. To determine the binding energy of silicon donors the experimental dependence of the position of the DAR line maximum on the excitation intensity J at $T = 4.2$ K was approximated by the theoretical dependence obtained in Ref. [7] for the three-dimensional case:

$$J = D \left\{ \frac{[h\omega_m - E_g + (E_A + E_D)]^3}{[2(E_g - (E_A + E_D) - h\omega_m) + e^2/(\epsilon R_B)]} \right\} \\ \times \exp \left\{ \frac{-2e^2/(\epsilon R_B)}{[h\omega_m - E_g + (E_A + E_D)]} \right\},$$

Fig. 5. Steady-state PL spectra of the $(\text{GaAs})_7/(\text{AlAs})_9$ superlattice with dopant δ -layers located near the AlAs/GaAs heterointerface. Spectra 1 and 2—excitation intensities of 15 and 30 W/cm^2 , respectively. Doping level $5 \times 10^{11} \text{ cm}^{-2}$.

where $h\omega_m$ is the position of the DAR line maximum, ϵ is the permittivity of the medium chosen to be 11.3, E_g is the band gap which was taken to be equal to the distance between the lowest electron quantization level in the AlAs layer and the lowest heavy hole level in the GaAs layer, $E_A + E_D$ is the sum of the binding energies of acceptor and donor, R_B is the acceptor Bohr radius, D is a proportionality factor, and e is the electron charge. The sum $E_A + E_D$ in SLs determined by the fit equal to 150 meV in the $(\text{GaAs})_7(\text{AlAs})_7$ SL and 140 meV in the $(\text{GaAs})_{11}(\text{AlAs})_{11}$ SL. The binding energy of donors in the AlAs layers can then be deduced from these data. Taking into account that the found acceptor binding energy may have decreased because of the Coulomb interaction and taking it equal to the binding energy of beryllium in a single QW, that is 40 meV, we obtain the binding energy of silicon in the AlAs layers of the $(\text{GaAs})_7(\text{AlAs})_7$ SL of 110 meV, and 100 meV in the $(\text{GaAs})_{11}(\text{AlAs})_{11}$ SL. It is seen that the donor binding energies in SLs obtained in the current work exceed the values reported for AlAs, which may be caused by the influence of the SL potential on the binding energy.

Next, the DAR in SLs with the dopant layers located near the heterointerfaces was studied. We found that in these asymmetric SLs the DAR line exhibits a complex structure and consists of two strongly overlapping bands separated by approximately 40 meV (Fig. 5). We believe that the appearance of the two bands is caused by the

possibility of carrier recombination in both directions—through both the direct and inverted heterointerfaces in such SLs.

To evaluate the distance between the dopant layers through which the interimpurity recombination is still possible, we separated the n- and p- δ -doped layers of the SL with several undoped layers. We found that the DAR line is observed in SLs where impurities are separated by two and even by four undoped SL layers, or by 4.3 nm and 7.2 nm, respectively.

The large shift of the DAR line with the excitation intensity that we observed (Fig. 2) is one of the peculiarities of donor–acceptor recombination in type II SLs. The larger line shift in comparison with the bulk data is explained by the increased impurity binding energies in SLs [8–10].

The increase of shallow impurity binding energies in an SL should be accompanied by a decrease of the recombination rate of a DAR line. On the contrary, a decrease of the distance between the δ -layers should increase the DAR rate. However, we observed that in the (GaAs)₁₁(AlAs)₁₁ SL the DAR decay is faster than in the (GaAs)₇(AlAs)₇ sample (Fig. 3). We therefore conclude that the effect of the SL potential on the impurity wavefunctions turns out to be stronger than the influence of the change of the distance between impurity δ -layers in the SL layers.

In summary, the following peculiarities of donor–acceptor recombination have been experimentally observed in δ -doped type II GaAs/AlAs superlattices: (1) the magnitude of the DAR line shift with excitation intensity is greater than in 3D, and (2) the DAR line decay kinetics is described by a power-law $1/t^\gamma$ with the power γ being dependent on the SL layer

thickness. The carrier binding energies of donors and acceptors in SLs have been determined. The possibility of donor–acceptor recombination in SLs with impurities separated by several undoped SL layers has been demonstrated.

The DX^- -centre formation at high electric fields in planar-doped GaAs:Si

M. Asche^{a,*}, O.G. Sarbey^b

^aGreifswalderstr. 88, D-10409 Berlin, Germany

^bInstitute of Physics, Prospekt Nauki 46, Kiev, Ukraine

Abstract

Investigating current transients, it is established that in the dark at low temperatures resonant energy levels in the conduction band can be transformed in the presence of hot electrons into metastable centres. There exist critical lower thresholds with respect to the applied electric field and the Si_{Ga} -concentration. These facts can be explained by carrier heating. It leads to a change of the potential wells. Due to their significant deepening more electrons are in subband states above the energy of the DX^- -centre and therefore allow the formation of metastable centres. The hot carriers also decrease the screening of the interaction between neighbouring Si_{Ga} -atoms. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

In homogeneously doped GaAs:Si, the DX-centre with 2 bound electrons and the Si atom shifted in $\langle 111 \rangle$ -direction towards an interstitial site [1,2] could explain the essential difference between the thermal and optical activation and persistent photoconductivity. This model provoked many discussions, and the description of some experimental results by such a centre was not always unambiguous.¹ However, in IR spectroscopy under high pressure a new line was detected and connected with the DX-centre [3]. Another proof of the model is the results of positron annihilation experiments, which exhibited a small “vacuum” at the Si_{Ga} site, when the DX^- -centre had been created, vanishing again when destroyed [4].

In highly doped delta-layers, in which group IV impurities are deposited on cation sites of III–V semiconductors, the wave functions of the donors and the conduction band edge overlap, and there are deep potential wells formed, in which the motion of the electrons is restricted perpendicular to the plane. Nevertheless, the DX-centres due to their localized wave function might be formed in delta layers. It had been suggested that DX^- -centres could be responsible for the well-known discrepancy between the concentrations of active donors and nominal deposited Si-atoms (e.g. Ref. [5]), since it was expected that in such planar structures due to the high electron concentration the Fermi level can reach the energy of the resonant states. However, in Ref. [6] the broadening of the potential wells at high donor concentration and growth temperature was shown to inhibit the DX^- -centre formation in the absence of pressure in contrast to a narrow potential profile. Yet persistent photoconductivity observed in a layer with a sheet donor concentration of 10^{13} cm^{-2} seemed to prove the existence of DX-centres [7]. Probably the different results are connected with the strong dependence of properties of delta-layers on the

¹Fits to experimental data neglecting the correlation between positively and negatively charged ions seemed to favour the AI type.

growth conditions. The occupation of resonant states due to an electron heating in high electric fields and the formation of DX⁻-centres in GaAs/AlGaAs heterostructure was thought to be the origin of a current decrease [8], yet it was probably connected with the Si dopants in the barriers of the MODFETs.

2. Experiments and results

We investigated GaAs:Si under the influence of high electric field pulses—of 240 ns duration each in order to eliminate Joule heating—applied within the doping plane to explore the enhanced average energy of the carriers for a possible formation of metastable centres. The measurements were performed in the dark in liquid nitrogen or helium baths.

Our GaAs:Si structures were grown by molecular beam epitaxy at comparatively high temperatures (550°C and 610°C) and low equivalent As partial pressure [9]. The main differences of the presented four structures are the substrate orientations and dopant concentrations: (001) for the first pair (A,B) with a doping of $7 \times 10^{12} \text{ cm}^{-2}$ and a second pair (C,D) 2° misoriented towards the (111)-Ga plane with a deposition of nominal $1.4 \times 10^{14} \text{ cm}^{-2}$ Si atoms by interrupted growth technique. The latter structures were especially grown under those conditions to obtain “wires” of Si pairs along the edges of the terraces [10]. They differ from each other by a reduced temperature during overgrowth for C. However, concerning our high field transport investigations, all the structures behave in a similar way as long as the concentration of electrically active donors is not below $3 \times 10^{12} \text{ cm}^{-2}$.

The results exhibit five particularities:

1. In the course of the applied high field pulses the current decreases remarkably as shown for type D in Fig. 1 with electric field strength as parameter. For decreased doping down to $7 \times 10^{12} \text{ cm}^{-2}$ and an estimated lower limit of conducting electrons by Hall measurements of 3.5×10^{12} – $5 \times 10^{12} \text{ cm}^{-2}$ by Shubnikov–De Haas measurements—(type B) the saturated current change was approximately alike, while for somewhat less electrically active donors (type A) it gained only a value of some percent, and no effect at all was to be seen for a less doped structure with only $4 \times 10^{12} \text{ cm}^{-2}$ Si atoms.²

2. A current decrease occurs realised only if the applied field is higher than a certain threshold field. The latter strongly depends on the concentration of electrically active donors being about 6 kV/cm for

Fig. 1. Current change as a function of applied field pulses normalised to its initial value for structure D with an Si doping concentration of $1.4 \times 10^{14} \text{ cm}^{-2}$ and a lower limit of electron concentration estimated as $4 \times 10^{12} \text{ cm}^{-2}$ by Hall measurements.

$1.5 \times 10^{13} \text{ cm}^{-2}$ (type C) to about 4 kV/cm for $3.5 \times 10^{12} \text{ cm}^{-2}$ (type B).

3. The new current value remains unchanged for days at low temperature. Besides a recovery to its initial value by thermal activation above 130 K or an optical excitation with an energy above 0.9 eV [11]—also typical for homogeneously doped GaAs—the conductivity can be partly restored by lower electric fields than used to form the centres.

4. In the beginning of the applied heating field the current changes proportional to the square root of time. Therefore, in order to analyse the data they were presented in dependence on $t^{1/2}$ and a fitting procedure with one of the expressions

$$\delta j(t)/j(0) = \delta j_s/j(0) \times \sqrt{t/\tau} / (1 + \sqrt{t/\tau})$$

or

$$\delta j(t)/j(0) = \delta j_s/j(0) \times \{1 - \exp(-\sqrt{t/\tau})\}$$

was used. The values of the time constants do not depend on the chosen fitting procedure and those of the saturation value of the normalised current changes only up to 10%. Then $\delta j_s/j(0)$ and τ obtained from the transients are shown in Fig. 2a and b as functions of the applied field. They can be presented by

$$\delta j_s/j(0) = \delta j_s(\infty)/j(0) \times \left\{ 1 - \exp\left(-\frac{F - F_0}{F_j}\right) \right\},$$

$$\tau = \tau(\infty) / \left\{ 1 - \exp\left(-\frac{F - F_0}{F_\tau}\right) \right\},$$

i.e., both expressions with a threshold field F_0 , and $j_s(\infty)$ as well as $\tau(\infty)$ denoting the values for $F \rightarrow \infty$.

5. For lower lattice temperature (helium bath) the characteristic features remain qualitatively the same,

²Remember that $4 \times 10^{12} \text{ cm}^{-2}$ is equivalent to about $8 \times 10^{18} \text{ cm}^{-3}$, while in homogeneously doped GaAs with pressure the DX⁻-centre was observed down to 10^{17} cm^{-3} .

Fig. 2. Normalised saturation current change (a) and time constant for the current decrease (b) as functions of applied field obtained by fitting procedures.

only the normalised current change at a given field strength is somewhat bigger.

Besides, the field dependences of the currents before and after creation of centres almost coincide, when normalised in the region of highest applied fields, and allow to conclude that the high field mobilities do not differ remarkably. Therefore, the normalised saturation current change equals the normalised carrier concentration change. Consequently the concentration of created DX^- -centres can be determined.

3. Discussion

Particularity 3 is an evidence that in our experiments metastable DX^- -centres are the cause of current decrease. To form these centres it is necessary to populate the resonant levels of Si in the Γ -conduction band. The carrier heating in strong electric fields, firstly, changes the form of the potential well as well as the energy of its bottom and, secondly, weakens the screening of the interaction of charged ions, consequently decreasing the energy difference between

Fig. 3. Self-consistently calculated potential Φ as well as quasi-Fermi level μ_F for $7 \times 10^{12} \text{ cm}^{-2}$ donors at electron temperatures of 77 and 900 K, respectively, and the energy level of DX^- for 900 K (being still positive for 77 K).

positively and negatively charged Si-ions. We estimated both the factors by self-consistent calculations of the energy levels and the quasi-Fermi energy in the two-dimensional potential well in local-density approximation as functions of electron temperature (Fig. 3). Then taking the energy of the resonant level equal to 280 meV we found that with increased heating more electrons in the Γ -subbands occupy states above the resonant level, and become able to initiate the creation of the DX^- -centre. The strong dependence of that fraction of electrons on donor concentration and field strength is responsible for both the apparent thresholds (particularities 1 and 2). Since the electron temperature at the high electric fields used in our experiments only weakly depends on the lattice temperature, particularity 5 follows.

4. Conclusion

We state that DX^- -centres can be formed in planar-doped GaAs by high electric fields since the potential wells are significantly deepened by carrier heating. Furthermore, the weakened screening can favour a shift of the Si-atom from the lattice site towards an interstitial site.

Study of vacancy-type defects after Cu diffusion in GaAs

V. Bondarenko*, K. Petters, R. Krause-Rehberg, J. Gebauer, H.S. Leipner

Martin-Luther-Universität Halle-Wittenberg, Fachbereich Physik, D-06099 Halle, Germany

Abstract

Semi-insulating GaAs was contaminated by Cu. For this purpose, a thin Cu layer (30 nm) was deposited by evaporation. The diffusion and the homogeneous distribution of the Cu was performed during an annealing step at 1100°C under defined As vapour pressures. The samples were quenched to room temperature. During a subsequent isochronal annealing experiment, vacancy clusters were found to be created, grown, and finally disappeared. The number, size, and distance depend on the annealing temperature and quenching speed. Positron lifetime measurements show that the clusters contain more than 10 vacancies. Moreover, Doppler-coincidence spectroscopy shows clearly that the clusters are surrounded by Cu atoms. The association of Cu-rich precipitates and voids with a diameter of up to 50 nm could be evidenced by analytical transmission electron microscopy. The smaller clusters have a crystallographic shape, while larger voids are spherical with a Cu-rich shell. The particles are frequently bound to dislocations. A possible model related to the out-diffusion of copper and the agglomeration of the formed vacancies is discussed. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Copper is one of the most common unintentional impurities in semiconductors. It diffuses rapidly even at low temperatures by interstitial diffusion process (the so-called kick-out mechanism) [1]. The diffusion coefficient in GaAs was reported to be as high as $D = 1.1 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ at 500°C [2]. The solubility was found also to be rather high $\sim 2 \times 10^{16} \text{ cm}^{-3}$ at 500°C and $7 \times 10^{18} \text{ cm}^{-3}$ at 1100°C [2].

In GaAs copper acts as a double acceptor, being incorporated at a substitutional lattice site as a Cu_{Ga} . But in spite of high solubility only a small fraction of the total Cu concentration is electrically active as acceptor after cooling to room temperature. The major part forms Cu–Ga precipitates [3].

In an earlier work [4] it was shown that vacancy clusters are formed during the post-annealing of the GaAs contaminated with Cu by diffusion. It was assumed that the copper atoms surround these clusters. The present paper is the continuation of the previous positron annihilation study of the Cu in- and out-diffusion in GaAs. The presence of Cu precipitates–vacancy cluster complexes was confirmed by transmission electron microscopy (TEM) and Doppler coincidence spectroscopy. We will show also that Cu out-diffusion depends on the in-diffusion conditions, in particular on the arsenic pressure during Cu diffusion.

2. Experimental details

Undoped semi-insulating GaAs samples of thickness 0.4 mm were covered by 30 nm Cu by evaporating it under UHV conditions. This corresponds to a volume concentration of $6 \times 10^{18} \text{ cm}^{-3}$ which is approximately the upper solubility limit of Cu in GaAs. The thickness of the deposited layer was controlled by a thickness

Fig. 1. Average positron lifetime as a function of sample temperature in undoped GaAs. Prior to the experiment, about $6 \times 10^{18} \text{ cm}^{-3}$ Cu atoms were introduced by evaporating 30 nm Cu to the sample surface and by a subsequent annealing at 1100°C under 2.62 bar of As pressure (3 h, quenched into water). The lifetime experiment was performed after each annealing step as indicated in the figure.

measurement device (frequency shift of a crystal oscillator). After Cu deposition at one surface, the samples were annealed in a two-zone furnace at 1100°C (sample temperature) under different arsenic pressure (0.2–10 bar) for 3 h corresponding to a Cu diffusion length of about 1.5 cm. After annealing, the samples were quenched in the quartz ampoules into water at room temperature. The samples were measured in the as-quenched state by Hall effect and thermoprobe measurements. Thereafter, the samples were isochronally annealed in the temperature range up to 900 K. The samples were cooled down slowly after each annealing step. After each annealing step positron annihilation lifetime, Doppler-broadening spectroscopy, and Hall-effect measurements were performed. The resolution of the spectrometers was 240 ps and 1.4 keV, respectively. The GaAs crystals were oriented with their (110) axis towards the Ge detector. The samples were investigated with TEM and energy dispersive X-ray spectroscopy (EDX).

Fig. 2. Positron lifetime results of the annealing experiments of undoped semi-insulating GaAs sample after in-diffusion of $6 \times 10^{18} \text{ cm}^{-3}$ Cu atoms at the 2.62 bar As vapour pressure: (a) average positron lifetime. (b) defect-related lifetime. The spectra were measured at 466 K. (c) Hall-effect measurements after each annealing step.

3. Results and discussion

Our semi-insulating undoped GaAs sample did not show any positron trapping. After Cu in-diffusion a small increase in the average positron lifetime in the high-temperature region was observed. In Fig. 1 the temperature-dependent measurements of the average positron lifetime after different annealing steps are shown. All the curves demonstrate a strong decrease of the average lifetime at low temperatures. This is a typical dependence for shallow positron traps, which tend to trap positrons in the extended region of the Coulombic potential, reflecting thereby the properties of the bulk [5]. At high temperatures, the existence of shallow traps can be neglected due to the high detrapping rate. In the case of copper in-diffusion these traps must be the Cu acceptors, whose concentration is up to $3 \times 10^{17} \text{ cm}^{-3}$ according to the Hall-effect measurements (Fig. 2c).

During the first annealing steps, average positron lifetime increases significantly up to the value of 273 ps, indicating the presence of vacancy-type defects. With a further increase of the annealing temperature we observed a rapid decrease of the average positron

Fig. 3. High momentum part of the positron annihilation momentum distribution, normalized by taking the ratio to GaAs:Zn reference values. In the upper part the spectrum for pure copper is shown, lower part represents spectra for GaAs:Si, GaAs:Cu after quenching from the diffusion temperature and after post-annealing at 500 K.

lifetime. This annealing behaviour of the average and defect-related lifetime is presented in Fig. 2a and b. It can be seen that the open volume of the detected objects increases during annealing. The defect-related lifetime is much higher than that for monovacancy (250–260 ps) [5] and may only be explained by positron trapping at large microvoids. The value of 480 ps corresponds to the clusters, which contain more than 10 vacancies. It was assumed that these clusters are decorated by Cu precipitates [4]. However, this cannot be concluded from positron lifetime results alone.

Fig. 3 shows the high momentum part of the positron annihilation momentum distribution, normalised to the GaAs:Zn reference. The upper part presents the curve for pure Cu, the lower contains three curves: one for $\text{Si}_{\text{Ga}}\text{-V}_{\text{Ga}}$ complex, corresponding to the Ga monovacancy, and the other two for GaAs contaminated with Cu in as-quenched state and after annealing at 500 K. It is obvious that the shape of GaAs:Cu momentum distribution is very similar to the one for pure Cu. This means that copper atoms surround the observed positron trapping centres.

The presence of such vacancy cluster–Cu precipitate complexes was found also by TEM performed together with the EDX measurements in all the samples after Cu in-diffusion and after further annealing. The results are presented in Fig. 4. One can see large vacancy clusters (light spot on the picture) surrounded by copper atoms and neighbored by a copper precipitate. These clusters

Fig. 4. (a) EDX scan measurements of the vacancy cluster–Cu precipitate complex in GaAs formed after Cu in-diffusion. (b) Transmission electron microscope image of this complex. The line on the picture indicates the scanned position of the EDX measurements.

Fig. 5. Average positron lifetime vs. annealing temperature for samples contaminated with Cu at different As vapour pressure (pressure is indicated). The measurements were performed at 466 K. Also the data for undoped Si–GaAs without Cu contamination are presented for comparison.

were observed for all samples after copper in-diffusion and after each annealing step. However, the distance between them is much higher than the mean positron diffusion length, so they should be invisible for positron annihilation. The large voids were earlier also found in GaAs after Zn in-diffusion [6].

Thus, we have two types of cluster–copper complexes: the relatively small number of large clusters after in-diffusion of copper, and the large number of smaller clusters after the applied annealing procedure, that are formed during out-diffusion of copper atoms. That means that Cu_{Ga} atoms dissolved during the annealing begin to leave their sites and form precipitates which are connected with vacancy clusters. This out-diffusion process can be seen clearly in Fig. 2c where the minimum of the hole concentration corresponds to the maximum of the defect-related lifetime, i.e. to the maximum size of the vacancy clusters. The origin of these clusters is easy to understand taking into account that the atomic density of GaAs ($4.43 \times 10^{22} \text{ cm}^{-3}$) is two times smaller than the atomic density of Cu ($8.48 \times 10^{22} \text{ cm}^{-3}$). Therefore, when Cu leaves the Ga sublattice and forms precipitates some open-volume defects must be formed. In the first place these are Ga vacancies. But according to the large defect lifetime, vacancies in both sublattices must be involved. That means that As atoms must go into the interstitial region. If it is so this process should be dependent on the quantity of the excess As in GaAs, i.e. on the stoichiometry. This was indeed observed.

Fig. 5 shows the results of the same annealing experiments for the samples that were contaminated with Cu at different As pressures (0.2–10 bar). The lower the As pressure during in-diffusion is (As deficiency), the easier the arsenic goes into the interstitial region, and the more remarkable is the process of voids formation (the maximum of the average positron lifetime is higher).

After annealing at 850 K the vacancy signal for all of the samples disappears. It is possible that the small vacancy clusters are dissolved at this temperature. But in this case the hole concentration should have a sharp increase at this temperature. That was not observed (Fig. 2c). Another probable reason is that small clusters combine with each other forming large voids with the distance between them being much longer than the mean positron diffusion length and thus become invisible for positron annihilation.

4. Conclusion

Positron annihilation together with electron microscopy and electrical measurements was used to study

undoped semi-insulating GaAs after Cu in-diffusion and during Cu out-diffusion. To summarize our experimental finding we can state the following:

- large vacancy clusters surrounded by Cu atoms and neighboured by Cu precipitates are formed during Cu in-diffusion and cooling; almost no positron trapping is found after quenching from diffusion temperature,
- during annealing, vacancy clusters decorated with Cu atoms are formed and grow up to a size more than 10 vacancies with increasing annealing temperature,
- according to the Hall-effect measurements the process of formation of these clusters relates to the Cu out-diffusion,
- as far as the vacancies in both sublattices must be involved the creation of the open-volume defects should be dependent on the stoichiometry of the GaAs system. A smaller quantity of excess As should support the formation of vacancy cluster, i.e. it is more simple for As atoms to go into interstitial region,
- with annealing at temperatures higher than 850 K the vacancy clusters grow and the distance between them becomes larger than the diffusion length of they positron: they become invisible for positron annihilation.

Abstract

Photoluminescence (PL) properties of GaAs doped with Dy by organometallic vapor phase epitaxy (OMVPE) have been investigated. In measurements at 4.2 K, characteristic luminescence has been successfully observed at around 1.1, 1.3, 1.7 and 2.8 μm , which is assigned to the intra-4f shell transition of Dy^{3+} ions. The Dy-related PL intensity depends strongly on growth temperature, though the spectrum is almost invariant. The intensity decreases with increasing growth temperature, while the Dy concentration remains almost constant against the growth temperature. This indicates that the formation of optically active atom configurations around Dy ions is suppressed at higher growth temperatures. Furthermore, new Dy-related emission lines appear in the Dy-doped GaAs with Er. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Dysprosium; GaAs; Intra-4f shell transition; Dy–Er center

1. Introduction

There has been a strong interest in rare-earth (RE) doped semiconductors because of their potential to combine sharp RE luminescence with the convenience of electrical excitation via the semiconductor host. One important feature of RE luminescence is that the emission wavelength is largely independent on both the host material and temperature, because the filled outer 5s and 5p electron shells screen the inner 4f electrons from interaction with the host. Er-doped semiconductors have been of particular interest. The intra-4f shell transition from the first excited state ($^4\text{I}_{13/2}$) to the ground state ($^4\text{I}_{15/2}$) of Er^{3+} ions results in emission at 1.5 μm . The wavelength of 1.5 μm lies in the range of minimum transmission loss in silica-based fibers.

We have intensively investigated Er-doped III–V semiconductors by organometallic vapor phase epitaxy

(OMVPE). In Er-doped InP, it has been found that there is a threshold growth temperature between 550°C and 580°C for Er incorporation into InP. The majority of Er atoms substitute In sublattice in the lower-temperature grown InP, exhibiting high luminescence efficiency [1,2]. In Er, O-codoped GaAs, the Er-related PL spectrum was dominated by seven emission lines under host-excited conditions at a low temperature [3,4]. The Er center has been identified as an Er atom located at the Ga sublattice with two adjacent O atoms (hereafter referred as Er–2O) [4]. The dependence of the Er-related PL spectra on the growth temperature also revealed the existence of a threshold growth temperature (543–585°C) [5]. Above the threshold growth temperature, the formation of the Er–2O center was suppressed greatly. Er-doped GaP produced several new emission lines by the addition of O_2 to the growth ambient. Some of them were quite similar to those due to an Er–2O center in Er, O-codoped GaAs, indicating that a similar atom configuration with two O atoms is successfully formed around Er ions in GaP [6].

Now we have paid particular attention to Dy among RE elements because it can potentially exhibit 1.3 and

E-mail address: fujiwara@numsc.nagoya-u.ac.jp (Y. Fujiwara).

2.8 μm emissions [7]. The wavelengths are technologically important for communication and medical applications, respectively. The other interesting viewpoint is that Dy is a well-known magnetic element. Dy ions doped in semiconductors have a feasibility to introduce the new degree of freedom induced by the interaction among carriers and the magnetic ions into semiconductor electronics. Recently, we described the first results on OMVPE growth of Dy-doped GaAs and observation of Dy-related luminescence in the infrared region [8]. However, the Er-related luminescence was also observed in the samples which originated from Er ions doped unintentionally by the contamination of the OMVPE growth system.

In this article, we report mainly on the Dy-related luminescence in Er-free Dy-doped GaAs and its dependence on the growth temperature.

2. Experimental

A low-pressure growth system with a vertical quartz reactor was utilized in this work [9]. TEGa and TBAs were used as source materials for GaAs growth. Dy was doped with trimethylcyclopentadienyldysprosium ($\text{Dy}(\text{CH}_3\text{C}_5\text{H}_4)_3$, $\text{Dy}(\text{MeCp})_3$). The Dy source was maintained mainly at a constant temperature of 100°C and introduced into the reactor by an H_2 flow through a source cylinder. The growth temperature was in the range of 530–610°C. The substrates for the growth were undoped or Si-doped (001)-oriented GaAs.

PL measurements were carried out mainly with the samples directly immersed in liquid He at 4.2 K. The photoexcitation source was a cw mode Ar^+ laser with a beam diameter of 1 mm and an incident power of 200 mW. The luminescence of the samples was dispersed using 0.91 m grating monochromator and detected with a liquid nitrogen-cooled Ge pin using a chopper and a lock-in amplifier.

3. Results and discussion

3.1. Dy-doped GaAs

Specular surface was successfully obtained in all Dy-doped GaAs grown in this work.

In-depth profiles of Dy concentration in GaAs layers were characterized by SIMS measurements. The measurements were performed using Cs^+ and O^+ as primary ions, accelerated at 6 kV, respectively. Dy concentration in the layers was evaluated in comparison with the ion intensity of Dy^{164} , which was calibrated using GaAs implanted at 180 keV with a Dy dosage of $5 \times 10^{14} \text{ cm}^{-2}$.

The resultant profiles exhibited a uniform Dy distribution along the growth direction in all the layers. Dy concentration in the layers was obtained in the range of 10^{17} – 10^{19} cm^{-3} , which was well controlled and increases with the H_2 flow rate through a Dy source cylinder and the cylinder temperature. The Dy concentration was almost independent of the growth temperature.

3.2. Dy-related luminescence in GaAs

In PL measurements at 4.2 K, characteristic luminescence was observed at around 1.1, 1.3, 1.7 and 2.8 μm . In comparison of results on Dy-doped oxides and fluorides [7], the luminescence can be assigned to intra-4f shell transitions between the Dy^{3+} states split by the spin-orbit interaction; ($^6\text{H}_{7/2}$, $^6\text{F}_{9/2} \rightarrow ^6\text{H}_{15/2}$), ($^6\text{H}_{9/2}$, $^6\text{F}_{11/2} \rightarrow ^6\text{H}_{15/2}$), ($^6\text{H}_{11/2} \rightarrow ^6\text{H}_{15/2}$) and ($^6\text{H}_{13/2} \rightarrow ^6\text{H}_{15/2}$) in order from the shorter wavelength side, respectively.

3.3. Growth temperature dependence of Dy-related luminescence

The Dy-related PL intensity depended strongly on the growth temperature, though the spectrum was almost invariant. Figs. 1–3 show the growth temperature dependence of Dy-related PL spectra around 1.1, 1.3 and 1.7 μm in Dy-doped GaAs. The intensity decreases with increasing growth temperature. SIMS measurements revealed that the Dy concentration is in the range of 10^{17} cm^{-3} and remains almost constant against the growth temperature. This indicates that the formation of optically active atom configurations around Dy ions is suppressed at higher growth temperatures. Similar

Fig. 1. Growth temperature dependence of the 1.1 μm PL spectra in Dy-doped GaAs. The PL intensity decreases with increasing growth temperature, while the spectrum is almost invariant.

Fig. 2. Growth temperature dependence of the 1.3 μm PL spectra in Dy-doped GaAs. The behavior is quite similar to that of the 1.1 μm luminescence.

Fig. 3. Growth temperature dependence of the 1.7 μm PL spectra in Dy-doped GaAs. The reduction in PL intensity against the increase in growth temperature is much larger than those of the 1.1 and 1.3 μm luminescence. This indicates that the 1.7 μm luminescence originates from a center different from a center for the 1.1 and 1.3 μm luminescence.

behavior was previously reported in Er-doped InP and GaAs [1,5].

The reduction ratio of the PL intensity against the increase in growth temperature is different for the three luminescence and it is classified into two groups. For the 1.1 and 1.3 μm luminescence, the reduction is quite moderate and their intensities are proportional each other. For the 1.7 μm luminescence, on the other hand, the intensity decreases steeper with increasing growth temperature. These observations suggest that the 1.7 μm

Fig. 4. Comparison of the 1.7 μm PL spectra in Er-free and Er-contaminated Dy-doped GaAs. Dy and Er concentrations are in the range of 10^{17} cm^{-3} . New emission lines appear in the sample with Er, indicating the formation of Dy-Er centers.

luminescence originates from a Dy center different from that for the 1.1 and 1.3 μm luminescence.

3.4. Dy-related luminescence in Dy-doped GaAs with Er

In comparison of PL spectra in Er-free and Er-contaminated Dy-doped GaAs, we have observed several new emission lines in the sample with Er. Fig. 4 shows the result for the 1.7 μm luminescence. New emission lines appear clearly in the sample with Er, which are shown by arrows, reflecting the formation of Dy-Er centers.

The appearance of the Dy-Er emission lines indicates the existence of Dy ions with Er at least in the second-nearest neighborhood. Dy and Er concentrations are, however, in the range of 10^{17} cm^{-3} in the sample with Er. Therefore, the formation of Dy-Er centers in spite of such low concentrations suggests strongly the presence of attractive interaction between Dy and Er ions in GaAs.

4. Conclusions

We have investigated luminescence properties of Dy-doped GaAs grown by OMVPE. SIMS measurements revealed a uniform Dy distribution along the growth direction. Dy concentration in the layers was obtained in the range of 10^{17} – 10^{19} cm^{-3} , which was well controlled and increased with the H_2 flow rate through a Dy source cylinder and the cylinder temperature. The Dy concentration was almost independent of the growth temperature. In PL measurements at 4.2 K, characteristic luminescence was observed successfully at around

1.1, 1.3, 1.7 and 2.8 μm . The luminescence was assigned to intra-4f shell transitions between the Dy^{3+} states split by the spin-orbit interaction; (${}^6\text{H}_{7/2}$, ${}^6\text{F}_{9/2} \rightarrow {}^6\text{H}_{15/2}$), (${}^6\text{H}_{9/2}$, ${}^6\text{F}_{11/2} \rightarrow {}^6\text{H}_{15/2}$), (${}^6\text{H}_{11/2} \rightarrow {}^6\text{H}_{15/2}$) and (${}^6\text{H}_{13/2} \rightarrow {}^6\text{H}_{15/2}$) in order from the shorter wavelength side, respectively. The Dy-related PL intensity depended strongly on the growth temperature, though the spectrum was almost invariant. The intensity decreased with increasing growth temperature, while the Dy concentration remained almost constant against the growth temperature. This indicates that formation of optically active atom configurations around Dy ions is suppressed at higher growth temperatures. The reduction ratio of the PL intensity against the increase in growth temperature was classified into two groups, 1.1 and 1.3 μm luminescence, and 1.7 μm luminescence. It suggests that the 1.7 μm luminescence originates from a Dy center different from that for the 1.1 μm and 1.3 μm luminescence. Furthermore, new Dy-related emission lines appeared in Dy-doped GaAs with Er, reflecting the formation of Dy–Er centers.

Abstract

Cu diffusion into semi-insulating GaAs was performed at 1150°C. The PICTS spectra of the diffused GaAs show several Cu-related peaks. The height of the characteristic low-temperature peak (Cu_A , $T \approx 150$ K) is proportional to the total Cu concentration determined by AES. The appearance and the peak heights of further Cu-related peaks in the spectra are obviously a function of the Cu concentration. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaAs; PICTS; Copper; Diffusion

1. Introduction

It is well known that Copper is a very quickly diffusing impurity in semiconductors. However, in most cases it is undesired, because Cu forms deep levels, e.g. in Si and GaAs.

Using both TDH (temperature dependent Hall effect) [1,2] and DLTS (deep level transient spectroscopy) [2,3] measurements in p-type Cu-diffused GaAs two Cu-related acceptor levels and hole traps, respectively, were detected: Cu_A with an activation energy of 0.15–0.17 eV and Cu_B with 0.44–0.49 eV.

By DLTS measurements on n-type Cu-diffused GaAs a drastic reduction of the intrinsic defects EL2 and EL6 enhancing with increasing diffusion temperature 500–650°C was found [4].

For the detection of Cu-related levels in semi-insulating (SI) GaAs, photo-induced current transient spectroscopy (PICTS) [5] and thermally stimulated currents (TSC) [6,7] were used. Also, in this case two Cu-related levels with activation energies of 0.14–0.20 and 0.40–0.43 eV, respectively, were observed. Additionally, a level with 0.51–0.52 eV has been found. However,

there are some discrepancies in the results concerning Cu in GaAs. Thus, for instance, no clear dependence of the heights of the Cu-related peaks in the spectra on the concentration of the in-diffused Cu was observed [5].

The aim of this work was to investigate Cu-diffused SI GaAs by PICTS and to correlate the dependence of measured spectra on the copper concentration decreasing with the depth below the Cu-covered surface.

2. Experimental

Starting material for the diffusion experiment was a cylindrical block of undoped LEC SI GaAs ($\rho = 5 \times 10^7 \Omega \text{cm}$) with a diameter of 25 mm and a length of 56 mm. Cu was deposited on one front of the block by evaporation of few droplets of a CuCl_2 solution ($[\text{Cu}]_{\text{surface}} \approx 3 \times 10^{17} \text{cm}^{-2}$) to give a low concentration. After diffusion at 1150°C (20 h), the block was cut into 44 wafers of 1 mm thickness parallel to the Cu-coated surface. Cu concentrations were determined by atom emission spectroscopy (AES). Electrical properties were obtained by conductivity and Hall effect measurements. Samples of dimensions $6 \times 3 \times 0.6 \text{mm}^3$ with Sn contacts alloyed at 400°C were used for the PICTS measurements. Optical excitation was made with a LED

Fig. 1. Normalized PICTS spectra (initial delay $t_1 = 14$ ms) of Cu-diffused SI GaAs. The samples were prepared from different depths below the Cu-covered surface.

($\lambda = 950$ nm, $t_p = 40$ ms). The current transients were evaluated using window technique with a constant ratio $t_2/t_1 = 2.7$ varying t_1 between 0.28 and 140 ms. For the determination of relative concentrations, the PICTS signal I_{PICTS} was normalized with the infrared photocurrent I_{ph} at the same photon flux.

3. Results

An influence of the Cu diffusion on the electrical properties of the GaAs block was detected to a depth of about 10 mm below the Cu-deposited surface. The uppermost samples (near to the surface) were high-resistivity p-type and the following were n-type and had resistivities decreasing from $7 \times 10^8 \Omega\text{cm}$ down to the starting level of $5 \times 10^7 \Omega\text{cm}$.

Fig. 1 shows normalized PICTS spectra of five SI samples (No. 4–8) from the diffusion region. Additionally, spectra of a sample (25) from the middle of the block as well as of a sample (44) from the surface opposite to the Cu-deposited one are given.

In samples 25 and 44, characteristic peaks (B, D) appear at about 160 and 250 K (at $t_1 = 14$ ms) which can be attributed to the electron traps EL6 and EL3 (DLTS signature) [8].

The PICTS spectra of the SI samples 4–8 show clear changes due to the Cu diffusion and a pronounced depth dependence. Peak A with the lowest maximum temperature (130 K at $t_1 = 14$ ms) decreases monotonously with the distance of the sample from the Cu surface (Fig. 2). Sample 25 was obviously not influenced by the Cu diffusion because peak A is absent. However, in sample 44 from the opposite surface the peak appears with a small height. According to its maximum temperature, the 130 K peak should correspond to the Cu_A level reported by other authors. However, the Arrhenius plot $\ln T^2/e$ versus $1/T$ yields for the activation energy of this peak in different samples values between 0.27 and

Fig. 2. Low-temperature part of the PICTS spectra of Fig. 1 including the Cu-related peak A and peak B (EL6).

Fig. 3. High-temperature part of the PICTS spectra of Fig. 1 including the Cu-related shoulder C, the Cu-related peaks E–H as well as peak D (EL3).

0.30 eV which are clearly higher than the values given by other authors for Cu_A .

As the next deeper Cu-related level (shoulder C) appears which shows a likewise clear depth correlation as the 130 K peak (Fig. 3).

The normalized PICTS peak height $I_{\text{PICTS}}/I_{\text{ph}}$ is under certain conditions proportional to the concentration of the corresponding trap. However, the determination of absolute trap concentrations by PICTS is only conditionally possible. By plotting $I_{\text{PICTS}}/I_{\text{ph}}$ of peak A and of shoulder C versus the total Cu concentration

Fig. 4. Normalized peak heights of peaks A and C versus Cu concentration determined by atom emission spectroscopy.

determined by AES (Fig. 4), a linear dependence results for peak A and a relation $I_{\text{PICTS}}/I_{\text{ph}} \sim [\text{Cu}]^{0.5}$ for shoulder C. From the former dependence the limit for the detection of Cu via the 130 K peak can be estimated to about $2 \times 10^{14} \text{ cm}^{-3}$ under these conditions.

Further Cu-related peaks (E–H) appear in the PICTS spectra which obviously depend on the Cu concentration. At moderate Cu concentrations (samples 6–8) peaks F and H at about 300–310 and 355–365 K, respectively, were observed (Fig. 3). The Arrhenius plot yielded activation energies of 0.87 ± 0.02 and 0.9 ± 0.1 eV for F and H, respectively. In samples 4 and 5, near to the surface two other peaks (E and G) occur at about 255 and 320 K, partly much higher than the 130 K peak (Fig. 1). Their activation energies were determined to be 0.64 ± 0.01 and 0.8 ± 0.1 eV, respectively.

Concerning peak B (EL6) with the maximum temperature between 155 and 163 K it can be stated that it is only moderately influenced by the Cu diffusion at 1150°C.

4. Discussion

In the Cu-diffused SI-GaAs samples, a clear correlation of the normalized peak height of the low-temperature peak A in the PICTS spectrum with the total Cu concentration determined by AES was found. Also, the shoulder C at about 215 K increases clearly with increasing Cu concentration. From this correlation, it can be deduced that PICTS allows a sensitive detection of Cu in GaAs as residual impurity arising, e.g. from Cu contamination by annealing or by other device processing techniques. The detection limit for Cu ($\approx 2 \times 10^{14} \text{ cm}^{-3}$) estimated from the plot of the

normalized peak heights, $I_{\text{PICTS}}/I_{\text{ph}}$, of Cu_A versus $[\text{Cu}]_{\text{AES}}$ corresponds to the total Cu concentration. However, the detection limit of the Cu_A level itself is clearly lower due to the existence of further Cu related levels.

Leon et al. [2] concluded from the comparison of the Cu_A concentration taken from the hole concentration of p-type Cu-diffused GaAs samples, determined by Hall effect at 300 K, with the total Cu concentration obtained by SIMS (secondary ion mass spectrometry) that only a small percentage of Cu was electrically active. However, this conclusion is doubtful because on the one hand, the hole concentration at 300 K in Cu-dominated GaAs samples is not identical with N_A and on the other hand, further Cu levels exist beside Cu_A .

The Arrhenius plot for the Cu_A peak deviates clearly from a straight line what can be caused, e.g. by a non-exponential transient and/or by the contribution of more than one levels to the analysed peak. This yields a reference to the difference between the activation energies obtained in this work (0.27–0.30 eV) and those obtained by other authors (0.14–0.20 eV).

Further four Cu related peaks appear in the PICTS spectra, but their occurrence depends on the Cu concentration.

Concerning the interaction of Cu with intrinsic defects present in the starting material only a weak lowering of the EL6 peak was observed at $[\text{Cu}] > 5 \times 10^{15} \text{ cm}^{-3}$. A similar behaviour shows the EL2 defect. This finding is in contradiction to the result of Yang et al. [4] mentioned above that the concentrations of EL6 and EL2 are drastically reduced after diffusion at 500–650°C. This discrepancy we attribute mainly to the different conditions (temperature, time, As vapour pressure) used for Cu diffusion by the authors and by Yang et al., respectively, because the interaction of Cu with the intrinsic defects in GaAs is obviously a function of temperature and thermal history.

Summarizing, it can be stated that there is a clear correlation between several peaks of PICTS spectra of Cu-diffused SI GaAs and the concentration of the in-diffused Cu.

However, there exist still obscurities concerning the variety of Cu-related levels and the interaction of Cu with intrinsic defects in GaAs. We believe that they are partly caused by different temperatures and Cu concentration used in the diffusion (or annealing) experiments. Therefore, further work is necessary to clear up these discrepancies.

The effect of Si site-switching in GaAs on electrical properties and potential fluctuation

H.G. Svavarsson, J.T. Gudmundsson, G.I. Gudjonsson, H.P. Gislason*

Science Institute, University of Iceland, Dunhaga 3, IS-107 Reykjavik, Iceland

Abstract

Si-doped GaAs layers were grown p-type at 700°C and n-type at 840°C by liquid phase epitaxy. Thermal annealing of the p-type samples at temperatures around 840°C converted the samples to n-type. We compare the as-grown and annealed samples by means of photoluminescence and temperature-dependent Hall and conductivity measurements. Highly doped samples converted to n-type through annealing become highly compensated. Their Hall mobility also increases more than an order of magnitude. Samples grown n-type at 840°C show up to three times higher mobility than the annealed ones. The compensation in each case was monitored through the shift of the photoluminescence bands with excitation intensity, up to 24 meV per decade of increase in the excitation power density for the highest compensation ratio. © 2001 Elsevier Science B.V. 1. Introduction

At high growth temperatures, Si-doped GaAs samples grown by liquid-phase-epitaxy (LPE) are n-type but highly compensated, while at lower growth temperatures they are p-type [1–4]. The actual crossover-temperature depends on silicon concentration and crystal orientation [5]. Gallium arsenide grown by LPE from gallium melt is expected to be low in gallium vacancies and possibly high in arsenic vacancies [6]. Under these conditions, Si should predominantly be a shallow acceptor on As site. However, growth at high temperatures evidently favors Si on Ga sites. In the present investigation, we study the highly compensated regime of GaAs:Si and potential fluctuations resulting from insufficient screening of ionized impurities by free carriers [7]. In highly compensated semiconductors, the fixed charge may

be randomly distributed and donor- and acceptor-rich regions may appear locally. Under normal circumstances, such fluctuations in the local potential are screened by mobile carriers, while the screening is insufficient in highly compensated samples. In photoluminescence (PL) measurements, potential fluctuations are manifested by a downward shift in photon energy of the near bandgap PL bands through localization of the charge carriers, as well as a shift of the localized PL bands to higher energy with increasing excitation power density. In GaAs, such fluctuations have been studied by photoluminescence in Li-compensated material [8] and highly Ge-doped material [9]. Here, we report on photoluminescence measurements of potential fluctuations in Si-doped GaAs, which has been converted from as-grown p-type to n-type by annealing above a certain transition temperature. Furthermore, we also correlate the defect density with the temperature-dependent Hall mobility of the majority carriers and compare the results from annealed samples with samples directly grown n-type.

2. Sample preparation and experiment

We grew about 1 μm thick GaAs films by liquid phase epitaxy on a semi-insulating GaAs (100) substrate. Four LPE batches were made. Keeping other growth conditions the same, the Si/Ga mass ratio in the growth solutions was altered from $(0.1\text{--}2.1)\times 10^{-3}$ or $(0.3\text{--}5.2)\times 10^{-3}$ mole fraction Si. Two GaAs samples were grown at 700°C, one with low Si concentration (sample #1), and another with higher Si concentration (sample #2). The other two LPE samples were grown at 840°C, one with low Si (sample #3) and the other with high Si (sample #4).

One piece of each sample #1 and #2 were baked in quartz ampoules at 840°C for 24 h with a subsequent quenching in liquid nitrogen. The sample derived from sample #1 was labeled #1a and similarly the one derived from sample #2 was labeled #2a. Table 1 summarizes the resulting data from the samples. To suppress arsenic vacancy V_{As} formation during baking, we placed a controlled amount of solid As into the ampoule prior to evacuation, giving an As gas pressure slightly below 1 bar at the baking temperature. Details of the sample preparation procedure are published elsewhere [10].

The free carrier concentration of the majority carriers and their Hall mobility were obtained by Hall measurements in the van der Pauw configuration. The Hall coefficient R_{H} was calculated from the slope of the Hall voltage versus the magnetic field in the range of 0–0.5 T, and an average of four values in each point was taken where the two pairs of contacts were interchanged and the current reversed. The conductivity was measured by the van der Pauw technique [11]. Then the Hall mobility is given by $\mu_{\text{H}} = R_{\text{H}}/\rho$, where ρ is the conductivity.

Photoluminescence measurements were performed at 14 K using the 532 nm line of a Verdi Nd:YVO4 laser from coherent as an excitation source. The excitation intensity was varied over several decades, from 0.001 to 0.1 W, and the laser beam was focused on an area of $\sim 1\text{ mm}^2$. For each series of excitation intensities the area was kept constant. The PL signal was detected via a double 0.85 m Spex 1404 grating monochromator using a cooled Ge detector.

3. Results and discussion

3.1. Annealing experiment

Both LPE samples grown at 700°C were p-type. Annealing of p-type samples around a crossover-temperature makes them highly compensated and eventually n-type at still higher temperatures. The compensation ratio is defined $N_{\text{A}}^{-}/N_{\text{D}}^{+}$ for n-type but $N_{\text{D}}^{+}/N_{\text{A}}^{-}$ in the case of p-type material [12], where N_{A}^{-} is the concentration of ionized acceptors and N_{D}^{+} that of ionized donors. This ratio can be varied with the annealing temperature. Annealing at 840°C converted samples #1 and #2 to n-type with rather similar electron concentration, sample #1a with $n = 3.9 \times 10^{17}\text{ cm}^{-3}$ and sample #2a with $n = 1.9 \times 10^{17}\text{ cm}^{-3}$. We note that in addition to the type conversion, there is a significant difference in the compensation ratio of sample #2 before and after annealing, since the net electron concentration in sample #2a is only about 10% of the original hole concentration. In the less Si-doped sample #1 the carrier concentration before and after annealing remains the same within a factor of two.

The type conversion from p- to n-type upon annealing may be caused by site-switching of silicon on arsenic site Si_{As} to form silicon on gallium site Si_{Ga} in As ambient gas according to the equation

Driving the reaction to the right by increasing the ambient As gas pressure, either during growth or through annealing increases the concentration of Si_{Ga} according to Eq. (1).

3.2. Photoluminescence measurements

In the as-grown sample #1 with low Si concentration, the spectrum is dominated by a broad PL band peaking around 1.445 eV for the lowest excitation intensity level

Table 1

The carrier concentration, mobility and conductivity obtained by Hall measurements at room temperature and PL peak shift with excitation intensity measured at 14 K in as-grown and annealed samples

Low Si-doping level				High Si-doping level			
Sample	Carrier conc. (cm^{-3})	Shift (meV/dec.)	Mobility ($\text{cm}^2/\text{V s}$)	Sample	Carrier conc. (cm^{-3})	Shift (meV/dec.)	Mobility ($\text{cm}^2/\text{V s}$)
#1	$p = 1.6 \times 10^{17}$	6	110	#2	$p = 2.0 \times 10^{18}$	5	20
#1a	$n = 3.9 \times 10^{17}$	2–5	880	#2a	$n = 1.9 \times 10^{17}$	24	820
#3	$n = 1.4 \times 10^{16}$	8	2500	#4	$p = 3.9 \times 10^{17}$	8	50

used, I_{\min} [10]. Increasing the excitation intensity shifts the peak position around 6 meV per decade of change, which we interpret as a shift caused by insufficient screening of ionized impurities. Annealing at 840 °C dramatically changes the spectrum. The intensity becomes much smaller and a weak band at 1.385 eV at I_{\min} shows a shift of 2–5 meV per decade of change in intensity.

The photoluminescence spectrum of the as-grown sample #2 with high Si concentration exhibits a broad, strong peak at 1.435 eV for an excitation level of I_{\min} . This peak shows a rather similar shift with excitation intensity as found in sample #1. In this sample, the annealing produces a strong shift in the PL spectrum as illustrated in Fig. 1. A broad peak around 1.35 eV at I_{\min} shifts some 24 meV per decade of change.

The shift rate of the two as-grown samples #3 (low Si concentration) and #4 (high Si concentration) is similar, close to 8 meV. Fig. 1 summarizes the dependence of the peak positions of the six as-grown and annealed samples on the excitation intensity. Table 1 also includes the observed shift rate of the PL bands. The localization caused by the potential fluctuation can be described as a lowering of the photon energy of PL transitions by twice the depth of a potential well [7]. In n-type semiconductors, this potential well depth is directly proportional to the ratio $N_t^{2/3}/n^{1/3}$ with p replacing n in p-type semiconductors. Here, N_t is the total concentration of charged impurities in the material which are assumed to have a Gaussian distribution. Hence, the well depth increases with increasing concentration of charged impurities, N_t , but decreases with increasing concentration of free charge carriers. Therefore, in the presence of potential fluctuations, one expects to find a shifting PL band at lowest photon energies in highly compensated semiconductors with a high original shallow

doping. Also, one expects a shift to higher energies with increased excitation intensity which increases the concentration of photo-excited carriers. This is indeed what we observe.

Comparing the as-grown spectra of samples #1 and #2, we see that the shift rate with excitation intensity in Fig. 1, is comparable for both samples while the peak position is somewhat lower in energy for sample #2 which has a higher Si concentration. This is in general agreement with the higher concentration of ionized impurities, although the higher concentration of free carriers in sample #2 reduces the corresponding well depth.

The type conversion from p- to n-type through annealing illustrates a way of obtaining a striking range of compensation ratios. A significant difference between the two samples is evident upon annealing as shown in Fig. 1. The highly doped sample #2a shows a substantial shift, whereas the shift rate of the weakly doped sample remains low. Although the electron concentration of the two samples after annealing is rather similar, the large shift of the PL band in sample #2a is typical of a high concentration of compensated ionized impurities. The PL shift accompanies a reduction of the free carrier concentration by a factor of 10 in addition to the type conversion. The measured Hall concentration in the as-grown sample #2 can, therefore, be concluded to reflect the true Si_{Ga} concentration and a low compensation ratio, whereas the Si_{Ga} and Si_{As} concentrations become roughly similar upon annealing, with a compensation ratio approaching one as a consequence.

3.3. Electrical measurements

In Fig. 2, the Hall mobilities of the three samples with low Si-doping level, are compared. Sample #3 is n-type

Fig. 1. PL peak position for different excitation intensity for the six samples. The slope of each curve represents the shift rate with excitation intensity.

Fig. 2. The Hall mobility of low Si-doped GaAs as a function of temperature. Sample #1 is p-type GaAs, as-grown at 700 °C; #1a is n-type GaAs, grown at 700 °C and annealed at 840 °C; #3 is n-type GaAs as-grown at 840 °C.

Fig. 3. The Hall mobility of high Si-doped GaAs as a function of temperature. Sample #2 is p-type GaAs, as-grown at 700°C; #2a is n-type GaAs, grown at 700°C and annealed at 840°C; #4 is GaAs as-grown at 840°C and is n-type below 105 K.

and has a Hall mobility of around 2500 cm²/Vs at room temperature, whereas sample #1 grown at 700°C is p-type with a Hall mobility of 110 cm²/Vs. After annealing at 840°C, the sample grown at 700°C has converted to n-type and its mobility increased nearly one order of magnitude, to 880 cm²/Vs at room temperature (sample #1a).

Fig. 3 shows the Hall mobility data for samples grown and annealed at the same temperatures as in Fig. 2 but at ~20 times higher doping level. Here, the annealed sample #2a has the highest Hall mobility, 850 cm²/Vs. Hall measurements show that the highly doped sample #4 exhibits p-type behavior at elevated temperatures but n-type behavior below 105 K. The minimum in the mobility curve for sample #4 is an artifact due to the Hall overshoot when $p = n(\mu_n/\mu_p)^2$ where the electrons and holes attempt to cancel the contributions of each other towards the Hall effect [13]. Here μ_n is the mobility of electrons and μ_p is the mobility of holes. Sample #3, grown at 840°C is n-type, whereas sample #4, grown at the same temperature but with much higher Si-concentration, is p-type above 105 K and n-type below. At this temperature the number of ionized donors and acceptors is equal.

Even though the mobility of samples #1 and #2 significantly increases upon annealing, it is still several times lower than that of sample #3. Most likely, the number of scattering centers has grown by the annealing. Presumably they include Ga vacancies and, to some extent, antisite defects.

4. Conclusion

Annealing at temperatures close to a transition temperature of 840°C resulted in closely compensated samples as verified by a shift of localized PL bands with excitation intensity. The presence of potential fluctuations is manifested through a shift of the PL peak position of up to 24 meV per decade of increase in the excitation power density. Furthermore, the annealing of p-type samples converted them into n-type with ~10 times higher mobility. We have correlated the observation of potential fluctuations with a possible site-switching of Si from As sites to Ga sites. Our results strongly suggest that the type conversion from p- to n-type may in fact be caused by such site-switching.

Incorporation and thermal stability of defects in highly p-conductive non-stoichiometric GaAs:Be

P. Specht^{a,*}, M.J. Cich^a, R. Zhao^a, J. Gebauer^a, M. Luysberg^b, E.R. Weber^a

Abstract

Non-stoichiometric GaAs is known to contain a high concentration of native point defects. The dominant defect in the epilayers is the arsenic antisite (As_{Ga}), a deep double donor, which is incorporated at low growth temperatures (commonly between 200°C and 300°C) in molecular beam epitaxy (MBE). Consequently, p-doping of non-stoichiometric GaAs is difficult because large concentrations of acceptors are compensated by the As_{Ga} . Recently, we found that despite this compensation effect we can achieve p-conductive GaAs:Be with almost one order of magnitude higher Be-doping than previously obtained in MBE grown GaAs. The kinetics of dopant incorporation during MBE growth at these low growth temperatures seem to allow pushing the doping concentration further beyond thermal equilibrium. The epilayers, which are about 1 μm thick, are pseudomorphic with a lattice mismatch to the substrate of up to $\Delta c/c = -0.4\%$. They remain free of structural defects such as dislocations and stacking faults. After annealing at 600°C only the highest doped epilayers show a reduction in the Be concentration although the layers remain ultrahigh p-conductive. The increased incorporation of Be as well as its unusual stability in non-stoichiometric GaAs is likely influenced by the native defects in these layers, double positively charged As_{Ga} defects and probably neutral gallium vacancies (V_{Ga}). This novel material which is solely achievable through low-temperature growth may significantly enhance III–V semiconductor applicability due to ultrahigh doping capability with increased thermal stability. © 2001 Elsevier Science B.V. 1. Introduction

Low-temperature (LT) molecular beam epitaxy (MBE)-grown III–V semiconductors have found many applications as highly resistive buffer layers for FETs [1], as radiation hardened layer for satellite technology [2] and in ultrafast opto-electronics [3–6]. Conductive LT-layers, however, never reached satisfying conduction because of the presence of electrically active, native defects, namely arsenic antisites (As_{Ga}) and gallium vacancies (V_{Ga}). The As_{Ga} defects, electrically active as deep double donors, which can be incorporated in

concentrations as high as $10^{20}/\text{cm}^3$ [7] compensate p-dopants (commonly Be or C) and also lead to a reduced mobility of the active carriers, usually electrons [8]. N-type conduction was identified to be dominated by nearest-neighbor hopping [9,10]. P-conduction was observed in highly compensated epilayers with low dopant activation or in the so-called stoichiometric LT-GaAs with Be doping concentrations up to $10^{19}/\text{cm}^3$ only [7,11].

The addition of Beryllium to a GaAs epilayer leads to a smaller lattice constant for high doping concentrations because the Beryllium which is commonly incorporated on the Ga-sublattice is smaller than the host atom Ga. At low growth temperatures this effect is compensated by the introduction of larger native point defects, the As_{Ga} antisite defects. These defects are also located in

the Ga-sublattice and dilate the epilayer lattice if present in large concentrations [7]. The strain compensation between the small Be_{Ga} and the larger As_{Ga} defects is expected to thermally stabilize the defects [12]. Even more important than this stabilization is the fact that the maximum concentration of Be which can be incorporated into LT-GaAs epilayers is largely enhanced. In this contribution, the electronic properties of the highly strained epilayers with several $10^{20}/\text{cm}^3$ Be incorporation are investigated. It is studied how the maximum free hole concentration and their thermal stability as well as the stability of the Be dopant atoms depend on the growth conditions.

2. Experimental

Be-doped LT-GaAs layers were grown by MBE on (100) GaAs wafers grown by Vertical Gradient Freeze (VGF substrates, AXT, Fremont, CA) at As/Ga beam equivalent pressure ratios of 20 (As-rich conditions) and a growth rate of $1\mu\text{m/h}$. The growth temperature measured by diffuse reflectance spectroscopy (Thermionics NW, Hayward, CA) was varied from 210°C to 300°C . Nominal Be doping levels between 1×10^{19} and $2 \times 10^{21}/\text{cm}^3$ were attempted. Be concentrations were determined by SIMS analysis at Applied Microanalysis Lab. in Santa Clara, CA. The wafers were annealed in proximity to a sacrificial GaAs substrate at 600°C for 30 min in nitrogen ambient. The structural properties were investigated by X-ray diffraction using (004) reflection conditions and in JEOL 4000EX and JEOL 4000FX transmission electron microscopes operated at 400 kV. For the latter technique samples were prepared in cross section by conventional techniques including Ar ion milling. Free carrier concentrations were determined with both electrochemical capacitance voltage profiling (ECV) and Hall effect measurements in Van der Pauw geometry. For more details on MBE growth see Refs. [13,14] for the electrical measurements.

3. Results and discussion

The lattice mismatch between the GaAs substrate and the epilayer gives a first indication for the large concentrations of incorporated Be acceptors in LT-GaAs:Be. With increasing Be concentration the epilayer lattice constant decreases resulting in lattice matching to the substrate [15]. For higher doping concentrations the lattice mismatch becomes negative and duplicates approximately the data from GaAs:Be grown at 580°C if extrapolated to high Be concentrations as can be seen in Fig. 1. It was concluded that the Be in the LT-grown epilayer is mainly incorporated on the Ga-sublattice resulting in a similar lattice mismatch to the GaAs

Fig. 1. Lattice mismatch in growth direction, $\Delta c/c$, between GaAs substrate and LT-GaAs epilayer dependent on Be-doping. The solid line, 600°C growth temperature, is extrapolated for Be doping levels above $10^{20}/\text{cm}^3$.

Fig. 2. ECV profiles of as-grown (dots) and at 600°C annealed (lines) LT-GaAs:Be epilayers. The large variation of $[p]$, especially at the surface of the higher doped layer, is mainly due to inhomogeneous etching. The free hole concentration does not change upon annealing.

substrate as it would theoretically occur in GaAs:Be grown at 580°C by MBE. Even at Be concentrations of about $8 \times 10^{20}/\text{cm}^3$ the lattice mismatch in growth direction, $\Delta c/c$, follows this extrapolated reference line. In cross-sectional TEM analysis no structural defects were found, the epilayers are grown pseudomorphic. The $1\mu\text{m}$ thick epilayer with a lattice mismatch of $\Delta c/c = -0.42\%$ shows a slightly broadened (004) peak in X-ray diffraction with a doubled FWHM if compared to the substrate, probably due to a bending effect.

The ECV profiles of two epilayers ($[\text{Be}] = 5 \times 10^{20}$ and $2.8 \times 10^{20}/\text{cm}^3$, $T_g = 240^\circ\text{C}$, Fig. 2) show the thermal stabilization of the hole concentrations upon annealing

Fig. 3. ECV (triangles) and SIMS (dots) profiles of a LT-GaAs:Be epilayer grown at 250°C with $8 \times 10^{20}/\text{cm}^3$ Be. The as-grown layer shows almost complete Be activation. Upon annealing at 600°C (open symbols), both the total Be concentration (SIMS) and the free hole concentration (ECV) are significantly reduced.

at 600°C (overgrowth condition). Only 10% of the Be contributes to the hole concentration in the lower doped sample which increases to over 40% in the higher doped layer. However, it shall be noted that the dopant activation presented here already exceeds the maximum hole concentration observable in GaAs:Be. Assuming the native point defects, As_{Ga} double donors, are compensating the Be_{Ga} , more than $1 \times 10^{20}/\text{cm}^3$ $\text{As}_{\text{Ga}}^{2+}$ have to be present in these layers. It is noted that such high concentrations of As_{Ga} defects were measured before in undoped, pseudomorphically grown LT-GaAs. Upon annealing at 600°C neither the total Be concentration, $[\text{Be}]$, nor the concentration of free holes $[p]$, changes and, consequently, also the lattice mismatch remains stable. This also indicates that the Be is not likely to be present as interstitials in large concentrations since Be interstitials are known to be fast diffusers and that the compensating antisite defects are thermally stable under these annealing conditions.

Fig. 3 depicts ECV and SIMS results of an epilayer grown at 250°C. An even higher doping concentration of $[\text{Be}] = 8 \times 10^{20}/\text{cm}^3$ is achieved. The average concentration of compensated Be is significantly lower than in the lower doped epilayers. Consequently, if As_{Ga} defects are present in this layer, their concentration must be significantly lower with a maximum value of about $4 \times 10^{19}/\text{cm}^3$ $\text{As}_{\text{Ga}}^{2+}$. Hall measurements of the as-grown layer confirmed the ECV results. Additionally, a hole mobility of $27 \text{ cm}^2/\text{Vs}$ was measured which agrees well with the extrapolated value for such high Be amounts. During annealing, part of the Be diffuses out of the epilayer. Simultaneously, the free hole concentration is

Fig. 4. Free hole concentrations achieved in GaAs:Be. The plot for high temperature grown MBE GaAs (solid line) is shown extrapolated (dotted line) for easier comparison with LT-growth. The small dots at hole concentration levels of $5 \times 10^{16}/\text{cm}^3$ represent the theoretically expected values for 300°C/240°C/210°C growth temperature, from left to right, respectively (Fermi Level calculation for constant native defect concentration for each T_g).

reduced. Roughly half of the remaining Be is still electrically active after annealing with only 30% of the inactive Be explicable due to the maximal present native defect concentration $[\text{As}_{\text{Ga}}^{2+}]$. This indicates that part of the Be is likely to be incorporated on interstitial sites and/or has formed Be clusters.

Fig. 4 summarizes the achieved free hole concentrations in 580°C grown GaAs and in various LT-GaAs epilayers. The maximal free carrier concentration is almost one order of magnitude larger in LT-GaAs than in GaAs grown at 580°C, retaining reasonable carrier mobility. Ultrahigh conductivity is achieved in a growth temperature range of at least 40°C although the maximum free hole concentrations vary with the growth temperature. In the p-conductive layers Be is by far more stable in LT-GaAs, a fact which was already observed for semi-insulating LT-GaAs:Be epilayers [12,15].

Reasons for both the enhanced incorporation of Be and its higher thermal stability in LT-GaAs are still under discussion. For low growth temperatures Be may simply be kinetically buried in the epilayer. It is still unclear why Be diffusion and precipitation seems to be suppressed resulting in stabilized high free carrier concentrations in the epilayers. Beryllium is known to diffuse fast on interstitial sites in GaAs which may certainly be suppressed in an up to 2% more dense crystalline structure. However, our observations rather indicate a correlation between a large compensation and a high thermal stabilization of Be. A lower compensation in the most dense epilayer resulted in insufficient Be stabilization. Because of our assumption that antisite

defects are responsible for the electrical compensation, the behavior of these native defects shall be investigated in more detail.

The As_{Ga} defects in ultrahigh Be-doped LT-GaAs can be indirectly estimated through the amount of compensated Be in the as-grown layers. For the other native defect, the gallium vacancy V_{Ga} , a concentration reduction and clustering is seen in ultrahigh Be-doped layers measured by positron annihilation spectroscopy. Details about this measurement technique can be found in Ref. [16]. It is likely that simultaneously the As_{Ga} defect concentration increases as it would in GaAs with a lowered Fermi energy level. From the amount of compensated Be an increase in antisite defects to concentrations of about $10^{20}/\text{cm}^3$ is expected. Therefore, we propose that the strain field of the As_{Ga} , whose average distance in LT-GaAs can be as low as 1.7 nm or 3 unit cells in the GaAs lattice, is mainly responsible for the thermal stabilization of the Be atoms. The As_{Ga} defects themselves may be thermally stabilized because the V_{Ga} assisted diffusion of As is suppressed in the ultrahigh Be-doped layers due to the lack of single V_{Ga} .

4. Summary

Ultrahigh p-conductive LT-GaAs:Be epilayers were grown with free hole concentrations as high as $7 \times 10^{20}/\text{cm}^3$. After annealing at 600°C about $2 \times 10^{20}/\text{cm}^3$ holes remain in the epilayers which are highly strained. The effect of ultrahigh Be-doping is fairly growth temperature insensitive within at least a 40°C temperature range, although the maximum amount of free holes is dependent on the growth temperature. A suppressed Be diffusion is observed, which is likely to be caused by residual As_{Ga} antisite defects, which are themselves thermally stabilized due to the lack of native single V_{Ga} . These highly p-doped epilayers may find an application for example as base layer in an AlGaAs/GaAs HBT. A considerably increased electron efficiency in the emitter due to a reduced bandgap and decreased resistivity of the base layer can benefit the clock rates in IC's. The minority carrier lifetime and mobility in such layers still has to be investigated.

Abstract

Native point defects in non-stoichiometric GaAs layers doped with Be were observed. Ga vacancies were identified by positron annihilation. As_{Ga} antisite defects were investigated by near infrared absorption and magnetic circular dichroism of absorption, respectively. We found the properties of the As_{Ga} antisites very similar to that of As_{Ga} in bulk GaAs, i.e. they exhibit the same MCDA spectra and quenching behavior. The concentration of native point defects was not influenced by the Be doping. Therefore, the thermal stability of non-stoichiometric GaAs:Be can not be explained with a different incorporation of native defects. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: LT-GaAs; Ga-vacancy; Arsenic antisite; MCDA

1. Introduction

Non-stoichiometric GaAs layers grown by molecular beam epitaxy (MBE) at low temperatures (LT-GaAs) attracted a large interest due to their unique properties, i.e. ultrafast carrier recombination and semi-insulating behavior after annealing. During the growth at low temperatures, a large As excess is incorporated in form of point defects [1,2]. The properties of (undoped) LT-GaAs are dominated by As_{Ga} antisites incorporated in concentrations up to 10^{20} cm^{-3} while V_{Ga} (with densities in the 10^{18} cm^{-3} range) is responsible for the compensation of positive As_{Ga} [3].

The major drawback of undoped LT-GaAs, however, is its thermal instability which restricted applications so far. Recently, doping with Be was found to thermally stabilize As_{Ga} defects therewith opening new prospects for the application of non-stoichiometric GaAs layers [4]. The origin of the thermal stability is uncertain. Ga

vacancies are believed to mediate the diffusion of As_{Ga} , thus, it has been suggested that Be doping reduces the concentration of V_{Ga} thereby suppressing the outdiffusion of excess As [5]. However, this hypothesis is supported by very few experiments [5,6]. Another possible explanation involves the formation of defect complexes such as $\text{As}_{\text{Ga}}\text{--Be}_{\text{Ga}}$ which would hinder the diffusion of As_{Ga} . In this work, we investigate the native point defects in LT-GaAs:Be and their concentration in relation to the doping concentration in order to understand the properties and thermal stability of that material.

2. Experimental

Non-stoichiometric GaAs layers were grown by MBE under arsenic-rich conditions with an As/Ga beam equivalent pressure (BEP) of 20 at temperatures from 200°C to 300°C. The Be doping concentration varied up to $8 \times 10^{19} \text{ cm}^{-3}$. The growth rate was 1 $\mu\text{m/h}$ and the layer thickness 1–1.5 μm . Positron annihilation spectroscopy (PAS) employing slow monoenergetic positrons was used to investigate vacancy defects [7]. Positron

trapping in vacancy defects can be observed as a change of the shape of the 511-keV annihilation peak, characterized by the lineshape parameters S and W . The experimental details are the same as in Ref. [8]. As_{Ga} antisites were observed by near infrared absorption (NIRA) and magnetic circular dichroism of absorption (MCDA). The experimental details of the absorption techniques are described in Ref. [2].

3. Detection of Ga vacancies by positron annihilation

PAS measurements as a function of incident positron energy showed results very similar to those reported earlier for undoped LT-GaAs [8]. Most important, the S parameter characteristic for the LT-GaAs layers was significantly higher than that one in defect free GaAs. This shows clearly positron trapping at vacancy defects. In order to identify the defects, we analyzed the correlation between S and W parameter. For all our LT-GaAs:Be samples, the data followed the same linear variation, previously shown to be due to Ga monovacancies [8]. Other defects in GaAs, e.g. vacancy cluster or As vacancies exhibit significantly different annihilation characteristics than V_{Ga} . Therefore, the vacancies in LT-GaAs:Be are also Ga monovacancies.

With that knowledge, we determined the V_{Ga} concentration from the S parameter characteristic for the respective LT-GaAs:Be layer from $c_v = \lambda_b \times (S - S_b) / (\mu_v(S_d - S))$. $\lambda_b = (229 \text{ ps})^{-1}$ is the annihilation rate in defect-free GaAs and $\mu_v = 10^{15} \text{ s}^{-1}$ is the trapping coefficient for V_{Ga} [7]. The S parameter S_d , specific for annihilation in V_{Ga} , is 1.017 [8]. In Fig. 1, we show the resulting V_{Ga} concentrations as a function of the Be concentration for LT-GaAs grown at different temperatures. The V_{Ga} concentration is independent on

Fig. 1. Concentration of V_{Ga} in LT-GaAs:Be as a function of the Be concentration. Lines are guide to the eyes.

Be doping up to the highest doping level investigated. Thus, Be doping has no influence on the incorporation of Ga vacancies during the MBE growth of GaAs at low temperatures.

4. Optical absorption spectroscopy of As_{Ga} antisites

Optical absorption spectroscopy was the major experimental tool to investigate As_{Ga} defects in LT-GaAs layers [1,2]. Nevertheless, considerable uncertainty remained because several features of As_{Ga} defects known from bulk GaAs were not observed in LT-GaAs. Often only a part of the As_{Ga} in LT-GaAs was found to be quenchable (if any at all) [2,9] while this property is one of the major fingerprints of As_{Ga}^0 in bulk GaAs. Moreover, the MCDA spectra of As_{Ga} defects in LT-GaAs, known to be sensitively dependent on the detailed microscopic structure of the defect, often seemed different from that known from bulk GaAs [2,10]. This section will therefore focus on a detailed investigation of the As_{Ga} related MCDA spectra in LT-GaAs.

In Fig. 2 (a), MCDA spectra from LT-GaAs and SI bulk GaAs are compared. The spectrum obtained from SI GaAs exhibits the one derivative, one bell shaped structure typical for the paramagnetic As_{Ga}^+ defects [11]. The spectrum in undoped LT-GaAs exhibits a similar negative band at $\sim 0.95 \text{ eV}$ but has also a negative band at $\sim 1.2 \text{ eV}$, significantly different from the two positive

Fig. 2. MCDA spectra of As_{Ga} defects in GaAs measured at $T = 1.8 \text{ K}$ and $B = 2 \text{ T}$ (a) Spectra from semi insulating bulk GaAs and undoped LT-GaAs grown at 250°C . (b) Spectra from Be doped LT-GaAs grown at 250°C with different Be concentrations as indicated.

bands in bulk GaAs. In contrast, the spectra from LT-GaAs:Be (Fig. 2b) are very similar to that in bulk GaAs. The MCDA band at 0.95 eV is known to be proportional to the As_{Ga}^+ concentration [11]. In Fig. 2 (b) its intensity is directly proportional to the Be doping, indicating that the As_{Ga}^+ compensate the Be acceptors. Thus, $[As_{Ga}^+]$ is close to the Be concentration (e.g. $\sim 3 \times 10^{19} \text{ cm}^{-3}$ in the highest doped sample).

It has been shown that As_{Ga} in its neutral charge state poses a characteristic MCD signal [12], albeit with lower intensity than that of As_{Ga}^+ . According to theory, the spectrum due to the paramagnetic As_{Ga}^+ has a strong temperature dependence while the spectrum due to the diamagnetic As_{Ga}^0 is independent on temperature [13]. Therefore, we performed MCDA measurements at a higher temperature (125 K) in order to separate diamagnetic and paramagnetic spectra. In Fig. 3, such measurements are shown for (a) LT-GaAs:Be and (b) the undoped LT-GaAs sample from Fig. 2. The spectra measured at 125 K have the same features in both samples, i.e. two negative bands at 1.2 and 0.94 eV with intensity ratio of ~ 1.8 . The spectrum is the same as the diamagnetic spectrum due to As_{Ga}^0 previously observed in bulk GaAs [12]. Similar measurements were done for a larger set of samples. The intensity of the two bands was directly proportional to the absorption coefficient at 1.2 eV, i.e. to the As_{Ga}^0 concentration. It is especially

notable that the diamagnetic spectrum is very similar to the MCDA which can be photoquenched. Thus, As_{Ga}^0 in our layers is fully quenchable, in contrast to previous results that As_{Ga} in LT-GaAs is not or only partly quenchable [2,9].

In Fig. 3, we show also the paramagnetic spectra obtained by subtracting the diamagnetic spectra from the total MCDA. In both cases, they are very similar to that of As_{Ga}^+ in bulk GaAs shown in Fig. 2. The total MCDA spectrum from undoped LT-GaAs can therefore be explained by the superposition of diamagnetic (due to As_{Ga}^0) and paramagnetic MCDA (due to As_{Ga}^+). For the undoped LT-GaAs sample in Figs. 2 and 3, $[As_{Ga}^0]$ is $\sim 3 \times 10^{19} \text{ cm}^{-3}$, significantly larger than $[As_{Ga}^+]$ ($\sim 6 \times 10^{17} \text{ cm}^{-3}$). Therefore, the diamagnetic spectrum dominates for this particular sample, explaining the overall shape of the MCDA spectrum.

The detailed investigation of the MCDA spectra in LT-GaAs shows that the As_{Ga} antisites in both charge states have properties very similar to that in bulk GaAs. We found this finding to be true for undoped as well as for Be doped LT-GaAs. Our data provide therefore no evidence that Be forms a complex with the As_{Ga} antisites.

With these results, we can now determine the As_{Ga} antisite concentration. $[As_{Ga}^+]$ increases with the Be doping because of charge compensation, but the total As_{Ga} concentration (i.e. $[As_{Ga}^0] + [As_{Ga}^+]$) is independent on Be doping. In Fig. 4, $[V_{Ga}]$ is plotted vs. the total $[As_{Ga}]$. $[V_{Ga}]$ is $\sim 1\%$ of the total $[As_{Ga}]$ in all samples (solid line). The data agree with previous results from undoped LT-GaAs. Therefore, doping with Be has no influence on the incorporation of *all* native point defects in LT-GaAs.

5. Discussion and summary

Our results exclude that a different incorporation of native point defects, especially V_{Ga} , is responsible for the thermal stability of LT-GaAs:Be. It has been suggested that $[V_{Ga}]$ should be reduced in LT-GaAs:Be because the Fermi level effect reduces the formation energy of V_{Ga} in p-doped GaAs [5]. However, the formation energy governs defect concentrations preferably in thermal equilibrium. Contrary, MBE growth at low temperature is a non-equilibrium process where defect concentrations are governed mainly by the growth kinetics.

The incorporation of As_{Ga} in undoped LT-GaAs has been explained by the evaporation and absorption of the incoming atomic species. With decreasing temperature, reduced As desorption leads to an increased $[As_{Ga}]$ concentration while the reduced Ga diffusivity at the surface leads to an increase of $[V_{Ga}]$ [14]. The universal relationship between $[V_{Ga}]$ and $[As_{Ga}]$ shown in Fig. 4 suggests the same growth mechanism also for

Fig. 3. MCDA spectra of LT-GaAs:Be (a) and undoped LT-GaAs (b) measured at 1.8 and 125 K. The spectra are compared to the MCDA quenchable at 1.8 K and to the paramagnetic MCDA obtained as the difference between the spectra at 1.8 and 125 K.

Fig. 4. Concentration of V_{Ga} as a function of the total As_{Ga} concentration (sum of $[\text{As}_{\text{Ga}}^0]$ and $[\text{As}_{\text{Ga}}^+]$) in LT-GaAs doped with Be (■) in comparison to undoped LT-GaAs grown at different temperatures with a BEP of 20 (○, Ref. [3]) and to undoped LT-GaAs grown at 200°C with variable BEP (△, Ref. [8]).

LT-GaAs:Be. The PAS and MCDA results gave no evidence for the formation of Be containing complexes. This indicates that the Be does not interact with the other defects. Because the Ga or As concentration at the surface is still much higher than the Be concentration, the defect concentrations will then be governed by the same kinetically factors as in undoped material.

Finally, we address the issue of thermal stability of LT-GaAs:Be. While we exclude that type and concentration of native point defects are changed it is known that the small Be atoms compensate the lattice strain caused by As_{Ga} antisites. Because thermal stabilization is best in layers where the net amount of strain is lowest [4], we conclude that the most likely explanation for

thermal stabilization in LT-GaAs:Be is strain compensation.

In summary, we studied native defects in non-stoichiometric LT-GaAs doped with Be. We found the same defects as in undoped LT-GaAs, i.e. As_{Ga} antisites and Ga vacancies. The As_{Ga} exhibited the same features as As_{Ga} defects in bulk GaAs, i.e. they have similar MCDA spectra and could be fully quenched. The concentration of native defects was not influenced by the Be doping and depends only on the growth conditions. Our results suggest that the most likely explanation for thermal stability of LT-GaAs:Be is the compensation of lattice strain by the Be atoms.

Abstract

Preliminary results on the study of deep levels associated with 4d-transition metal, rhodium, in crystalline GaAs grown by metal-organic chemical vapour deposition (MOCVD) technique are reported for the first time. Deep level transient spectroscopy on n-type GaAs doped in situ with Rh during MOCVD growth reveals a broad majority carrier emission peak. The peak corresponds to a band of deep levels extending over the energy range 0.57–0.65 eV below the conduction band edge with lower-energy states having lower electron capture cross-sections. The deep levels show a pronounced dependence of electron emission rate on the junction electric field. Minority carrier (hole) emission spectra at zero bias show a pronounced Rh-related deep-level peak with a low-temperature shoulder. The dominant level in the lower half-gap is found to have a position $E_v + 0.44$ eV, with a field-dependent emission rate signature. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Transition metals; GaAs; DLTS; MOCVD

1. Introduction

The study of transition metal (TM) impurities is a subject of continuing importance in semiconductor physics owing to their fundamental and technological importance. In this regard, the role of heavier, 4d- and 5d-TM impurities is of particular importance in compound semiconductors as shown by our recent work on InP [1–3]. For example, the 5d-TM ruthenium (Ru) has been shown to provide a thermally stable, compensator dopant for producing semi-insulating InP needed for InP-based semiconductor technology [2]. This paper reports the results of the first ever DLTS investigation of the 4d-TM impurity rhodium (Rh) in GaAs, to our knowledge.

2. Material and samples

Epitaxial layers of n-type GaAs grown by low pressure, metal-organic chemical vapour deposition

(LP-MOCVD) doped in situ with Rh have been used in this study. The temperature and pressure during growth were 720 °C and 20 mbar, respectively. p⁺-layers doped with Zn were grown on these layers by metal-organic chemical vapour deposition (MOCVD) in the same reactor to fabricate mesa p⁺-n-junction diodes suitable for performing DLTS investigations, after providing appropriate metallic ohmic contacts on the two sides by vacuum evaporation. A sensitive deep-level spectrometer based on lock-in detection system has been used for DLTS measurements from 77 K upwards in temperature. Identically prepared reference samples without any intentional Rh doping were used to identify the Rh-related deep-level defects in Rh-doped samples.

3. Results

3.1. Majority carrier deep levels

The typical DLTS spectra for majority carrier (electron) emission obtained from the reference and Rh-doped samples are shown in Fig. 1. While no

Fig. 1. Majority carrier (electron) emission DLTS spectra of (a) p^+n -GaAs reference sample at 500 μ s capture pulse width. (b)–(e) Rh-doped p^+n -GaAs at (b) 5 μ s, (c) 50 μ s, (d) 500 μ s and (e) 5 ms capture pulse widths, respectively. $V_R = -2.0$ V and $V_P = -0.5$ V for all spectra.

Fig. 2. Majority carrier (electron) emission DLTS spectra for Rh-doped n -GaAs at different reverse biases (V_R) showing the effect of electric field: (a) $V_R = -5$ V, (b) -4 V, (c) -3 V, (d) -2 V, (e) -1 V; $V_P = -0.5$ V and $t_P = 500$ μ s for all spectra.

significant deep level emission signal is observed from the reference samples in the temperature range used, the Rh-doped samples show a prominent, broad peak corresponding to electron emission to the conduction band. This peak shows a strong increase in the width and height, with a pronounced broadening towards low-temperature end, as the width of the electron capture pulse is increased from 5 μ s to 5 ms, as shown in Fig. 1. This clearly shows that Rh introduces a band of deep-level states in the upper half-gap with lower-energy levels having lower electron capture cross-sections as compared to the higher-energy (deeper) states. DLTS scans at different applied quiescent biases show a significant shift in the peak position towards lower temperatures with the increase of the junction electric field along with the accompanying broadening, as shown in Fig. 2. This is a clear indication that most of the Rh-related deep levels comprising the broad peak have field-dependent emission rates. Attempts to resolve this band into component peaks, at least at the high-temperature end, by using smaller capture pulse widths did not yield clear single peaks when tested against theoretical DLTS line-shape formula [4,5]. The DLTS spectra for low (250 ns) and high (500 μ s) capture pulse widths are shown in Fig. 3. In view of the strong electric field dependence, double-correlation DLTS (DDLTS) was used to obtain information on the limiting positions of the energy levels comprising the above-mentioned band. The Arrhenius plots of the electron emission rate data so obtained for these limiting cases, given in the inset of Fig. 3, show the activation energies of the levels corresponding to the low- and high-temperature ends of the emission band to be approximately 0.57 and 0.65 eV, respectively, at an electric field of $\sim 6 \times 10^4$ V/cm. The respective apparent electron capture cross-sections for these two ends of the band, obtained from

Fig. 3. Majority carrier (electron) emission DLTS spectra for Rh-doped sample at (a) 250 ns and (b) 500 μ s pulse width. The inset shows the Arrhenius plots, obtained in the DDLTS mode for the peaks E_L and E_H corresponding to the low- and high-temperature ends, respectively, of the emission band.

the intercepts of the Arrhenius plots of the respective emission rate signatures, are given in Table 1.

3.2. Minority carrier deep levels

Fig. 4 shows DLTS spectra obtained with minority carrier injection at zero volt quiescent bias. High injection ($+2.0$ V) and large pulse width (500 μ s) spectrum, trace (a), clearly shows a prominent, broad negative peak with a shoulder at the lower-temperature end, corresponding to at least two deep-level states in

Table 1
Characteristics of deep levels observed in n-GaAs:Rh

Deep level position (eV)	Capture cross-section $\sigma(\times)(\times 10^{-12} \text{ cm}^2)$
$E_c - 0.57^a$	5.17
$E_c - 0.65^a$	4.08
$E_v + 0.44$	0.33

^a These levels correspond to the low- and high-temperature ends of the DLTS emission band.

Fig. 4. Minority carrier (hole) emission DLTS spectra for Rh-doped n-GaAs at two different pulse widths (a) 500 μs and (b) 0.5 μs . The inset shows Arrhenius plots of minority carrier emission peak observed under the following conditions (a) DLTS mode; $V_R = 0 \text{ V}$, $V_P = +2.0 \text{ V}$, $t_P = 250 \text{ ns}$; (b) DDLTS mode; $V_R = -5 \text{ V}$, $V_{P1} = +2.0 \text{ V}$, $V_{P2} = 0 \text{ V}$, $t_P = 500 \mu\text{s}$ and (c) DDLTS mode; $V_R = -1 \text{ V}$, $V_{P1} = +2.0 \text{ V}$, $V_{P2} = 0 \text{ V}$, $t_P = 500 \mu\text{s}$.

the lower half-gap of our material. Lowering the injection pulse width leads to the disappearance (or strong reduction in the strength) of the shoulder, as shown by trace (b) in Fig. 4, indicating a significantly lower hole capture cross-section for the lower-energy deep-level component. The measured hole emission-rate signature of the dominant minority carrier deep level is shown as plot (a) in the inset of Fig. 4, yielding an activation energy of $\sim 0.44 \text{ eV}$ for this level. It is pertinent to point out that the minority carrier injection scans with non-zero quiescent reverse bias (V_R) show either no negative peak (for $V_R < -2 \text{ V}$), or a much smaller (by a factor of 2, approximately) negative peak (for $V_R > -2 \text{ V}$) superposed on the dominant majority carrier emission band, while the injection DLTS spectrum at zero quiescent bias shows only the minority

carrier peak, as expected. However, DDLTS using an injection pulse followed by a zero volt majority carrier excitation pulse, which would eliminate at least a major part of the majority carrier emission peaks, if not completely, would circumvent this problem and clearly show minority carrier emission peaks even at non-zero quiescent reverse bias. This is indeed what is observed, allowing measurement of the emission rate signature at an applied reverse bias, which is also included in the inset of Fig. 4 (plot b). Plot (c) in the same inset is the emission rate signature for the same peak measured in the DDLTS mode at a lower applied bias of -1 V , keeping all other parameters the same as for plot (b). This clearly shows that this hole-emitting level has a strongly field-dependent emission rate.

DLTS investigations on the reference diodes show much smaller minority carrier emission features in similar (but not identical) temperature regions. However, while the higher-temperature peak is too weak to allow detailed measurements, careful measurements show that the lower-temperature peak in these samples has a significantly different emission rate signature than that of the minority carrier emission peak in the Rh-doped samples. The minority carrier emission peaks seen in Rh-doped GaAs are either exclusively Rh-related or combined with the much smaller peaks, corresponding to deep levels in close-by positions in the band gap, seen in the reference samples. The much stronger hole emission peaks in the Rh-doped samples may, thus, originate from isolated Rh impurity or some complexes of Rh with the pre-existing/growth-related inadvertent defects in the as-grown MOCVD material. Unambiguous resolution of these aspects and some other unusual properties of the small minority carrier peaks in the reference samples require detailed further work, which is in progress.

4. Conclusions

In conclusion, Rh impurity is seen to introduce deep-level defect states in the bandgap of n-type GaAs crystals grown by LP-MOCVD at energy positions extending from $E_c - 0.57$ to $E_c - 0.65 \text{ eV}$ in the upper-half gap. Most of this band of levels appear to have electric field dependent emission characteristics. In the lower-half gap, a Rh-related deep level at $E_v + 0.44 \text{ eV}$ is found to dominate the DLTS spectrum. In addition, unresolved hole-emitting deep-level signals are also observed both on the lower- and higher-temperature sides of this dominant peak in the hole emission spectra. The 0.44 eV hole level is also found to exhibit electric field dependent emission rate signature. Theoretical efforts to resolve the majority carrier deep-level band and detailed quantitative analysis of the field dependence of these components are in progress.

Abstract

The effect of beryllium doping on defect structure of the 1.5 μm thick GaAs:Be films grown by MBE on GaAs substrate as well as the effect of high temperature–high pressure treatment (HT–HP) on structural changes in that material were investigated by X-ray, electrical and SIMS methods. For As-grown GaAs:Be with Be concentration $\leq 2.7 \times 10^{19} \text{ cm}^{-3}$, the Be doping-related decrease of lattice parameter, a , corresponded to that calculated from the Vegard law, accounting for the effect of holes on that parameter. For GaAs:Be with the higher Be concentration, a decrease of the a value was lower than that calculated. This effect can be explained assuming creation of Be inclusions. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaAs:Be; High hydrostatic pressure; Beryllium inclusion; X-ray

1. Introduction

Heavily doped p-type GaAs makes it easier to produce ohmic contact and is very desirable in device structures such as tunnel diodes or heterojunction bipolar transistors. Beryllium is the most frequently used dopant for preparing p-type GaAs. Beryllium incorporation in GaAs produces a shallow donor at about 19 meV level above the valence band.

Doping with electrically active atoms changes the lattice constant of the semiconductors owing two factors: (i) size effect and (ii) presence of free charges. The effect of inclusions on the lattice constant ought to be also taken into account for the case of highly doped semiconductor. Linear dependence of the lattice constant value on the beryllium concentration has been reported [1].

As it follows from recent investigations of the high temperature–high hydrostatic pressure, HT–HP, effect on strained, hydrogen- and oxygen-implanted silicon, Si:H and Si:O [2–4] and on the thin AlGaAs layers deposited on the GaAs substrate [5], the HT–HP treatment can result in:

- (i) change of thin layer strain;
- (ii) change of components diffusivity;
- (iii) creation of additional nucleation sites for newly created bulk and interface defects;
- (iv) change of dislocation mobility; and
- (v) creation of defects at the thin film/matrix boundary.

An influence of enhanced hydrostatic pressure of ambient gas on the layer strain can be neglected for the GaAs:Be/GaAs samples due to similar bulk moduli [5] of the layer and substrate materials. It means that the GaAs:Be lattice parameter value after the HT–HP treatment would depend mainly on the primary defect structure of the layer material. Therefore, the HT–HP treatment was applied in our work to obtain information on the defect structure of the GaAs:Be layer modified by beryllium doping.

2. Experimental

The epitaxial GaAs:Be layers were grown on the semi-insulating (100)-oriented GaAs substrates at 870 K with a growth rate of 1.0 $\mu\text{m}/\text{h}$ in the Katun's MBE system. The layers thickness was equal to 1.5 μm . The GaAs:Be layers were separated from the GaAs substrate by a 100 nm thick superlattice comprising five pairs of (AlAs)/(GaAs) subsequent layers, each layer with 10 nm thickness. The GaAs:Be layers were covered by a 30 nm thick capping AlAs layer.

The Be and carrier (hole) concentrations were determined by secondary ions mass spectrometry, SIMS and Van der Pauw measurements, respectively. The last measurements were performed at room and liquid nitrogen temperatures.

The GaAs:Be/GaAs structures were HT–HP treated for 1 h under 1.2 GPa argon pressure at 870 K, the same temperature as that of layer growth.

The lattice constant of the layer material, before and after the HT–HP treatment, was determined by the Fewster method [6] using X-ray high-resolution diffractometer. A set of high Bragg angle reflections (006, 335 and 117) was used. The relaxed lattice parameter of the layer material, a_{relax} , was calculated using the following equation:

$$a_{\text{relax}} = (a_{\perp} + 2Ca_{\parallel}) / (1 + 2C), \quad (1)$$

where a_{\perp} is the lattice parameter perpendicular to the layer/substrate interface, a_{\parallel} is the lattice parameter parallel to that interface and $C = (1 - \nu)/(1 + \nu)$, where ν is the Poisson ratio, equal to 0.311 for GaAs.

3. Results and discussion

The Hall and SIMS data for investigated samples are given in Table 1. The designations correspond to GaAs:Be with different Be concentration.

Beryllium is substitutionally incorporated into the Ga sublattice where it becomes an acceptor. A decrease of hole concentration with decreasing temperature was observed for the 906 and 907 layers (Table 1). The

hole concentration at 77 K was the same as the Be concentration in the Ga sublattice. However, it was not possible to determine the nature and concentration of deeper acceptors revealed at 300 K. It is necessary to notice that similar deep acceptors were reported earlier for the undoped MBE grown GaAs layers [7].

As it follows from the data in Table 1, the SIMS-detected Be concentration was higher than that determined by the Van der Pauw method. It means that the Be concentration in the GaAs:Be layers was higher than that corresponding to Be incorporated into the Ga sublattice. That additional Be atoms occupy interstitial positions or create the Be composed inclusions. The similar effect was reported also for GaAs:Si [8]. In the case of sample 907, the Be concentration in the Ga sublattice was lower than that for the 906 sample; however, the Be concentration, determined by SIMS, was higher, quite opposite to before mentioned observation. It means that the creation of Be inclusions or/and of Be interstitials is not directly dependent on the Be concentration.

The change of the relaxed lattice constant of the layer material is given in Table 2.

For all investigated layers, the parallel lattice constant of GaAs:Be, a_{\parallel} , was equal to the lattice constant of GaAs substrate. However, the decreased perpendicular and relaxed lattice parameters were detected for all investigated GaAs:Be layers (the lattice constant of GaAs equals to 5.65332 Å). The relative change of lattice parameter, a , for the p-type semiconductor of the zinc blend structure, related to the size and hole concentration effects, is given by the formula [9–11]

$$\Delta a/a = \beta_s N_d + \beta_p N_p, \quad (2)$$

where N_d is the Be dopant concentration in the Ga sublattice (N_d is equal to the hole concentration at 77 K—see Table 1), N_p the hole concentration in the top of valence band (we took into account the hole concentration at 300 K—Table 1), β_s and β_p describe

Table 1

^a Concentration of holes, N_p , and beryllium concentration, c_{Be} , at 300 and 77 K, respectively.

Table 2
Decrease of calculated and experimentally determined relaxed lattice parameter, Δa_{relax} , for As-grown GaAs:Be (in comparison to a_{GaAs}), and increase of the lattice parameter after the HT–HP treatment, $\Delta a'_{\text{relax}}$, in comparison to lattice parameter a of the As-grown GaAs:Be samples

Samples	As-grown $\Delta a \pm 0.5 \times 10^{-4}$ (Å)		After HT–HP $\Delta a' \pm 0.5 \times 10^{-4}$ (Å)
	Exp.	Calc.	Exp.
903	–1	–0.5	<0.5
905	–3.7	–3.8	1
906	–8.6	–10.1	1.5
907	–6	–9.2	2

the size effect (corresponding to the Vegard law) and the effect of presence of holes:

$$\beta_s = 4(R_d - R_s)/\sqrt{3}aN_0 = 2.03 \times 10^{-24}, \quad (3)$$

$$\beta_p = D/3B = 0.4978 \times 10^{-24}, \quad (4)$$

where $N_0 = 2.21 \times 10^{22} \text{ cm}^{-3}$ is the Ga density in a non-doped GaAs, R_d and R_s the covalent radii of Be (1.11 Å) and of Ga (1.22 Å), respectively, B the bulk modulus of GaAs, equal to $7.5 \times 10^6 \text{ N/cm}^{-2}$, D the deformation potential of the top valence band, equal to 0.7 eV.

As it follows from Table 2, the experimentally detected decrease of the relaxed lattice constant is smaller than that calculated from the formula (2). This effect is probably caused by the creation of Be-related defects. If such Be containing inclusions are created during the layer growth, the HT–HP treatment would influence the defect structure of GaAs:Be and so the treatment-induced lattice parameter changes would be observed.

Indeed, the GaAs:Be samples subjected to the HT–HP treatment indicate an increase of the lattice parameters (Table 2). The HT–HP treatment, due to the different (in respect to that of the matrix material) compressibility and thermal expansion of the Be containing inclusions, results in creation of additional defects influencing the lattice parameter value. It is known that, at sufficiently severe HT–HP conditions, the stress at the precipitate/matrix material can reach the critical value for emitting dislocations loops and other defects [12].

Our results suggest that a part of Be atoms create, during the GaAs:Be layer growth, some Be containing defects. Just their presence is the most probable explanation of the HT–HP induced effects in the GaAs:Be samples.

4. Conclusions

The Be containing defects (inclusions ?) were detected in the GaAs:Be samples with the Be concentration higher than $2 \times 10^{19} \text{ cm}^{-3}$. The increased lattice constant

value was detected for GaAs:Be after the treatment at 870 K, 1.2 GPa. It was shown that effects of the HT–HP treatment can be considered as a specific indicator of the primary defect state of the GaAs:Be samples.

Carbon incorporation during growth of GaAs at low temperatures

J. Herfort^{a,*}, W. Ulrici^a, M. Moreno^a, M. Luysberg^b, K.H. Ploog^a

Abstract

Heavily C-doped GaAs layers grown by solid-source molecular beam epitaxy at low substrate temperatures, $195^{\circ}\text{C} < T_G < 375^{\circ}\text{C}$, are investigated using infrared absorption measurements. The heavy C-doping (about $2 \times 10^{19} \text{ cm}^{-3}$) causes a compensation of the strain created by the simultaneously formed As antisite defects, As_{Ga} . The contents of As_{Ga} and substitutionally incorporated carbon, C_{As} , are determined as a function of T_G . Additionally, for $T_G < 400^{\circ}\text{C}$ the local vibrational mode absorption lines of four C-containing complexes are found. These lines, located at frequencies around 1800 cm^{-1} , are most likely due to C–C stretching modes. For $T_G < 250^{\circ}\text{C}$ the C-complexes are responsible for the strain compensation, as no C_{As} is detectable. After annealing at 600°C the content of C_{As} is not changed, but the C-complexes completely disappear. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: LT-GaAs; Carbon; Local vibrational modes; Molecular beam epitaxy

1. Introduction

GaAs grown by molecular beam epitaxy (MBE) at low substrate temperatures (LT-GaAs) has gained increasing interest because of its special properties which lead to a wide range of opto-electronic applications [1–3]. Most attractive are the ultrashort carrier trapping times and, upon annealing, very high resistivities [4,5]. These properties are explained by the presence of a very high content of As_{Ga} antisite defects formed during the growth. Carrier trapping times even shorter than in undoped material are expected for p-doped LT-GaAs owing to the higher concentration of charged antisite defects [6,7]. Furthermore, strain compensation is achievable, as the lattice expansion created by the As_{Ga} can be compensated by the lattice contraction created by the acceptors. These efforts have been concentrated on Be-doped LT-GaAs [8–10]. Compared to carbon, however, Be has a much higher diffusion coefficient [11] which can lead to undesirable diffusion

and precipitation at high doping levels although this might be less pronounced for growth at low temperatures [6].

C incorporation in LT-GaAs has been studied by Liu et al. [12] using a CBr_4 gas source. They found that the C-doping is unavoidably accompanied by a significant unfavorable bromine incorporation. In a recent paper [13] we have investigated the C incorporation into LT-GaAs layers grown by solid source MBE at different growth temperatures T_G and C concentrations. From double crystal X-ray diffraction (DCXRD) measurements on LT-GaAs:C with $p = 2.5 \times 10^{19} \text{ cm}^{-3}$, it was derived that layers grown at $T_G \approx 220^{\circ}\text{C}$ are almost lattice matched to the GaAs substrate [13]. The good quality of these layers was evidenced by the interference fringes appearing in the X-ray rocking curves. Below (above) this growth temperature, the tensile (compressive) strain produced by As_{Ga} and C_{As} , respectively, is detected. Here, we investigate by infrared absorption measurements on such LT-GaAs:C layers, how the incorporation of C_{As} and As_{Ga} , and the formation of C-containing complexes depends on T_G and how this is affected by subsequent annealing.

2. Experimental details

Two sets of LT-GaAs:C samples were grown by MBE on semi-insulating GaAs(001) substrates at various growth temperatures T_G , between 195 and 375°C. The C-concentrations for the two sets as determined from Hall effect measurements of reference samples grown at high T_G , i.e. 550°C, were 1.2×10^{18} and $2.5 \times 10^{19} \text{ cm}^{-3}$, respectively. Secondary-ion mass spectroscopy (SIMS) revealed that the total carbon content $[C_T]$ is apparently larger by about a factor of 4 in case of the higher doping concentration, but most important, it remains constant when T_G is decreased.

The LT-GaAs:C layers with a thickness of about 300 nm were deposited with a growth rate of 0.5 µm/h after growing a 200 nm thick GaAs buffer layer at 570°C. The As₄:Ga BEP ratio was about 20 to have stable arsenic rich conditions. For more details of the sample growth we refer to Ref. [13]. One piece of each sample was subsequently annealed in the growth chamber at 600°C for 20 min under As overpressure. The infrared absorption experiments have been performed with a Bruker IFS 120 HR Fourier-transform spectrometer operating with spectral resolutions of 0.2–2 cm⁻¹ with the samples kept at $T = 80 \text{ K}$ in a cryostat.

3. Results and discussion

In Fig. 1 the absorption features measured at $T = 80 \text{ K}$ on LT-GaAs:C layers in the frequency region

Fig. 1. Infrared absorption spectra measured at $T = 80 \text{ K}$ on LT-GaAs:C samples grown at different substrate temperatures $210^\circ\text{C} < T_G < 280^\circ\text{C}$. Different parts are measured on samples grown at different T_G to show all investigated vibrational absorption lines. The inset shows the correlation between the integrated intensities A of the vibrational absorption lines at 793 and 1905 cm⁻¹.

from the two-phonon cut-off at $\approx 550 \text{ cm}^{-1}$ up to the electronic edge of GaAs at $\approx 12\,000 \text{ cm}^{-1}$ are summarized. These spectra were measured on the set of samples with high C content ($p = 2.5 \times 10^{19} \text{ cm}^{-3}$). At high wavenumbers the broad absorption with the EL2-like spectral shape can be seen which is due to electronic transitions from the As_{Ga}^0 midgap level into the conduction band of GaAs as characteristic for LT-GaAs [14]. This absorption allows evaluating the concentration of neutral As_{Ga}^0 antisite defects $[\text{As}_{\text{Ga}}^0]$, using the known photoionization cross sections [15] of As_{Ga} in single crystalline bulk GaAs. The local vibrational mode (LVM) absorption line at 582.5 cm^{-1} due to substitutional carbon, C_{As} , can be well detected. However, in contrast to bulk GaAs with low C_{As} content, the isotope structure due to the surrounding ^{69}Ga and ^{71}Ga is not resolved, and the half-width of the line is larger and increases with decreasing T_G . This broadening is probably caused by strain due to the presence of a high concentration of nonstoichiometric defects in LT-GaAs. Nevertheless, the concentration of C atoms on arsenic sites $[\text{C}_{\text{As}}]$ can be determined using the calibration factor $f = 7 \times 10^{15} \text{ cm}^{-1}$ [16] for the integrated intensity of the LVM absorption line at 582.5 cm^{-1} .

The concentrations of As_{Ga}^0 and C_{As} determined for as-grown layers with high C content ($p = 2.5 \times 10^{19} \text{ cm}^{-3}$) at different substrate temperatures T_G are shown in Fig. 2. As can be seen, $[\text{As}_{\text{Ga}}^0]$ increases strongly with decreasing T_G in the same manner, as

Fig. 2. Concentration of arsenic antisite defects $[\text{As}_{\text{Ga}}^0]$ and substitutionally incorporated carbon $[\text{C}_{\text{As}}]$ in LT-GaAs as a function of the growth temperature T_G for as-grown layers (full symbols) and after annealing at 600°C (open symbols). The C concentration corresponds to $2.5 \times 10^{19} \text{ cm}^{-3}$.

it is known for undoped LT-GaAs [5]. On the other hand, below $T_G = 250^\circ\text{C}$ a drastic decrease of $[C_{As}]$ is observed. A qualitative similar behavior is found for the LT-GaAs:C layers with lower C content ($p = 1.2 \times 10^{18} \text{ cm}^{-3}$). Annealing at 600°C reduces the $[As_{Ga}]$ below the detection limit (here $< 10^{19} \text{ cm}^{-3}$) for all T_G in the same manner as for undoped LT-GaAs. The concentration of C_{As} , however, remains unchanged after annealing at 600°C for all samples. This is expected (and desired) because of the low diffusion coefficient of C in GaAs [11] causing C to be immobile at this temperature.

From Fig. 1 it can be seen that in the frequency region from 700 to 2000 cm^{-1} additional five LVM lines with small half width Γ are detected for low T_G , never observed before in LT-GaAs or bulk GaAs. Three of them are quite intense (their integrated intensities are comparable with that of C_{As} at $T_G > 250^\circ\text{C}$) and located at 792.9 cm^{-1} ($\Gamma = 1.5 \text{ cm}^{-1}$), 1859.0 cm^{-1} ($\Gamma = 4.8 \text{ cm}^{-1}$), and 1905.3 cm^{-1} ($\Gamma = 0.9 \text{ cm}^{-1}$). The inset in Fig. 1 shows that the intensities of the narrow lines at 793 and 1905 cm^{-1} are correlated, indicating that they are caused by a single defect called C_{LT}^A . In Fig. 3 the integrated intensities A of the three lines are shown as measured for the samples grown at different T_G . For low $T_G < 240^\circ\text{C}$ only the lines of defect C_{LT}^A are measured and they decrease in the region $240^\circ\text{C} < T_G < 375^\circ\text{C}$. On the other hand, in this region of T_G the line at 1859 cm^{-1} grows up, which is obviously due to a different center called C_{LT}^B . The dashed line for C_{LT}^B in Fig. 3 means that for $T_G = 550^\circ\text{C}$ also this center was not detectable. It should be noted that C_{LT}^A is

observed also in the LT-GaAs:C layers with lower C content ($p = 1.2 \times 10^{18} \text{ cm}^{-3}$), but the intensity of the 1905 cm^{-1} line is lower by a factor of ≈ 50 (Γ amounts to only 0.3 cm^{-1}). There are another two LVM lines shown in Fig. 1 at 1721.8 cm^{-1} ($\Gamma = 2.0 \text{ cm}^{-1}$) and 1751.9 cm^{-1} ($\Gamma = 3.5 \text{ cm}^{-1}$) which are detected only in samples grown at $T_G < 240^\circ\text{C}$. Their intensities are smaller by a factor of about 10 compared with the other three lines. Annealing at 600°C causes the complete disappearance of all the five LVM absorption lines, i.e., the responsible centers are destroyed at this temperature without any detectable increase of $[C_{As}]$.

These results suggest that in LT-GaAs:C grown at $T_G < 250^\circ\text{C}$ carbon is not incorporated substitutionally on As sites but in the form of at least three different complexes giving rise to the observed LVM absorption lines. For $250^\circ\text{C} < T_G < 400^\circ\text{C}$ two complexes coexist. These complexes, however, have still to be part of the GaAs lattice, as they contribute to the strain compensation as derived from the DCXRD experiments [13]. Especially in the region around $T_G = 220^\circ\text{C}$, where complete strain compensation is observed, this compensation must arise from these complexes rather than from C_{As} . The formation of As precipitates seems also to be affected by the different C incorporation since we observe As precipitates in annealed LT-GaAs:C with $p = 2.5 \times 10^{19} \text{ cm}^{-3}$ for $T_G = 210^\circ\text{C}$ whereas for $T_G = 250^\circ\text{C}$ no precipitates could be resolved by transmission electron microscopy.

Concerning the structure of the C complexes the following arguments must be considered. They certainly contain C, as they are observed only in C-doped LT-GaAs. Other defects must be involved which at $T = 600^\circ\text{C}$ can diffuse away from or onto the complexes to destroy or convert them. Due to the high content of the complexes (several 10^{19} cm^{-3}), these defects can only be As_{Ga} , interstitial As_i , and possibly vacancies.

As for the assignment of the vibrational lines, two types of bonds are possible taking into account the described experimental results. First, the complexes consist of a C–As core, i.e., the C–As vibration is responsible for the lines, where the manifold comes from the possibility to have additional defects in the neighborhood. The destruction by annealing might be explained by the diffusion away of As to form As precipitates. However, there are experiments [17] and calculations [18,19] for the C_{As} – As_i complex in bulk GaAs. These results suggest that the frequencies of the C–As vibrations are around 600 cm^{-1} , i.e., considerably smaller than those observed here.

Second, the complexes consist of a C–C core and the lines are due to C–C vibrations. In this case, the destruction of the complexes during annealing at 600°C by C diffusion is not possible. However, As_{Ga} and/or As_i can diffuse at this temperature onto the C–C complexes forming As-precipitates containing C-inclusions, which

Fig. 3. Integrated intensities A of the vibrational absorption lines at 793 , 1859 , and 1905 cm^{-1} measured in LT-GaAs:C layers grown at different temperatures T_G . C concentration as in Fig. 2.

causes also a disappearance of the complexes. The vibrational frequencies of the C–C molecule in the gas phase are around 1800 cm^{-1} [20]. In highly carbon doped GaAs [21] and AlAs [22] two dicarbon centers have been detected by Raman scattering with their C–C stretching modes around 1750 and 1856 cm^{-1} . These centers were interpreted as $(\text{C-C})_{\text{As}}$ complexes having two different orientations. Therefore, the frequencies of the absorption lines due to the complexes in LT-GaAs:C are quite accurate by the region of the known C–C vibrations. This suggests that most probably C–C complexes with slightly different surroundings be formed in LT-GaAs:C during the growth. The line at 793 cm^{-1} can be interpreted as a bending mode of $\text{C}_{\text{LT}}^{\text{I}}$ with its stretching mode at 1905 cm^{-1} . The stretching modes of the $(\text{C-C})_{\text{As}}$ complexes in GaAs and AlAs [21,22] have no dipole moment and are, therefore, detectable only by Raman scattering. In LT-GaAs:C, however, the C–C bonds are certainly disturbed by adjacent intrinsic defects (As_{Ga} , As_{i} , vacancies) which cause a redistribution of the symmetric electron density around the C–C bond, so that a dipole moment of the C–C vibrations is induced and they become infrared active. Such an effect has been convincingly demonstrated for the vibrations of the H_2 molecule in Si disturbed by interstitial oxygen [23].

Abstract

Depth distribution and annealing behavior of deep level defects in epitaxial n-GaAs exposed by atomic hydrogen treatment are investigated. By the analysis of hydrogen-related metastable defect M3/M4 and EL2 center depth profiles it is shown that M3 defect contains one hydrogen atom and the relation of M3 defect with EL2 is quantitatively confirmed. The reversible changes of space charge density under metastable transition are revealed. It is shown that these changes are determined by the second component of M4 defect that is one more metastable hydrogen-related defect could be assumed. © 2001 Elsevier Science B.V. Keywords: GaAs; Hydrogen; M3/M4 defects; Metastability

1. Introduction

The nature and properties of metastable M3/M4 defects firstly observed in n-GaAs grown by metal-organic chemical-vapor deposition (MOCVD) [1,2] were extensively studied [3–7]. It was shown that these defects are hydrogen-related [3] and that their formation correlates with the existence of arsenic antisite [4] or EL2 center [5,6], which are the most probable precursors for the M3/M4 defects.

In spite of the studies, the knowledge concerning the formation and behavior of M3/M4 defects is still incomplete. So, the relationship between EL2 centers and M3/M4 defects was not quantitatively supported. In addition, in the most studies the concentration of M4 defect essentially exceeds that of M3 and can be even higher than the initial EL2 concentration. To explain this contradiction, it was assumed [6] that the deep level transient spectroscopy [8] (DLTS) peak related to M4 consisted of two components. Recently, these two components were separated [7] by the isothermal constant-capacitance-voltage transient spectroscopy (CCVTS) [9]. One of these components was assumed

to be the second metastable state of M3 defect while the origin of other one is unclear up to now. Moreover, in the mentioned works the “average concentration over some region” was used for the comparison of M3, M4 and EL2 concentrations that could lead to wrong conclusions if the defects have the different depth distribution. To avoid the confusions and to obtain the complete picture of defect transformations, the accurate depth profiling is required.

In the present work, the depth distributions of all electrically active deep level (DL) defects after each step of sample treatment (hydrogenation, reverse bias (RBA) and zero bias annealing (ZBA)) are studied by DLTS and capacitance-voltage (CV) profiling. The analysis of depth profiles quantitatively confirms that EL2 is a precursor for the M3 formation. It is shown that the M3 center contains one atom of hydrogen. It is found that changes in free carrier concentration under the metastable transition are determined by second metastable component of M4 defect.

2. Experimental

The samples of Sn doped n-GaAs with the carrier concentration $(4-5) \times 10^{15} \text{ cm}^{-3}$ grown by the metal-

organic vapor-phase-epitaxy (MOVPE) on (100) n^+ -GaAs:Te substrates were used for atomic hydrogen exposure. Ohmic contacts were made by the electrochemical deposition of GeNi+Au with subsequent annealing at 450°C for 5 min. Before the hydrogen treatment a native oxide was removed in the mixture $\text{NH}_4\text{OH}:\text{H}_2\text{O}$ (1:5) and a 5 nm SiO_2 film was deposited on the surface to avoid the direct impact of hydrogen atoms. The samples were treated in atomic hydrogen flow produced by the arc-reflected-discharge-based source with a hollow cathode and a self-heating electrode [10]. The samples were placed at the distance of 12 cm from the source of atomic hydrogen that prevents a surface damage. Sample temperature during the treatment was 200°C or 300°C (below referred to as samples 2 and 3, respectively) and the exposure time was 45 min. The Schottky diodes for the CV and DLTS measurements with an area of $1.95 \times 1.95 \text{ mm}^2$ were formed by thermal evaporation of Au through the windows opened in SiO_2 . Control samples were made by the same procedure excluding the atomic hydrogen treatment.

Annealing (400 K, 15 min) under 10 V reverse or zero bias was used to stimulate the transitions between the metastable states of M3/M4 defect. Depth distributions of all DL defects were controlled by the DLTS technique. To avoid defect transformations under DLTS spectra recording, the temperature during measurements did not exceed 310 K. The isothermal capacitance transient spectroscopy (ICTS) [11] at 295 K with following computer processing of capacitance transient was used for EL2 profiling. The changes in free carrier concentration profiles were controlled by the CV technique.

3. Results and discussion

3.1. DL defects introduced under atomic hydrogen treatment

Two DL defects with energy levels $E_C-0.39 \text{ eV}$ and $E_C-0.80 \text{ eV}$ are found in the DLTS spectra of control sample (Fig. 1, curve 1). The deeper level corresponds to well-known EL2 center while the shallower one is similar to EL5 [12]. Hydrogenation leads to an appearance of three DL in the DLTS spectra while the EL2 peak amplitude is significantly decreased. The most prominent of arising peaks ($E_C-0.54 \text{ eV}$) disappears under following RBA while the other large peak ($E_C-0.29 \text{ eV}$) appears (Fig. 1, curves 2, 3). These changes are reversible under subsequent ZBA and RBA. Parameters and behavior of these traps completely correspond to those of known metastable M3/M4 defects. The changes in EL2 concentration under annealing are negligible in

Fig. 1. DLTS spectra of n-GaAs samples after hydrogenation and RBA. 1—control sample, 2—after hydrogenation (sample 3), 3—after hydrogenation and RBA (sample 3). The EL2 peak amplitude after hydrogenation is obtained from ICTS.

comparison with the EL2 decrease due to hydrogenation.

Concentrations of other two peaks with energy levels $E_C-0.46 \text{ eV}$ and $E_C-0.19 \text{ eV}$ (EX3 and EX4 in Fig. 1) are found to decrease with a depth therefore they also could be associated with hydrogen. But because of rather small concentration and annealing behavior revealed, they unlikely participate in transformations of EL2 and M3/M4 defects and will not be discussed here.

3.2. Depth profiles of DL defects in hydrogenated samples

One can see (Fig. 2a) that the tails of M3 profiles and a depth dependence of the difference between the shallow donor concentrations in the bulk and in the hydrogenated near-surface layers ΔN_d for both type of samples (2 and 3) can be approximated by the exponential law. As shown in Ref. [13], if the hydrogen concentration decays exponentially (that is often the case for the strong hydrogen capture), the tail part of hydrogen-related defect depth distribution is described as $NH_i \propto \exp(-ix/L_0)$, where NH_i is the concentration of centers containing i hydrogen atoms, x is the depth from the surface, L_0 is the characteristic length of hydrogen depth distribution in the crystal. Since L_0 can be estimated from the distribution of ΔN_d , the comparison of hydrogen-related defect profile with that of ΔN_d allows to derive the number of hydrogen atoms in the complex.

The values of ΔN_d and L_0 in the samples 2 and 3 are different (see Fig. 2a). But for the both samples the slopes of the M3 depth profile in semi-logarithmic scale are close to that of corresponding ΔN_d profiles. Since shallow donors are known to be passivated by one hydrogen atom [14], it can be concluded that M3 center also contains one hydrogen atom.

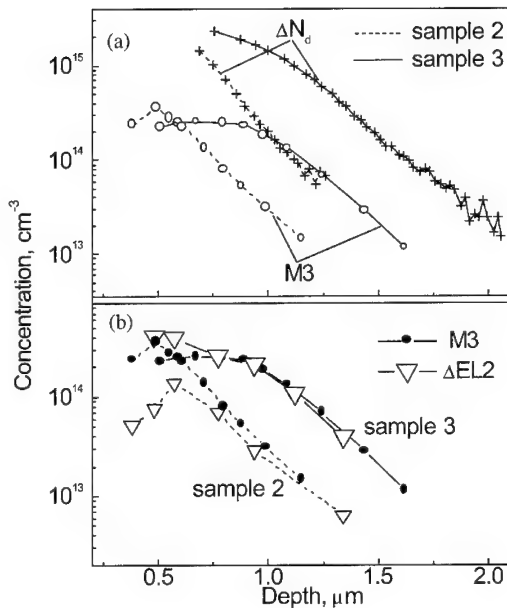

Fig. 2. Depth profiles in as-hydrogenated samples 2 and 3. (a) M3 and passivated shallow donors ΔN_d ; (b) M3 and the EL2 deficiency caused by hydrogenation.

As seen in Fig. 2b, the EL2 deficiency caused by hydrogenation ($\Delta EL2$) rather well coincides with the M3 depth profile for the samples with different hydrogen profiles. This evidences that EL2 or products of its dissociation participate in the M3/M4 formation and quantitatively confirms the conclusion made in Refs. [5,6].

3.3. Two metastable components of M4 defect

As seen in Fig. 3, the M4 concentration essentially exceeds that of M3 near the surface but this difference comes to be rather small at higher depths. This corresponds to the assumption [6,7] that M4 consists of two components which below will be referred to as M4a (the other metastable state of M3 defect) and M4b, and shows that the concentration of M4b component also decreases with the depth. Since the total M4 concentration near the surface is higher than that of EL2 in the control sample (see Fig. 3), M4b defect could not be related to EL2 center.

It is found that the reversible changes in a free carrier concentration accompany the metastable transition (Fig. 4). Under RBA when M4 peak appears the free carrier concentration is increased by $\Delta N_{RBA}(x)$. Under ZBA, when M4 peak disappears and M3 peak is recovered, the carrier concentration decreases to that before RBA. The sum of ΔN_{RBA} and M3 depth profiles well coincides with the profile of M4 (see Fig. 3). It brings us to the conclusion that the changes in carrier

Fig. 3. Depth profiles of M3 and M4 defects in the sample 3 in comparison with that of EL2 in control sample and with the ΔN_{RBA} profile in sample 3.

Fig. 4. The reversible changes in free carrier concentration in hydrogenated n-GaAs under the metastable transition.

concentration under metastable transition are determined by the M4b component. It should be noted that the metastable behavior of charge density was observed in Ar-plasma-irradiated n-GaAs [15] but no correlation with the changes in DL spectra was established.

The analysis of the possible (donor or acceptor) nature of the regarded defects based on value and sign of ΔN_{RBA} gives an additional information about the second metastable state of M4b. As M3 was identified as a donor [2,7], two possible models satisfy our experimental data. If both M4a and M4b defects are donors, then the second metastable state of M4b (let us call it M3b) is electrically neutral, i.e. it is electrically inactive or has a donor level in the lower half of the gap. If M4a is a donor and M4b is an acceptor, then M3b should be an acceptor with the energy level in the lower half of the gap that leads to a compensation of shallow donors. Taking into account that one of the M4 defect components was shown to be a donor while the other one an acceptor [7], the second model looks more preferable.

Thus, the existence of another metastable hydrogen-related defect different from M3/M4a could be assumed. This defect is revealed as M4b in one state and, more probably, has an acceptor DL in the lower half of the gap in the other one. The depth profile of M4b component obtained as difference of M4 and M3 defect depth distributions is steeper than that of M3. Thus, M4b should contain more than one hydrogen atom.

4. Conclusion

New data concerning metastable hydrogen-related defects M3/M4 are obtained from the analysis of the results of DLTS and CV profiling. It is shown that M3 defect contains one hydrogen atom and that EL2 defect or products of its dissociation participate in formation of M3. The reversible changes of free carrier concentration under metastable transition are revealed. It is shown that these changes are associated with the changes in the M4b component charge state and the existence of one more metastable hydrogen-related defect can be assumed.

Abstract

We have investigated the simultaneous diffusion of Zn and Ga in a ⁶⁹GaAs/⁷¹GaAs isotope multilayer structure at temperatures between 618°C and 714°C. Diffusion profiles of Zn, ⁶⁹Ga, and ⁷¹Ga were measured with secondary ion mass spectrometry. Accurate modeling of the simultaneous diffusion of Zn and Ga is achieved on the basis of a Ga vacancy and Ga interstitial controlled mode of Zn diffusion. This result is at variance with the generally accepted model of Zn diffusion via Ga self-interstitials. We discuss the consequences of our approach against the background of Zn and Cd diffusion experiments performed earlier. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Following the conclusions of Gösele and Morehead [1] and more recent results of Yu et al. [2] and Bösker et al. [3], Zn diffuses in GaAs via the kick-out mechanism

Zn_i^+ , Zn_{Ga}^- , and $\text{I}_{\text{Ga}}^{2+}$ denote, interstitial Zn, Zn occupying a Ga lattice site, and a Ga self-interstitial, respectively, with charge states indicated by the corresponding superscripts. In addition to a contribution of $\text{I}_{\text{Ga}}^{2+}$, a contribution of $\text{I}_{\text{Ga}}^{3+}$ was proposed by Bösker et al. [3].

The research effort aimed at understanding the diffusion behavior of Zn stems, in part, from the discovery of Zn-induced disordering of AlAs/GaAs superlattice structures [4]. A qualitative simulation of Zn-induced interdiffusion of AlAs/GaAs layers on the

basis of reaction (1) has been performed by Zimmermann et al. [5]. These authors concluded that the enhanced Al–Ga interdiffusion is mainly caused by the increase in the equilibrium concentration of $\text{I}_{\text{Ga}}^{2+}$ with increasing Zn doping. However, a more quantitative analysis of Zn-induced AlAs/GaAs layer disordering is difficult because the Al–Ga interdiffusion is concentration-dependent [6]. Moreover, little is known about Zn diffusion in AlAs. These drawbacks are overcome by studying Zn diffusion in ⁶⁹GaAs/⁷¹GaAs multilayer isotope structures.

2. Experimental

An undoped GaAs isotope superlattice with 10 periods of ⁶⁹GaAs/⁷¹GaAs layers was grown by molecular beam epitaxy on a semi-insulating GaAs substrate at 580°C. The thickness of each GaAs isotope layer is about 45 nm. Rectangular samples, 1 × 3–4 mm² in size, were cut and rinsed in organic solvents, etched in diluted HCl and purged with deionized water. The isotope samples were placed on a

E-mail address: bracht@uni-muenster.de (H. Bracht).

polished semi-insulating GaAs carrier wafer and sealed in evacuated quartz ampoules together with about 30 mg of a Ga–Zn alloy. Alloys with 10 and 20 at% Zn were used as diffusion source to alter the Zn partial pressure and hence the concentration of Zn at the sample surface. Diffusion anneals were performed at temperatures between 618°C and 714°C. The temperature was controlled with an accuracy of ± 2 K. The diffusion process was terminated by rapidly cooling the ampoule with water down to room temperature. After annealing the surface of the samples remained specular.

Concentration profiles of Zn, ^{69}Ga , and ^{71}Ga were measured with secondary ion mass spectrometry (SIMS) (CAMECA IMS-3f) using a Cs^+ ion-beam with an energy of about 2 keV. The depths of the craters left from the SIMS analysis were measured with a surface profilometer with an accuracy of about 10%. The secondary ion counts of Zn, ^{69}Ga and ^{71}Ga were converted into concentrations taking into account Zn-implanted GaAs calibration standards and the known compositions of the stable Ga isotopes in natural GaAs. Additionally, the Zn-diffused GaAs carrier wafers were analyzed with electrochemical capacitance voltage (ECV) profiling to determine the maximum Zn-doping level.

3. Experimental results

Fig. 1 shows concentration profiles of Zn and Ga after annealing at 666°C for 180 min utilizing a 10% Ga–Zn

Fig. 1. Concentration depth profiles of ^{69}Ga (\circ), ^{71}Ga (\square) and Zn ($+$) measured with SIMS after diffusion of Zn in a GaAs isotope heterostructure at 666°C for 180 min utilizing a 10 at% Ga–Zn alloy source. The concentration of electrically active Zn (\times) measured by means of ECV profiling is shown for comparison. For clarity only very second data point is plotted. The solid lines represent simulations of Zn and Ga diffusion which were performed on the basis of reactions (2)–(4). The inset shows the whole Zn profile with a penetration depth of about 2.3 μm . The dashed line represents a simulation of Zn diffusion on the basis of reaction (1).

source. Within experimental accuracy the concentrations of total and electrically active Zn are identical. Similar Zn and Ga profiles were obtained after diffusion at 618°C, 666°C and 714°C. All Zn profiles exhibit a kink-and-tail shape (see inset of Fig. 1). Enhanced Ga diffusion is only observed across the near-surface kink of the Zn profile.

4. Discussion

In accord with earlier Zn diffusion studies [2,3], we attempted to describe the simultaneous diffusion of Zn and Ga on the basis of reaction (1). Partial differential equations which consider the diffusion and reaction of the point defects involved and a differential equation for Ga diffusion were solved numerically. Assuming that under the considered Zn-doping conditions I_{Ga}^{2-} mainly controls Ga diffusion, the experimental Ga profiles could be reproduced (not shown in Fig. 1). However, the calculated Zn profile only describes the near-surface kink of the experimental profile. The profile tail at Zn concentrations of about 10^{18} cm^{-3} and below is not reproduced (see dashed line in Fig. 1). All experiments were first analyzed on the basis of reaction (1), although it is obvious that the Zn profiles cannot be completely described. Solid symbols in Fig. 2a and b show the I_{Ga}^{2-} - and Zn-related diffusion coefficients, respectively, obtained from this analysis. Fig. 2a reveals that the I_{Ga}^{2-} contribution to Ga self-diffusion (see solid circles) is in good agreement with results reported by Yu et al. [2] (see lower solid and dashed line). This may indicate that the Zn profiles analyzed by Yu et al. actually also have an extended tail. Unfortunately, this cannot be verified because the profiles analyzed by Yu et al. extend only to concentrations of 10^{18} cm^{-3} .

Fig. 2b illustrates that the Zn diffusion coefficients (see solid square) which were obtained on the basis of reaction (1) systematically deviate from literature data (see solid and dashed line). This deviation shows that Zn diffusion is systematically underestimated in the case when the tail of the experimental Zn profile is ignored.

Kink-and-tail profiles of Zn are known to develop in the very high Zn concentration region ($C_{\text{Zn}} \geq 10^{20} \text{ cm}^{-3}$). These profiles are associated with the formation of voids and interstitial-type dislocation loops [2,8–11]. After Zn diffusion the dopant concentration profile in our isotope samples looks similar to the profile of Zn-diffused natural GaAs samples which contain no voids or dislocation loops [3]. These profiles given by Bösker et al. [3] also reveal a kink-and-tail shape although no extended defects were detected. The authors proposed that Zn diffusion is controlled not only by I_{Ga}^{2-} but also by I_{Ga}^{3+} and they could fit their experimental profiles fairly well. However, a major drawback of their diffusion model is that the high equilibrium concentra-

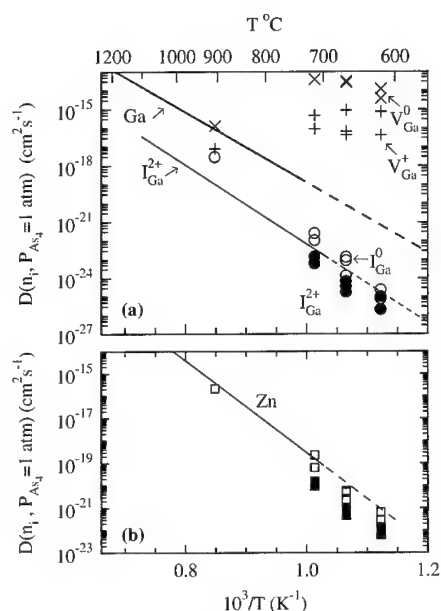

Fig. 2. Temperature dependence of (a) V_{Ga} and I_{Ga} contributions to Ga diffusion and (b) Zn diffusion in GaAs. Data were obtained from modeling the simultaneous diffusion of Zn and Ga in isotope heterostructures and from fitting the Zn profile shown in Fig. 3. All data were reduced to electronically intrinsic conditions and an As_4 pressure of 1 atm. (a): I_{Ga}^{2+} (thin solid line: [2], \bullet : this work), I_{Ga}^0 (\circ : this work), V_{Ga}^0 (\times : this work), and V_{Ga}^+ ($+$: this work) contributions to Ga diffusion in comparison to the direct measured Ga diffusivity (thick solid line: [7]). (b): Zn diffusivity obtained from modeling Zn diffusion on the basis of reaction (1) (\blacksquare) or reactions (2)–(4) (\square). Solid and dashed lines represent the Zn diffusivity under isoconcentration conditions [2].

tion of I_{Ga}^{2+} , which is required to reproduce the tail of the Zn profile, leads to almost complete electrical compensation of the Zn acceptors near the diffusion front [3]. Had the authors considered compensation, the calculated Zn profile would not be as steep at the diffusion front as the profile observed experimentally.

Systematic simulations of Zn diffusion show that kink-and-tail profiles can be described by

V_{Ga}^0 , V_{Ga}^+ , I_{Ga}^0 , and h denote neutral and singly positively charged Ga vacancies, neutral Ga self-interstitials, and holes, respectively. On the basis of this model the kink-and-tail Zn profile as well as the interdiffusion of the $^{69}\text{GaAs}/^{71}\text{GaAs}$ layers are reproduced as demonstrated by the solid lines in Fig. 1. Moreover, this approach solves the compensation

problem associated with the $I_{\text{Ga}}^{2+,3+}$ controlled diffusion mode proposed by Bösker et al. [3,12] for Zn and Cd diffusion in GaAs whose diffusion, as shown in Fig. 3, is also accurately described by reactions (2)–(4). On the basis of this approach the near surface kink is a consequence of a V_{Ga}^0 and V_{Ga}^+ controlled mode of dopant diffusion whereas the tail of the profiles is determined by I_{Ga}^0 . Accordingly, the interdiffusion of the $^{69}\text{GaAs}/^{71}\text{GaAs}$ layers, which is limited to the near-surface kink of the Zn profile (see Fig. 1), should be controlled by V_{Ga}^0 and V_{Ga}^+ .

In order to test the consistency of our Zn diffusion model, the values obtained from fitting our experimental profiles are shown in Figs. 2a and b in comparison to data from Ga self-diffusion and Zn diffusion under isoconcentration conditions, respectively. Based on the generally accepted interpretation that Ga diffusion in intrinsic GaAs is mainly controlled by Ga vacancies [7], the I_{Ga}^0 component of Ga diffusion is lower than Ga self-diffusion. Fitting of the Zn and Cd profiles shown in Fig. 3 yields values for the I_{Ga}^0 component of Ga diffusion which are mutually consistent within a factor of 3. Moreover, Fig. 2b indicates that the Zn diffusivity is in excellent agreement with data of Zn diffusion under isoconcentration conditions. However, the V_{Ga}^0 and V_{Ga}^+ components which were obtained from fitting the simultaneous diffusion of Zn and Ga in the GaAs isotope superlattice exceed Ga self-diffusion (see Fig. 2a). On the other hand, data for these components used to model the Zn and Cd profiles for As-rich conditions shown in Fig. 3 are in acceptable agreement with Ga self-diffusion whereas the Cd profile for Ga-rich condition yields a V_{Ga}^0 component which is two orders of magnitude higher than the value for As-rich conditions. This shows that the V_{Ga} component of Ga diffusion deduced from Zn diffusion under Ga-rich conditions and reduced to standard conditions (electronically intrinsic conditions and an As_4 pressure of 1 atm) exceeds the data for the directly measured Ga

Fig. 3. Concentration depth profiles of Zn after annealing at 906°C for 29 h under an As_4 pressure of 0.5 atm [3] and of Cd after annealing at 907°C for 7 d under Ga-rich (\times) and As-rich ($+$) ambients [12]. Solid lines represent best fits on the basis of reactions (2)–(4).

self-diffusion. This finding is taken as an evidence that reactions (2)–(4) very likely not represent the actual mechanisms which control the interference between Zn and Ga diffusion and the diffusion of Zn and Cd in GaAs although these reactions provide a remarkable good fit to the experimental profiles. It is noteworthy that our approach also describes the diffusion profiles of Zn in GaSb [13] and GaP [14] more accurately than reaction (1). However, Zn diffusion in GaSb is accurately described by reaction (4) only yielding data for the I_{Ga}^0 component of Ga diffusion which are consistent with the directly measured Ga diffusion coefficients [13]. On the other hand, modeling of Zn diffusion in GaP on the basis of reactions (2) to (4) yields V_{Ga}^0 and V_{Ga}^+ components which also exceed data for Ga diffusion in GaP [14].

5. Conclusions

Accurate modeling of the interference between Zn and Ga diffusion in GaAs isotope heterostructures and of recent Zn and Cd diffusion profiles given in the literature suggests that V_{Ga}^0 , V_{Ga}^- and I_{Ga}^0 rather than I_{Ga}^{2+} and I_{Ga}^{3+} control Zn and Cd diffusion. On the basis of this model, the Zn-induced interdiffusion of $^{69}\text{GaAs}/^{71}\text{GaAs}$ layers seems to be controlled by V_{Ga}^0 and V_{Ga}^- . However, the V_{Ga}^0 and V_{Ga}^- contributions to Ga diffusion exceed the data for Ga self-diffusion even after a reduction to standard conditions whereas corresponding data for I_{Ga}^0 are consistent with Ga self-diffusion. The physical reason for this deviation, which appears to be limited to Ga-rich and heavy p-type doping conditions, is not yet known but indicates that the proposed diffusion model needs to be improved. An improved model can be based on reactions similar to those considered in this paper but may involve e.g. $V_{\text{Ga}}V_{\text{As}}$ or ZnV defect pairs or even more complex defects. Although a consistent interpretation of Zn diffusion in GaAs is not yet evident, our results on the interference of Zn and Ga diffusion put the earlier interpretation of Zn and Cd diffusion in GaAs into question and will stimulate further investigations.

Vibrational modes of a hydrogen-impurity centre in LEC-GaAs

W. Ulrici^{a,*}, M. Jurisch^b^a Paul-Drude-Institut für Festkörperelektronik, Hausvogteiplatz 5-7, D-10117 Berlin, Germany^b Freiburger Compound Materials GmbH, Am Junger Löwe Schacht 5, D-09599 Freiberg, Germany

Abstract

Two sharp vibrational absorption lines at 3079.2 and 983.3 cm⁻¹ are investigated, occurring in semi-insulating LEC-grown GaAs with their intensities strictly correlated. After doping with deuterium, two additional correlated lines appear at 2288.3 and 729.1 cm⁻¹. These lines are due to the stretching and wagging mode of a single hydrogen (or deuterium) atom bonded to a light impurity atom, most probably oxygen. Illumination with sub-band gap light at $T < 100$ K results in a decrease of the intensity of the four lines and the simultaneous appearance of four new ones. This effect is explained as due to the recharging of the hydrogen centre by capturing photogenerated holes. The centre forms an electronic level in the gap between E_v and about $E_v + 0.5$ eV. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Hydrogen is a residual impurity in the III–V materials grown by the liquid encapsulation Czochralski (LEC) technique. The LEC-GaAs crystals with diameters up to 6 in are grown for semi-insulating substrates used in the production of microelectronic devices. The synthesis and growth of the GaAs also imply the unavoidable presence of further light-element impurities such as carbon, boron, nitrogen, and oxygen in the grown material. The origin of hydrogen in the material is the water-containing boric oxide (B₂O₃) encapsulant.

By the FT-IR spectroscopy, several vibrational absorption lines have been detected on LEC-GaAs in the frequency region above 3000 cm⁻¹ [1,2]. The high frequencies indicate that the stretching modes of bonded hydrogen must be responsible for these lines. One of these lines at 3300.0 cm⁻¹ ($T = 7$ K) could be identified as due to an (O–H) centre by the detection of the ¹⁸O-isotope satellite. This O–H bond can orient along two

nonequivalent crystallographic directions as derived from uniaxial-stress experiments [1]. Another two lines at 3235.2 and 3108.0 cm⁻¹ have been tentatively assigned to two centres with hydrogen bonded to interstitial oxygen (O_i) because of the nearly identical properties with two lines found in GaP [3] and the same structure of the O_i centres in GaAs and GaP [4,5].

The most important experiment to clarify the nature of a hydrogen-containing centre is the additional doping with deuterium. The appearance of the isotope-shifted deuterium line proves the hydrogen identity, and the number of the additional lines gives information about the number of hydrogen atoms involved in the centre. In this paper, we investigate the vibrational absorption line at 3079.2 cm⁻¹ (line 4 in Ref. [1]) and the associated wagging mode, their deuterium analogues, and the photoinduced recharging of the responsible hydrogen centre.

2. Experimental details

The undoped semi-insulating GaAs samples were grown by the LEC-technique from p-BN crucibles under

E-mail address: ulrici@pdi-berlin.de (W. Ulrici).

N₂ or argon inert gas. Additionally, undoped polycrystalline GaAs was investigated, which has been synthesized in a separate high-pressure equipment using p-BN crucibles under 70 bar N₂ or Ar inert gas. In order to introduce deuterium into the ingots, the boric oxide encapsulant was wetted with heavy water in both kinds of preparation. In this study, mainly those samples were investigated containing the isolated interstitial oxygen (O_i) [4] and the off-centre substitutional oxygen (oc-O_{As}) [6] impurities with an amount of about 10¹⁵–10¹⁶ cm⁻³. The infrared absorption experiments have been performed with a Bruker IFS 120 HR Fourier-transform spectrometer operating with resolutions of 0.02–0.1 cm⁻¹. The samples were held at $T = 7$ or 80 K in an Oxford Instruments cryostat Optistat^{CF}.

3. Vibrational modes

In Fig. 1a, the very narrow vibrational absorption line at 3079.2 cm⁻¹ is shown together with a vibrational line at 983.3 cm⁻¹, which has also been reported earlier in Refs. [1,7]. Fig. 2 demonstrates that the integrated intensities A of both lines are strictly correlated, indicating that both lines are caused by the same centre. The intensity ratio $A^{983}/A^{3079} \approx 2$ and their frequency ratio of about 0.3 suggest that these two lines are the

Fig. 1. The infrared absorption spectra measured at $T = 7$ K on the GaAs:H (a) and the GaAs:H:D (b).

Fig. 2. The correlation between the integrated intensities A of the 3079 and 983 cm⁻¹ H-lines (circles) and the 2288 and 729 cm⁻¹ D-lines (squares). The points represent different samples.

stretching mode (3079 cm⁻¹) and the twofold degenerate wagging mode (983 cm⁻¹) of a bonded hydrogen atom located in an antibonding position. To check this assumption, GaAs samples containing both hydrogen and deuterium were investigated. In addition to the mentioned lines at 3079 and 983 cm⁻¹, two new lines are measured on the GaAs:H:D samples at 2288.3 and 729.1 cm⁻¹ (see Fig. 1b). These lines are assigned to the corresponding stretching and wagging mode of D replacing H in the centre as can be derived from their frequency ratio $r = \omega(\text{H})/\omega(\text{D}) \approx 1.347$ (see Table 1) and from the correlation of the integrated intensities $A^{729}/A^{2288} \approx 4$ (see Fig. 2). The result that in the GaAs:H:D samples only two D-modes are measured besides the two H-modes proves that the centre responsible for these lines contains only a single hydrogen atom. The rather low r -values indicate that the H(D) atom cannot be bonded to lattice atoms (Ga or As), but must be bonded to a light impurity atom Z with a mass $M_Z < 20$ amu. The centre is provisionally labelled (Z–H). The lines at 3079, 2288, and 983 cm⁻¹ could be measured up to $T = 300$ K proving their vibrational nature. Whereas the H- and D- stretching modes shift only very weakly ($d\omega/dT \approx 1 \times 10^{-3}$ K⁻¹ cm⁻¹), the frequency of the H-wagging mode exhibits a

Table 1

(Z–D)*	723.6	1	1.344

considerable shift to lower energies ($d\omega/dT = -1 \times 10^{-2} \text{ K}^{-1} \text{ cm}^{-1}$).

Illumination of the samples with light at low temperatures (<100 K) results in a decrease of the intensity of the four absorption lines. Simultaneous to this decrease, a set of four new lines appears at slightly shifted frequencies summarized in Table 1. This effect has already been reported for the H-lines in Refs. [1,8]. The r -values for the lines appearing under illumination are the same as those in the dark confirming that the new lines are due to a photoinduced state called (Z–H)*. It has to be clarified whether (Z–H)* is a different charge state or a metastable excited state of (Z–H). The decrease of the integrated intensity of the (Z–H) and (Z–D) lines under illumination (A_{ill}) was measured as a function of the photon energy $h\nu_{\text{exc}}$. This decrease, normalized to the line intensity A_{dark} measured in the dark, is shown in Fig. 3 investigated on two types of samples with different positions of the Fermi level E_F . It should be noted that each data point in Fig. 3 is measured after long-time illumination ($\approx 10^4$ s, cf. Ref. [8]). As can be seen, the onsets as well as the spectral shapes of the decrease are different for the two kinds of samples. However, the intensity of the (Z–H) and (Z–D) lines decreases nearly by the same amount at each distinct $h\nu_{\text{exc}}$ value confirming once again the correlation between the stretching and wagging modes.

In the course of the present study, we also observed the line at 3000.0 cm^{-1} on the GaAs:H:D samples, which has been identified by Pajot and Song [1] as due to an (O–H) centre. To make a distinction between the different hydrogen centres, this centre will be called here (O–H)^A. Together with this line, one corresponding line due to the deuterium containing centre (O–D)^A was found at 2455.0 cm^{-1} . For the new line appearing under illumination (photon energy 1.2 eV) at 3296.4 cm^{-1} [1], its deuterium counterpart was detected at 2451.6 cm^{-1} (all frequencies measured at $T = 7$ K).

Fig. 3. The normalized integrated intensity $A_{\text{ill}}/A_{\text{dark}}$ of the absorption lines of Fig. 1 under illumination with different photon energies $h\nu_{\text{exc}}$ measured at $T = 80$ K on two samples with different Fermi-level positions E_F .

These results prove that the (O–H)^A centre contains only one hydrogen atom.

4. Discussion

From the experimental results, especially those of the GaAs:H:D, it is clearly evident that the investigated vibrational lines of the (Z–H) centre are due to the stretching and wagging mode of one hydrogen atom bonded to a light impurity atom Z. The rather high frequency of the wagging mode (about one-third of that of the stretching mode) indicates that the H atom should be located in an antibonding position. Among the four possible candidates for Z in LEC-GaAs (C, B, N, and O), carbon and boron can be definitely ruled out by spectroscopic arguments. The (Z–H) centre was detectable only in the samples containing sufficient isolated oxygen centres (oc-O_{As} and O_i). This suggests the assumption that Z is oxygen. However, as in all investigated samples the N–H centre [9] was also found; N cannot be completely excluded as the partner in the (Z–H) centre.

The spectral dependence of the photoinduced change (Fig. 3) gives information about the nature of this change. The sample with its Fermi level at the EL2^{0/+} mid-gap level ($E_v + 0.78 \text{ eV}$) shows the onset of the photoinduced decrease at about 0.8 eV, and its spectral

shape is roughly that of the photoionization cross-section σ_{p1} of the transition $EL2^- + h\nu \rightarrow EL2^0 + \text{hole}_{vb}$ [10]. However, the sample with E_F at the $EL2^{+2+}$ level ($E_v + 0.54$ eV) shows the onset of the photoinduced decrease at about 0.5 eV, and the spectral dependence corresponds to that of the photoionization cross-section σ_{p2} of the transition $EL2^{2-} + h\nu \rightarrow EL2^- + \text{hole}_{vb}$ [11]. Obviously, in both kinds of samples, the holes in the valence band created by these transitions will be captured by the (Z–H) centre forming the state (Z–H)*, which is, therefore, a recharged state (Z–H)⁺. These results suggest that the (Z–H) centre forms an electronic level (Z–H)/(Z–H)⁺ in the region between E_v and $E_v + 0.5$ eV within the gap of the GaAs. This conclusion is supported by the measurements on a p-type GaAs:H sample exhibiting both lines at 3079 cm^{-1} (Z–H) and 3099 cm^{-1} (Z–H)⁺ without illumination. Finally, the maximum concentration of the (Z–H) centre detected in the LEC-GaAs is in the region between 10^{13} and 10^{14} cm^{-3} , if the calibration factor for the C–H stretching mode [12] is used.

Nitrogen solubility and N-induced defect complexes in epitaxial GaAs:N

S.B. Zhang*, Su-Huai Wei

National Renewable Energy Laboratory, 1617 Cole Blvd., Golden, CO 80401, USA

Abstract

Previous calculations suggested low-equilibrium N solubility in bulk GaAs. In epitaxial growth, however, N solubility can be significantly enhanced to as much as a few %. First-principles total-energy calculations show that this large difference is due to the lack of low-energy nucleation sites of GaN during epitaxy. As a result, the atomic chemical potential of N can be significantly larger. This gives rise to new defect physics distinctly different from those in GaAs. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Impurity solubility; Doping; Impurity-defect complexes

Substitution by first-row elements in semiconductors is an interesting problem. For example, with a few percent of N, the bandgap of $\text{GaAs}_{1-x}\text{N}_x$ dilute alloy can be significantly smaller than GaAs [1]. As such, $\text{GaAs}_{1-x}\text{N}_x$ is a potential candidate for infrared lasers and as an absorber for high-efficiency tandem solar cells. It is also a natural buffer layer for the epitaxial growth of cubic-phase GaN on GaAs, thus integrating two important optoelectronic materials. However, the doping mechanism of GaAs:N is largely unknown. The thermodynamic solubility of N in bulk GaAs is exceedingly low ($[\text{N}] < 10^{14} \text{ cm}^{-3}$ at $T = 650^\circ\text{C}$) [1–3] due to the formation of a fully relaxed, secondary GaN phase; yet, single-phase epitaxial films grown at $T = 400\text{--}650^\circ\text{C}$ with $[\text{N}]$ as high as $\sim 10\%$ have been reported [4–9]. To explain this giant eight orders of magnitude difference in GaAs:N, surface-reconstruction-induced subsurface strain has been implicated [3]. However, the calculated $[\text{N}]$ by this model is four orders of magnitude too small. Another puzzle about GaAs:N with high $[\text{N}]$ is the considerable degradation of the minority carrier lifetimes [10,11], not seen in ordinary binaries.

Recently, we suggested [12] by first principles calculations that the formation of the secondary GaN phase could be suppressed during epitaxial growth. This is because having well-defined growth surface often eliminates many defective, therefore chemically active, sites for secondary phase nucleation. Indeed, a key factor in fabricating high $[\text{N}]$ homogeneous GaAs:N films is to eliminate the formation of GaN precipitates, as well as the amorphous phase of GaN on the epitaxial surface [11]. As such, there exists a new region of the atomic chemical potentials ($\mu_{\text{Ga}}, \mu_{\text{As}}, \mu_{\text{N}}$), available for epitaxial growth but not for equilibrium bulk growth. The chemical potentials are the energies of individual atoms in the reservoirs (such as in the gas sources) that affect impurity substitutional energy [13]. As a result, the calculated maximum solubility $[\text{N}]$ at $T = 650^\circ\text{C}$ is about 4%, instead of $< 10^{14} \text{ cm}^{-3}$ for equilibrium growth. Because defect formation energies are also functions of the chemical potentials, defect physics at high N concentration is qualitatively different from defect physics at low $[\text{N}]$. For example, the dominant charge-neutral defect is no longer the As antisite in GaAs but the N–N split interstitial in GaAs:N. While the As antisite has a doubly occupied (and relatively benign) mid-gap state, the N–N split interstitial has a singly occupied mid-gap state. Thus, depending on the capture

E-mail address: szhang@nrel.gov (S.B. Zhang).

cross sections the split interstitial could be a deep trap for both electrons and holes. This suggests a microscopic mechanism for the so-far mysterious degradation of the minority carrier lifetimes in epitaxial GaAs:N.

Equilibrium N solubility: Physically, the solubility limit is reached when N starts to precipitate into GaN. The formation energy of a charge-neutral defect is defined [13] as

$$\Delta H_f = E_{\text{tot}}(\text{Defect}) - E_{\text{tot}}(\text{Host}) + n_{\text{Ga}}\mu_{\text{Ga}} + n_{\text{As}}\mu_{\text{As}} + n_{\text{N}}\mu_{\text{N}}, \quad (1)$$

where $E_{\text{tot}}(\text{Host})$ is the total energy of a supercell containing 32 GaAs, $E_{\text{tot}}(\text{Defect})$ is the total energy for the same supercell but with a defect, and $n = (n_{\text{Ga}}, n_{\text{As}}, n_{\text{N}})$ is the number of particles being removed (upon the defect formation) from the host to a reservoir of chemical potentials $\mu = (\mu_{\text{Ga}}, \mu_{\text{As}}, \mu_{\text{N}})$. If we set the energies of bulk Ga, bulk As, and N_2 gas as the reference zeros, then the chemical potentials satisfy

$$\mu_{\text{Ga}} \leq 0, \quad \mu_{\text{As}} \leq 0 \quad \text{and} \quad \mu_{\text{N}} \leq 0. \quad (2)$$

This happens because if $\mu > 0$, an elemental solid (or gas) will spontaneously form that hinders any further increase of μ . For GaAs to be thermodynamically stable, it also requires that $\mu_{\text{Ga}} + \mu_{\text{As}} = \mu_{\text{GaAs}} = \Delta H(\text{GaAs}) = -0.62 \text{ eV}$. Thus, defect formation energies in GaAs:N are functions of only two independent variables, $(\mu_{\text{As}}, \mu_{\text{N}})$, satisfying (see Fig. 1)

$$-0.62 \text{ eV} \leq \mu_{\text{As}} \leq 0 \quad \text{and} \quad \mu_{\text{N}} \leq 0. \quad (3)$$

Spontaneous formation of the secondary bulk GaN phase puts a further restriction on the chemical

potentials, namely

$$\mu_{\text{Ga}} + \mu_{\text{N}} \leq \mu_{\text{GaN}}. \quad (4)$$

Because $\mu_{\text{GaN}} = \Delta H(\text{GaN}) = -1.57 \text{ eV}$, the upper limit for μ_{N} is not $\mu_{\text{N}}^{\text{max}} = 0$ in Eq. (3), but $\mu_{\text{N}}^{\text{max}} = \mu_{\text{GaN}} - \mu_{\text{Ga}} = \mu_{\text{GaN}} - (\mu_{\text{GaAs}} - \mu_{\text{As}}) = -1.57 + 0.62 + \mu_{\text{As}} = -0.95 \text{ eV}$ at $\mu_{\text{As}} = 0$. This defines the “original region” in Fig. 1. Nitrogen substitution is a special case of Eq. (1)

$$\Delta E_{\text{sub}} = \Delta E_{\text{tot}} - \mu_{\text{N}} + \mu_{\text{As}}, \quad (5)$$

where $\Delta E_{\text{tot}} = E_{\text{tot}}(\text{N}_{\text{As}}) - E_{\text{tot}}(\text{GaAs})$. The higher the $\mu_{\text{N}}^{\text{max}}$ (and the lower the $\mu_{\text{As}}^{\text{min}}$), the lower the minimum $\Delta E_{\text{sub}}^{\text{min}}$ is. The calculated $\Delta E_{\text{sub}}^{\text{min}}$ is 1.64 eV, which accounts for the low [N] in equilibrium grown GaAs:N.

Surface enhanced solubility: In the epitaxial growth, relaxed GaN phase can form only if both of the following conditions are satisfied: (1) Formation of the GaN phase at the surface is energetically favored (namely, spontaneously). (2) The size (and/or thickness) of the surface GaN cluster exceeds the critical size for dislocation formation. Condition (1) proceeds condition (2) and sets the physical limit on μ_{N} in epitaxial GaAs:N [cf. Eq. (4)]:

$$\mu_{\text{Ga}} + \mu_{\text{N}} \leq \mu_{\text{GaN}}^{\text{Surf}}, \quad (6)$$

where $\mu_{\text{GaN}}^{\text{Surf}} = \Delta H^{\text{Surf}}$ is the heat of formation of the GaN layer on a specific surface. The spontaneous formation of the GaN layer is equivalent to having the single nitrogen substitutional energy $\Delta E_{\text{sub}}^{\text{Surf}}$ [cf. Eq. (5)] equal zero. Thus, to find the N solubility in epitaxial GaAs:N films, we first solve

$$\Delta E_{\text{sub}}^{\text{Surf}}(\mu_{\text{As}}^{\text{min}}, \mu_{\text{N}}^{\text{max}}) = 0 \quad (7)$$

to find $(\mu_{\text{As}}^{\text{min}}, \mu_{\text{N}}^{\text{max}})$ using a $\beta 2(2 \times 4)$ surface reconstruction [14], as detailed in Ref. [12]. Second, we plug $(\mu_{\text{As}}^{\text{min}}, \mu_{\text{N}}^{\text{max}})$ into Eq. (5) to determine $\Delta E_{\text{sub}}^{\text{min}}$, as shown in Fig. 2. The corresponding [N] is calculated to be 4% at $T = 650^\circ$.

Nitrogen-induced defects: At the high N concentration, the defect physics changes from low [N] in two fundamental ways: (1) the dominant defects are no longer the same, (2) the electronic properties of the leading defects are qualitatively different. The calculations were done with a 64-atom supercell and a 25 Ry plane-wave cutoff energy. All the atoms are relaxed. More details can be found in Ref. [13]. Several defects are shown in Fig. 3. (1) The N–N split interstitial. Here, an N_2 molecule replaces an As atom. Each N is threefold co-ordinated. The N–N is important because of the exceptionally strong N–N bond, at the same time the strong Ga–N bonds, and the small size of the N atom. The calculated N–N bondlength is 1.39 Å, compared to 1.10 Å for N_2 molecule. The calculated Ga–N bondlength is 2.01 Å, compared to 1.95 Å for bulk GaN. The calculated N–N–Ga and Ga–N–Ga bondan-

Fig. 1. The physically accessible region of the chemical potentials, $(\mu_{\text{As}}, \mu_{\text{N}})$, is shown.

gles are 114° and 132° , respectively. (2) The N–As split interstitial. Here, the calculated N–As bondlength is

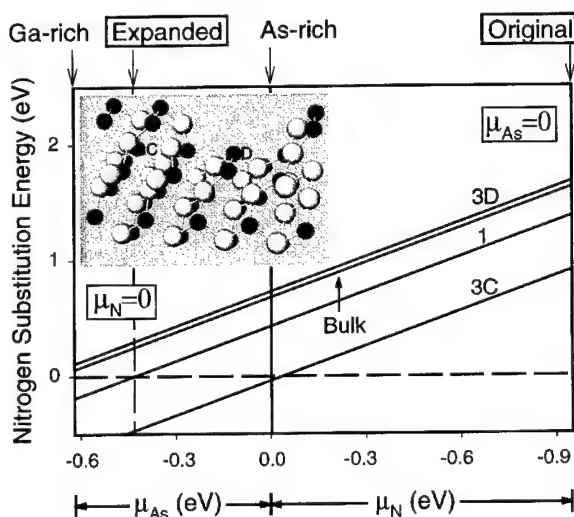

Fig. 2. N substitutional energies ΔE_{sub} as functions of $(\mu_{\text{As}}, \mu_{\text{N}})$. The inset is the GaAs(2×4) surface, indicating the various substitution sites. The anion is denoted by a dark circle while Ga is denoted by a light circle.

1.85 Å, the Ga–As bondlength is 2.37 Å, and the Ga–N bondlength is 1.94 Å, respectively, compared with 1.62 Å for diatomic N–As, 2.44 Å for bulk GaAs and 1.95 Å for bulk GaN. All the calculated bondangles are within the range of 103 – 144° . (3) The $(\text{As}_{\text{Ga}}-\text{N}_{\text{As}})_{\text{nn}}$ pair, where nn stands for nearest neighbor. The N_{As} attracts the As_{Ga} because N_{As} is associated with compressive strain due to the small size of N, while As_{Ga} is associated with tensile strain due to two extra electrons in the non-bonding orbital. The $(\text{As}_{\text{Ga}}-\text{N}_{\text{As}})_{\text{nn}}$ pair has a 0.5-eV binding energy. Thus, at high [N] the formation of $(\text{As}_{\text{Ga}}-\text{N}_{\text{As}})_{\text{nn}}$ may eliminate isolated As_{Ga} . The N–As separation in the nn-pair is 2.86 Å, 47% larger than the sum of atomic radii. Hence, the nn-pair, where both N and As are threefold coordinated, is qualitatively different from any other distant $\text{As}_{\text{Ga}}-\text{N}_{\text{As}}$ pairs. (4) The $(\text{V}_{\text{Ga}}-\text{N}_{\text{As}})_{\text{nn}}$ pair. Despite being the nearest neighbor, the binding energy (< 0.05 eV) is negligible.

Fig. 4(a) shows the charge-neutral defect formation energy ΔH_f as a function of atomic chemical potentials. At the N solubility limit $[(\mu_{\text{As}}^{\text{min}}, \mu_{\text{N}}^{\text{max}}) = (-0.44, 0 \text{ eV})]$, the dominant defect in GaAs:N is the $(\text{N}-\text{N})_{\text{spl}}$ split-interstitial, not the As_{Ga} in GaAs. The calculated $\Delta H_f(\text{N}-\text{N})_{\text{spl}} = 1.52 \text{ eV}$ is considerably smaller than As_{Ga} (2.24 eV), $(\text{As}_{\text{Ga}}-\text{N}_{\text{As}})_{\text{nn}}$ (1.96 eV), and $(\text{N}-\text{As})_{\text{spl}}$

Fig. 3. Atomic structures for (a) N_{As} , (b) N–N, (c) N–As split interstitials, and (d) $(\text{As}_{\text{Ga}}-\text{N}_{\text{As}})_{\text{nn}}$ complex. As is the dark circle, Ga is the light circle, and N is labeled.

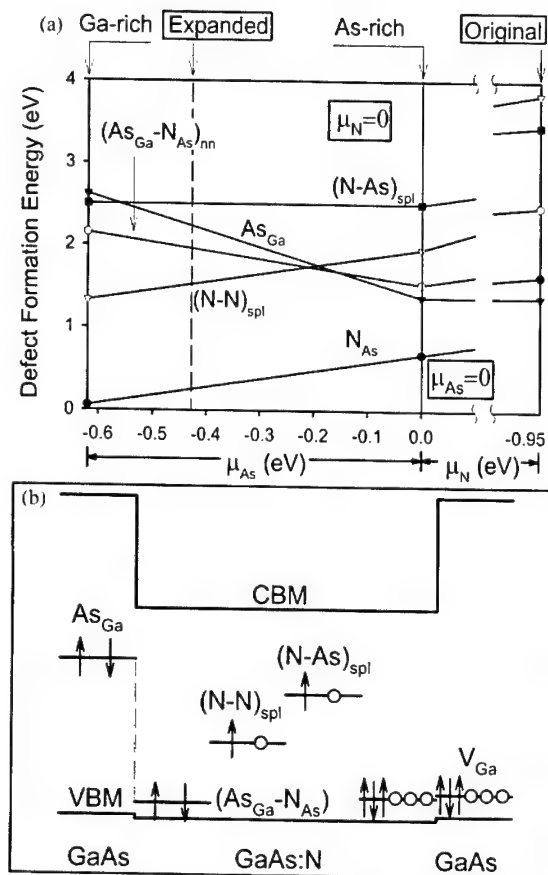

Fig. 4. (a) Defect formation energies. The ordinates and legends are the same as in Fig. 2. (b) Calculated single-particle defect energy levels with electron occupation indicated by arrows.

(2.49 eV). This gives an $(N-N)_{spl}$ concentration at $T=650^\circ\text{C}$ of $[C]=1 \times 10^{14} \text{ cm}^{-3}$. In the relative N-poor conditions $[(\mu_{As}, \mu_N) = (0, -0.95 \text{ eV})]$, the most abundant defects are As_{Ga} (1.38 eV), N_{As} (1.64 eV) and $(As_{Ga}-N_{As})_{nn}$ (2.47 eV), instead.

Fig. 4(b) shows the calculated single-particle gap states, along with the bandgaps of bulk GaAs and GaAs:N at $x=3.125\%$ (i.e., one N in a 64-atom supercell). Inside GaAs, As_{Ga} forms a mid-gap double donor state, whereas V_{Ga} forms several shallow acceptor states. Inside GaAs:N, the As_{Ga} mid-gap state disappears with the formation of the $(As_{Ga}-N_{As})_{nn}$ pairs:

the N_{As} state near the conduction band minimum (CBM) pushes down the As_{Ga} gap state to near the valence band maximum (VBM). On the other hand, the effect of N_{As} on V_{Ga} is negligible. Both $(N-N)_{spl}$ and $(N-As)_{spl}$ have a deep level (0.38 and 0.62 eV above the VBM or 0.66 and 0.42 eV below the CBM, respectively) with single electron occupancy. Assuming reasonable capture cross sections, we anticipate that the split interstitials will be important recombination centers for the minority carrier.

In summary, we showed that one can significantly increase the N chemical potential and subsequently the N solubility in epitaxial GaAs:N. At such high N concentration, the physics of defects changes qualitatively from that of GaAs. Nitrogen split interstitials, which are potentially detrimental to minority carrier lifetimes, could become important. This work is supported by the U.S. DOE under contract No. DE-AC36-99GO10337.

Plasmon-like oscillations of the electrons localized by the DX centers in doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$

Yu.A. Pusep*, A.J. Chiquito, W. Fortunato, J.C. Galzerani

Universidade Federal de São Carlos, 13565-905 São Carlos SP, Brazil

Abstract

Raman scattering of the plasmon-like coupled excitations, which permits to detect both the polarization of free and localized electrons was explored in the heavily doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys. Complementary information about the localized electrons was obtained by the electric measurements: the temperature dependencies of the Hall concentrations and mobilities and the photoexcited DC conductivities. It was shown that the characteristic decrease of the Hall concentration observed with the increase of the concentration of Al in alloys was accompanied by a corresponding decrease of the frequency of the plasma oscillations of free electrons. The observed decreases of both the Hall conductivity and the plasma frequency were caused by the DX centers. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Plasmons; Localization; AlGaAs alloys

Two fundamentally distinct states of the matter will be discussed here. They are an insulator and a conductor which are distinguished at zero temperature by the different behavior of DC conductivity: it vanishes for an insulator and remains finite for a conductor. Another important property which allows to distinguish insulators and conductors is the macroscopic polarization (essential in insulators and negligible in conductors). Both, the DC conductivity and the polarization can be used to determine the metal-to-insulator transition—a phenomenon, which occurs when the localization length of electrons reveals different behavior: it diverges for metals and is a finite quantity for insulators [1].

In this work, we studied the localization properties of electrons in $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys and compared it with those of the GaAs/AlAs superlattices where the metal-to-insulator transition can be achieved. In the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys doped with Si, the strong localization of electrons is provided by the deep DX centers [2],

number of which depends on the contents of alloy. While, the alteration of the widths of the barriers results in a change of the coupling between electrons in adjacent wells thus, presenting a possibility to produce an insulator (thick barriers) and a metal (thin barriers) states of the electron system in superlattices. We demonstrate that the alterations of both the DC conductivity and the polarization which occur when the metal-to-insulator transition takes place, are strongly coupled with the character of the state of the electron system in the samples under investigation.

The photoresistance and the Hall measurements were utilized in order to study the DC conductivity, while the Raman scattering of the plasmon-LO phonon coupled excitations was performed to explore the electric polarization of the electrons.

The current source Keithley-237 was used for the electrical measurements; the tungsten lamp was utilized for the optical excitation during the electrical measurements. The unpolarized back-scattered Raman spectra were performed at $T = 10\text{ K}$ with a “Instruments S.A. T64000” triple grating spectrometer supplied with a CCD detector cooled by nitrogen; the 4764 Å line of an Ar^+ laser was used for excitation. The closed circle cryostats Janis-350CS were used to cool the samples.

The $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys and the GaAs/AlAs superlattices both doped with Si were grown on the (001) oriented GaAs substrates by molecular beam epitaxy.

The Raman spectra of the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys with different contents of Al (x), nominally doped with the concentration of $N_{\text{Si}} = 2 \times 10^{18} \text{ cm}^{-3}$, together with the Hall data are shown in Fig. 1. The LO mode of GaAs originated from the depletion surface layer was detected at 295 cm^{-1} together with two plasmon-LO phonon modes: the low-frequency acoustic mode ω^- and the high-frequency optic one ω^+ . As expected, three coupled modes were found in the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloy with $x = 0.2$: the acoustic ω^- mode, and two optic ω_1^+ (GaAs-like) and ω_2^+ (AlAs-like) modes. In addition, the LO_1 GaAs-like mode of the depletion layer was observed at 286 cm^{-1} . The GaAs-like (TO_1 and LO_1) and the AlAs-like (TO_2 and LO_2) bulk optical phonons, evidencing the absence of the plasmons, were found in the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys with $x = 0.4$. The Hall data shown in Fig. 1(b) reveal the strong decrease of the concentration of the electrons and their mobilities with the increase of the Al contents. The thick arrows in Fig. 1(a) show the frequency positions of the high-frequency coupled modes calculated with the Hall concentrations in the corresponding alloys.

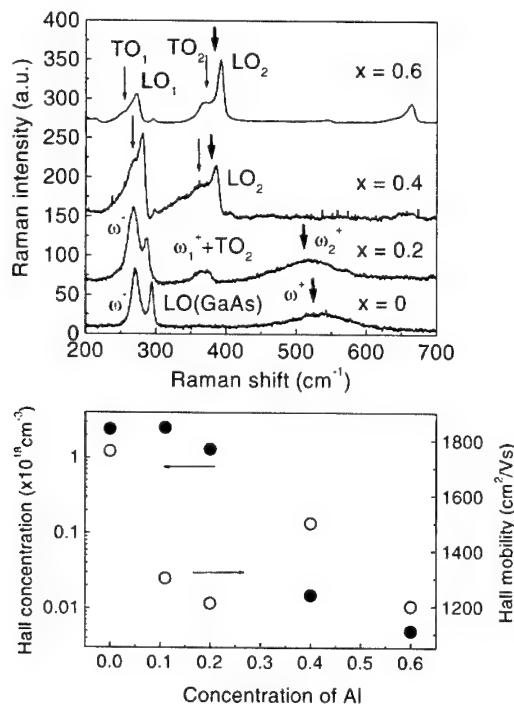

Fig. 1. (a) Raman spectra and (b) the Hall data of the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys with the nominal doping concentration $N_{\text{Si}} = 2 \times 10^{18} \text{ cm}^{-3}$ measured at $T = 10 \text{ K}$. The thick arrows show the calculated frequencies of the coupled plasmon-LO phonon modes.

Fig. 2. Dependencies of the resistance on the temperature measured in the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys with the nominal doping concentration $N_{\text{Si}} = 2 \times 10^{18} \text{ cm}^{-3}$ with the illumination (dashed lines) and in the dark (solid lines).

The results of the photoresistance measurements, clearly showing the presence of the DX centers are plotted in Fig. 2. The low temperature resistance was found smaller in the optically excited samples than in the dark. The difference between the illuminated resistance and the dark one increased with the increase of the concentration of Al. According to Ref. [2], the difference between the illuminated and dark resistances is caused by the optical excitation of the electrons localized by the DX centers. Clearly is seen in Fig. 2, that the concentration of the DX centers increased with the increase of the concentration of Al in the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloy resulting in the increase of a number of the localized electrons. This caused the decrease of the Hall concentration and of the plasma frequency which is observed in Fig. 1.

The localization of electrons resulting in the decrease of the superlattice plasma frequency (the frequency of the plasmons polarized along the superlattice axis) was observed in the doped GaAs/AlAs superlattices with thin enough thicknesses of the barriers. The Raman spectra of some of the superlattices with different thicknesses of the barriers are depicted in Fig. 3. In the superlattices $(\text{GaAs})_{17}(\text{AlAs})_2$, where the numbers denote the thicknesses of the corresponding layers expressed in the monolayers, all the three expected

Fig. 3. Raman spectra of the (a) $(\text{GaAs})_{17}(\text{AlAs})_2$ ($N = 7.0 \times 10^{17} \text{ cm}^{-3}$) and (b) $(\text{GaAs})_5(\text{AlAs})_5$ ($N = 5.0 \times 10^{18} \text{ cm}^{-3}$) doped superlattices measured at $T = 10 \text{ K}$.

plasmon-LO phonon coupled modes were found. Calculations made by the envelope function approximation show that in this superlattice the lowest broad miniband (with the width $W_{\text{SL}} = 65 \text{ meV}$) is formed by the Γ electron states of the wells and the barriers. While, in the $(\text{GaAs})_5(\text{AlAs})_5$, as in the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys with $x = 0.4$, no evidences of the plasmons were found; instead, the GaAs-like and the AlAs-like TO and LO phonons were observed even in heavily doped samples.

According to the calculations, in this superlattice the very narrow lowest miniband ($W_{\text{SL}} = 2 \text{ meV}$) is formed by the X electron states. The width of the miniband is considered as a measure of the coupling between the electrons in the wells of a superlattice; or equivalently, as a measure of the electron localization. Therefore, the broad minibands of the $(\text{GaAs})_{17}(\text{AlAs})_2$ superlattices provided free motion of electrons along the superlattice axis and as a consequence, the superlattice plasmons were observed. While, in the $(\text{GaAs})_5(\text{AlAs})_5$ the narrow minibands resulted in a strong modulation of the electron density along the superlattice axis producing

the localization of electrons in the wells. As a consequence, no superlattice plasmons were observed.

In this work we studied the Raman scattering of the plasmon-like coupled excitations, which permits to detect both the polarization of free and localized electrons in the heavily doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys. Complementary information about the localized electrons was obtained by the electric measurements: the temperature dependencies of the Hall concentrations and mobilities and the photoexcited DC conductivities. It was shown that the characteristic decrease of the Hall concentration observed with the increase of the concentration of Al in alloys was accompanied by a corresponding decrease of the frequency of the plasma oscillations of free electrons. The measurements of the conductivity caused by the photoexcited electrons revealed the presence of the DX centers with the concentration strongly increasing with the increase of the concentration of Al. Thus, it was shown that the observed decreases of both the Hall conductivity and the plasma frequency were caused by the DX centers. The Raman spectra of the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys with different x were compared with those of the GaAs/AlAs superlattices with various strengths of the coupling between the wells. It was shown that the decrease of the coupling between the wells of the superlattices acts similar to the increase of the contents of Al in the alloys both decreasing the plasma frequency of free electrons. In the superlattices, the electrons become more localized in the wells with the decrease of the coupling between them, while in the alloys, the DX centers are responsible for the analogous electron localization. In addition, an evidence of the formation of the coherent clusters was found in the Raman spectra of both the doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$ alloys and the doped GaAs/AlAs superlattices.

Abstract

The effects of external and internal strains and of defect charges on the formation of vacancies, antisites and interstitials in GaAs and $\text{In}_{0.5}\text{Ga}_{0.5}\text{As}$ have been investigated by *first principles* density functional methods. Present results show that strain and doping permit a *defect engineering* of III–V semiconductors. Specifically, they predict that doping may have major effects on the formation of antisites while vacancies may be favored only by extreme conditions of compressive strain. Interstitials may be moderately favored by doping and tensile strain. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Defects; Theoretical methods; III–V semiconductors

1. Introduction

Investigations on the formation of defects in III–V semiconductors have been stimulated by an increasing interest in the *defect engineering* of semiconductors, namely, a controlled introduction of defects aimed to tuning the material properties. As an example, materials for ultrafast optical devices have been obtained by growing GaAs or InGaAs at low temperature (LT) by molecular beam epitaxy (MBE) [1,2]. This growth should favor the formation of As antisites [3] and Ga vacancies. A key quantity describing the behavior of defects is represented by the defect formation energy [4,5]. Defect formation energies depend on the chemical potentials (μ_{Ga} , μ_{As}) and on the electron chemical potential, μ_e , which defines the reservoir of electrons [4,5]. In a supercell approach, the formation energy Ω_D of a defect D in GaAs may be written as in Ref. [4]:

$$\Omega_D = E_D - n_e \mu_e - n_{\text{Ga}} \mu_{\text{Ga}} - n_{\text{As}} \mu_{\text{As}}, \quad (1)$$

E-mail address: aldo.amore@mlib.cnr.it (A. Amore Bonapasta).

where E_D is the energy of a supercell containing n_{Ga} Ga atoms, n_{As} As atoms, and one D defect and n_e is the number of electrons transferred from an electron reservoir with a chemical potential μ_e to the defect D in a given charge state. In equilibrium, several restrictions apply to the chemical potentials [4]: $0 \leq \mu_e \leq E_g$ and $-\Delta H \leq \Delta\mu \leq \Delta H$, where $\Delta\mu$ is the chemical potential difference $(\mu_{\text{Ga}} - \mu_{\text{As}}) - (\mu_{\text{Ga(B)}} - \mu_{\text{As(B)}})$, $\mu_{\text{X(B)}}$ is the chemical potential of the X species in the bulk, E_g is the energy gap and ΔH is the heat of formation of GaAs [4]. $\Delta\mu = -\Delta H$ and $\Delta\mu = \Delta H$ correspond to the As-rich limit and the Ga-rich limit case, respectively, i.e., to different growth conditions which may affect the formation of defects. Different values of μ_e are related, instead, to different doping levels, $\mu_e = 0$ corresponding to a Fermi level at the top of the valence band. In the case of InGaAs, further restrictions apply to the chemical potentials of the cations [5]. In a previous paper [6], the formation of defects favored by As-rich conditions, i.e., gallium vacancies (V_{Ga}) and arsenic antisites (As_{Ga}), has been investigated in GaAs and $\text{In}_{0.5}\text{Ga}_{0.5}\text{As}$. This investigation has been extended here to defects favored by Ga-rich conditions, i.e., arsenic vacancies (V_{As}) and

gallium antisites (Ga_{As}) and to the interstitials Ga_i , In_i , As_i , in the same materials.

2. Methods

The defect energy E_D and the total energies related to the $\mu_{X(B)}$ potentials have been calculated in the local density approximation [7] by using supercells, separable ab-initio pseudopotentials [8], plane-wave basis sets, the special-points technique for k -space integration [9], and the exchange-correlation functional of Ceperley–Alder [10]. The geometry of a given supercell has been fully relaxed by minimizing the forces on the atoms. Convergence tests have been carried out by using plane-wave cutoffs ranging from 12 to 20 Ry, supercells of 32 and 64 atoms, and k -point meshes equivalent to a (4, 4, 4) or (8, 8, 8) Monkhorst-Pack mesh in the zinc-blend unit cell. The results presented here have been achieved by using 64-atom supercells, the (4, 4, 4) k -point Monkhorst-Pack mesh in the zinc-blend unit cell, and cutoffs of 18 Ry.

3. Results and discussion

Generally, a ternary alloy may be assumed to be given by a binary compound where a fraction of the cations have been substituted with cations of a different species. In the case of GaAs and $\text{In}_{0.5}\text{Ga}_{0.5}\text{As}$, this substitution induces two competing effects: (i) increase of the lattice constant (a_0); (ii) emergence of an *internal strain*. These effects have been investigated separately by introducing two model materials, “strained” GaAs, with a_0 extended to that of $\text{In}_{0.5}\text{Ga}_{0.5}\text{As}$ (GaAs-ext), and “strained” $\text{In}_{0.5}\text{Ga}_{0.5}\text{As}$, with a_0 contracted to that of bulk GaAs ($\text{In}_{0.5}\text{Ga}_{0.5}\text{As-ctd}$). These model materials provide also a first, qualitative estimate of the effects of an external

strain on the formation of vacancies and antisites, although they do not fully reproduce the structure of strained, pseudomorphic heterostructures grown by MBE. The previous investigation of the As_{Ga}^0 , $\text{As}_{\text{Ga}}^{+2}$, V_{Ga}^0 and $\text{V}_{\text{Ga}}^{-3}$ defects in the above four materials [6] has suggested that *doping* and *strain* may have major effects on the defect formation when the *defect electronic states are closely related to bonding (or antibonding) interactions* between the atoms around the defect site, which implies that the *local charge* on the defect is closely related to its *local geometry*. This picture is supported by the formation energies calculated here for the Ga_{As} , V_{As} and interstitial defects, see Table 1. Both the Ga_{As} and V_{As} defects induce one electronic level in the energy gap. The V_{As} defect has also two electrons occupying a level close to the top of the valence band. Ga_{As} is a double acceptor, while V_{As} may have an amphoteric behavior. The occupancy levels estimated for these defects indicate that the Ga_{As}^0 and $\text{V}_{\text{As}}^{+1}$ are stable charge states when $\mu_e = 0$. When the Fermi level is at midgap ($\mu_e = E_g/2$), the stable states are, instead, $\text{Ga}_{\text{As}}^{-2}$ and V_{As}^0 . When the Fermi level is at the bottom of the conduction band ($\mu_e = E_g$), the $\text{V}_{\text{As}}^{-1}$ state of the defect has formation energies close to (or smaller than) those of the neutral defect, see Table 1. In the case of Ga_{As}^0 , the length of the $\text{Ga}_{\text{As}}\text{--Ga}$ and $\text{Ga}_{\text{As}}\text{--In}$ bonds formed by the defect with its nearest neighbor (NN) atoms is reported in Table 2. In GaAs, the atomic arrangement around the defect has a C_{3v} symmetry induced by the formation of *three* stable $\text{Ga}_{\text{As}}\text{--Ga}$ bonds and by a non-bonding interaction of the Ga_{As} with the fourth NN Ga atom. In GaAs-ext, the increased a_0 leads only to an increase of the distance between the not bonded Ga atom and the Ga_{As} , which reduces Ω_D . In $\text{In}_{0.5}\text{Ga}_{0.5}\text{As}$, the internal strain breaks the C_{3v} symmetry. Furthermore, only two stable bonds are formed having lengths of 2.30 and 2.48 Å, see Table 2. This change of the local geometry of the defect agrees with the increase of Ω_D . Finally, in $\text{In}_{0.5}\text{Ga}_{0.5}\text{As-ctd}$,

^a X–X distances (X = Ga or In) between a Ga antisite and its nearest neighbors (NN) are reported in the upper part of the table together with the X–X distances between the NN of an arsenic vacancy. Ga–In and In–In distances are given in italic and bold characters, respectively. Y–Y distances (Y = Ga or As) between an interstitial atom and its NN are reported in the lower part of the table. Ga–In, Ga–As and In–As distances are given in italic, bold and bold-italic characters, respectively. *n* distances with an equal value *d* are represented by *n* × *d*. The distances should be compared with those given by covalent radii of Ga, In and As (1.26, 1.44 and 1.2 Å, respectively). All values are given in Å.

the contraction of a_0 favors a bonding interaction of Ga_{As} with its NN atoms, thus leading to a reduction of the formation energy. In the case of Ga_{As}⁺² defect, in GaAs this defect forms four stable Ga_{As}–Ga bonds, thus indicating that the defect electronic states are closely related to bonding interactions between the Ga_{As} and its NN atoms. As a consequence, the Ga_{As}⁺² formation energy results to be significantly affected by the position of the Fermi level, as shown by the large reduction of its value in the case of $\mu_c = E_g$ (i.e., n-type doping). Furthermore, strain has appreciable effects on the Ga_{As}⁺² formation energy like for the neutral defect. Similar results were found for the As_{Ga}⁺², which are favored by p-type doping. In the case of V_{As}⁰, generally the vacancy dangling bonds are not involved in an internal reconstruction. However, the three electrons of the vacancy may give rise to some bonding interaction in the presence of a compressive strain. This defect is characterized therefore by a small coupling between local charge and local geometry. In fact, an analysis of the results reported in Table 1 and 2 for the different charge states of V_{As} shows that the doping and strain have smaller effects on the formation energies of arsenic vacancies. Similar results were found in the case of gallium vacancies. In the case of interstitials, it as to be taken into account that the Ga_i⁺¹ occupies a tetrahedral site, while the Ga_i⁻¹, As_i⁻¹ and Ga_i⁻¹ are characterized by an (110)-split, (110)-split and (100)-split geometries [11], respectively. The results given in the Tables show a common behavior of these defects. They are favored by an increase of the lattice constant and hindered by an internal strain because they need to relax their local geometry. As a related effect, changes of the local charge (as induced by different doping) have limited effects on the reduction of the formation energies.

4. Conclusions

Previous and present results on the formation of antisites and vacancies show that these defects have quite different behaviors when vacancies do not give rise to internal reconstruction. In that case, indeed, antisites are characterized by stronger relationships between defect levels and bonding interactions involving the defect. This implies that antisites are more sensitive to lattice and local-charge rearrangements than vacancies. As a consequence, an efficient defect engineering seems possible for antisites, difficult for vacancies. In fact, in the case of Ga (As) antisites, a n-type (p-type) doping and a compressive (tensile) strain permit to reach very small formation energy values. On the other hand, both gallium and arsenic vacancies reach small formation energies only in extreme conditions of compressive strain. Interstitials present an intermediate behavior with respect to that of antisites and vacancies.

Abstract

Photoluminescence and photoreflectance spectroscopy are used to investigate the electronic properties of $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y/\text{GaAs}$ heterostructures treated with low-energy atomic hydrogen. With increasing hydrogen doses, the $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$ optical gap blue-shifts until it reaches the value of a corresponding N-free reference sample. This effect is ascribed to the formation of N–H bonds, which leads to an electronic passivation of N and, hence, to a reopening of the material band gap. Thermal annealing of the samples restores the band gap the $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$ had before hydrogenation and gives an activation energy for the dissociation of N–H complexes equal to 2.28 eV. © 2001 Elsevier Science B.V. 1. Introduction

Nitrogen introduction in $\text{In}_x\text{Ga}_{1-x}\text{As}$ -based materials leads to striking effects on the band structure of the host material, the most relevant being a large band gap reduction for increasing N concentration [1]. A model based on quantum repulsion between the states of the conduction band minimum of the host material and a N-related level resonant with the former states has been firstly proposed in order to explain the dependence of the $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$ band gap on nitrogen content [2]. On the other hand, pseudopotential supercell calculations show that the N-mediated coupling between the host crystal band edge states (Γ , L , and X) also accounts for the band gap decrease of $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$ with y [3]. Regardless of the exact mechanism leading to the

strong modification of the $\text{In}_x\text{Ga}_{1-x}\text{As}$ conduction band subsequent to N incorporation, the observed effects originate from the large mismatch in size and electro-negativity between N and its lattice neighbors.

In this work, we exploit the high diffusivity and strong chemical activity of atomic hydrogen in order to perturb the nitrogen bond with the cation sublattice atoms. By means of photoluminescence (PL) and photoreflectance (PR) measurements, we show that the insertion of H in $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y/\text{GaAs}$ single quantum wells (QWs) increases the band gap to the value the material had before N incorporation, i.e., the value of a reference QW without nitrogen. Thermal annealing at 550°C restores, instead, the optical properties the $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y/\text{GaAs}$ QW had before hydrogenation. We discuss these results in terms of the formation (dissociation) of N–H bonds which decreases (increases) the effective N content and consequently increases (decreases) the band gap energy of the well.

A number of $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y/\text{GaAs}$ single QWs grown by solid source molecular beam epitaxy have been investigated. N_2 cracking was achieved by using a radio frequency plasma source. Indium and nitrogen concentrations in the samples are $x = 0.0 - 0.41$ and $y = 0.0 - 0.052$, respectively. The N concentration has been determined by a combined analysis of X-ray diffraction and optical data. For each subset of quantum wells having the same indium content and well width, L , but differing in terms of the nitrogen concentration, a reference sample without nitrogen has been grown. L ranges from 6.0 to 8.0 nm. All samples have a 100 nm thick GaAs capping layer. Post-growth treatment with atomic hydrogen was obtained by ion-beam irradiation from a Kaufman source with the samples kept at 300°C. The ion energy was about 100 eV and the current density was few tens of $\mu\text{A}/\text{cm}^2$. Several hydrogen doses ($d_H = 1, 5, 50, 270$, and 690×10^{16} ions/ cm^2) have been used in this study. One hour thermal annealing was performed at 10^{-6} Torr at temperatures ranging between 220°C and 550°C. PL was excited by the 515 nm line of an Ar^+ laser, dispersed by a single 1 m monochromator and detected by a cooled Ge detector. PR measurements were performed at near normal incidence. The probe source was a 100 W halogen lamp, the excitation source was an He–Ne laser (power 2 mW) chopped at 220 Hz.

Fig. 1 shows the PR spectra at $T = 90$ K of an $\text{In}_{0.32}\text{Ga}_{0.68}\text{As}_{0.973}\text{N}_{0.027}/\text{GaAs}$ QW (gray full dots), of the same sample irradiated with hydrogen at $d_H = 6.9 \times 10^{18}$ ions/ cm^2 (black full dots), and of the N-free reference QW (open dots). The dashed lines are a simulation of the PR data based on the model of Ref. [4]. In PR, two transitions are observed and attributed to heavy (HH)- and light (LH)-hole excitons. Firstly, it can be noted how the presence of a few percent (0.027) of nitrogen results in an HH energy red-shift of about 0.17 eV. A similar energy shift is found for the light-hole exciton (~ 0.19 eV). H treatment leads, instead, to a blue-shift of both HH- and LH-hole excitons, as well as to a change on the low energy side of the HH exciton transition lineshape, which suggests the insurgence of an H-related level in the QW band gap. In the N-free QW (not shown here), H irradiation does not affect the energy of the exciton-related transitions, which gain a factor 10 in intensity because of likely passivation of surface states. Also, PR linewidth broadens upon hydrogenation indicating an increase of microscopic disorder. We point out that heat treatment like that experienced during H irradiation, but in absence of H, has no effect on the sample linewidth and peak energy.

The band gap reopening subsequent to the H treatment described above has been observed in all samples considered ($y = 0.007 - 0.052$). We will focus then on the results obtained in a QW with $x = 0.34$, $y = 0.007$, and $L = 7.0$ nm and its corresponding N-free reference.

Fig. 1. Photoreflectance spectra at $T = 90$ K of an untreated $\text{In}_{0.32}\text{Ga}_{0.68}\text{As}_{0.973}\text{N}_{0.027}/\text{GaAs}$ QW (gray full dots), of the same sample irradiated with hydrogen at $d_H = 6.9 \times 10^{18}$ ions/ cm^2 (black full dots), and of the N-free reference QW (open dots). The dashed lines are a simulation to the data by means of the model of Ref. [4]. HH and LH indicate the heavy- and light-hole exciton transitions, respectively. Vertical arrows indicate the transition energies as determined by the simulation procedure.

Fig. 2 shows the room temperature PL spectra recorded on a N-containing QW (continuous lines) treated with different hydrogen doses (graphs (a)–(c)). Graphs (b')–(d) show the effect of thermal annealing performed on the same QW hydrogenated at $d_H = 5.0 \times 10^{17}$ ions/ cm^2 (graph (b)). For comparison purposes, the PL spectra of the N-free reference QW (dashed lines) treated and untreated with hydrogen are also shown. Let us consider the effects of hydrogen treatment first. In the nitrogen containing QW, the PL peak shifts towards higher energy for increasing hydrogen doses until it saturates at the value it has in the N-free QW, whose peak energy does not change with d_H (see dashed lines in the figure). As observed in the PR spectra of Fig. 1, hydrogen treatment leads also to an increased microscopic disorder, mainly in the N-containing QW, whose PL linewidth is appreciably broader than that of the reference QW even at the lowest d_H .

The effects of hydrogen treatment can be reversed by thermally annealing the sample. The N-containing QW hydrogenated at a dose $d_H = 5.0 \times 10^{17}$ ions/ cm^2 (graph (b)) has been annealed at various temperatures ranging from 220°C to 550°C. Fig. 2 shows the room temperature PL spectra for increasing T_a (graphs (b')–(d)). The PL band of the hydrogenated $y = 0.007$ QW moves

Fig. 2. Graphs (a)–(c): Room temperature peak normalized photoluminescence spectra of hydrogenated $\text{In}_{0.34}\text{Ga}_{0.66}\text{As}_{1-y}\text{N}_y/\text{GaAs}$ QWs with $y = 0.007$ (continuous lines), and $y = 0.0$ (dashed lines) for different hydrogen doses d_H ($H_0 = 5.0 \times 10^{16}$ ions/cm²). Graphs (b')–(d): Room temperature peak normalized photoluminescence spectra of the $\text{In}_{0.34}\text{Ga}_{0.66}\text{As}_{0.993}\text{N}_{0.007}$ QW hydrogenated at $d_H = 10 H_0$ and annealed at different temperatures. T_a . Laser power density $P = 70$ W/cm² for all spectra.

towards lower energy until its lineshape nearly coincides with the PL spectrum of the H-free, not annealed, $y = 0.007$ QW (compare graphs (a) and (d)); instead, the PL band of the reference QW (not shown here) is not affected by the annealing process.

We can account for the band gap opening induced by H in $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$ in the framework of H bonding to point defects in semiconductors [5]. The charge transfer from the group III atoms towards the strong electronegative N atoms favors the formation of H–N bonds in $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y\text{H}$. This is consistent with theoretical predictions of an N antibonding equilibrium position for H^+ in p-type GaN [6].¹ A “molecular orbital” formed by hydrogen and nitrogen leads to a bonding level with electronic properties different from and with an energy level lower than those of the original N level. This neutralizes the N electrical activity with a decrease of the effective number of N atoms and an

¹ Nominally, undoped GaAs grown by molecular beam epitaxy is generally slight p-type due to the residual C in the growth chamber.

Fig. 3. Dependence of the residual percentage of H, R_H , left into an $\text{In}_{0.34}\text{Ga}_{0.66}\text{As}_{0.993}\text{N}_{0.007}$ QW hydrogenated at $d_H = 5.0 \times 10^{17}$ ions/cm² and annealed for one hour at temperature T_a . The dashed line is a simulation to the data by means of Eq. (1), which gives a value of the activation energy for the dissociation of the N–H complexes equal to 2.28 ± 0.26 eV.

increase of the band gap. Thermal annealing breaks the H–N bonds, thus increasing back the effective number of N atoms, accordingly with the results shown in Fig. 2.

In order to determine the bond strength of the H–N complexes we analyzed the shift of the PL peak energy as a function of the annealing temperature, T_a . We assume zero residual hydrogen when the $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$ QW emission energy coincides with the same quantity measured in the H-free sample (i.e., $T_a > 800$ K). Instead, the not-annealed hydrogenated $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$ QW corresponds to residual H equal to one. For a given T_a value, we (i) first estimate the effective N content from the PL peak energy;² (ii) then obtain the residual hydrogen assuming that each H atom interacts with a single N atom [7]. The results of this analysis are shown in Fig. 3. If R_H is the residual percentage of H atoms present in the sample after annealing, we can estimate the activation energy of dissociation for N–H complexes, E_a , by using [8]

$$R_H = \int_0^1 e^{-E_a/k_B T_a} G(E - E_a) dE, \quad (1)$$

where $f(E, T_a) = \exp(-E/k_B T_a)$ and $G(E - E_a)$ is a Gauss function introduced for taking into account a distribution of activation energies around a mean value, E_a . t_a is the annealing time (one hour in this case) and ν is the attempt frequency equal to 93 THz, as derived

² For determining the effective N concentration, we used $E_p(y \neq 0) = E_p(y = 0) - 2.2 y^{0.7}$, where E_p is the PL peak energy in eV. The above formula has been obtained by means of a fit to the experimental E_p 's measured in the untreated $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$ samples.

from the N–H stretch frequency measured in $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$ [9]. The dashed line shown in Fig. 3 is a fit of R_{H} to the data, which yields $E_{\text{a}} = 2.28 \text{ eV}$ and a standard deviation for $G(E - E_{\text{a}})$ equal to 0.26 eV . The E_{a} value found here may be compared with those found typically for H-donor complexes in GaAs ($\sim 2.1 \text{ eV}$) [10] and Si ($\sim 1.4 \text{ eV}$) [8], and H-acceptor complexes in GaN ($\sim 2.2 \text{ eV}$) [11].

To conclude, we have shown that hydrogen strongly perturbs the electronic properties of $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$, restoring the band gap energy to the value it has in the N-free crystal. We account for this effect by the formation of H–N bonds, which effectively diminish the N content of the samples. Therefore, present results indicate that the N-associated wavefunction in $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y$ maintains a strongly impurity-like character up to $y = 0.052$. Therefore, the so-called “alloy” limit may have not been fully reached even for such high N contents.

Abstract

Zn diffusion experiments in GaSb at temperatures between 500°C and 650°C were performed using Ga–Zn alloy sources. For surface Zn concentrations exceeding 10^{20} cm^{-3} , extended defects were detected using cross-sectional transmission electron microscopy (TEM). These defect networks correlate directly with the observed kink and tail profile shape. For lower Zn doping levels the kink disappears. The profiles of these samples reflect the diffusion behavior of Zn in virtually defect-free GaSb and are accurately described by a Ga interstitial controlled mode of Zn diffusion via the kick-out mechanism. Neutral and singly positively charged Ga interstitials mediate Zn diffusion at Zn doping levels of $1\text{--}2 \times 10^{19}$ and $3\text{--}10 \times 10^{19} \text{ cm}^{-3}$, respectively. The contribution of neutral Ga interstitials to Ga diffusion deduced from fitting experimental Zn profiles is in agreement with the directly measured Ga self-diffusion coefficient in GaSb isotope heterostructures. This provides strong evidence that Ga diffusion in undoped GaSb under Ga-rich conditions is mainly mediated by neutral Ga interstitials. Published by Elsevier Science B.V.

1. Introduction

The understanding of both self- and foreign-atom diffusion in semiconductor systems is of fundamental importance. Diffusion in semiconductors is mediated by native point defects in the crystalline lattice. Diffusion is one of only a few methods that can provide information on point defect properties such as equilibrium concentrations, formation and migration energies, as well as charge states. From the technological point of view, diffusion processes govern the dopant profiles that form the junctions in all microelectronic devices. As devices are engineered with ever shrinking dimensions and higher dopant concentrations, the quantitative understanding and control of diffusion becomes more and more important.

Research in the GaSb system has recently intensified due to applications in high speed electronics as well as infrared lasers, detectors, and photovoltaics. Particular success has been seen in GaSb based heterojunction

bi-polar transistors (HBTs), where switching speeds exceeding 250 GHz have been reported [1]. We have recently shown that Sb diffuses about 1000 times more slowly than Ga in intrinsic GaSb, all the way up to the melting point [2,3]. This atypically low value for Sb self-diffusion makes GaSb a very interesting material from the diffusion and point defect standpoint.

In order to learn more about the influence of the Fermi level position on diffusion in GaSb, we have performed Zn doping experiments. Kyuregyan and Stuchebnikov [4] first showed that Zn diffusion from a constant surface concentration source cannot be described by the complementary error function. Instead, the diffusion coefficient is a function of the local zinc concentration. Since this publication, many groups have published results further exploring these initial findings, but no clear identification of the diffusion mechanism of Zn in GaSb has been made [5–10]. Conibeer et al. propose that Zn diffuses via a substitutional-interstitial mechanism [8], yet they lack sufficient evidence to support either the vacancy (Frank and Turnbull [11]) or kick-out (Gösele and Morehead [12]) mechanism.

This work aims to identify the diffusion mechanism of Zn in GaSb and to apply this knowledge towards a more complete understanding of Ga diffusion in this compound semiconductor than can be achieved by self-diffusion studies alone.

2. Experimental

Cz-grown undoped p-type GaSb wafers (100) from Atomergic Chemetals Corp. with a carrier concentration of $1\text{--}2 \times 10^{16} \text{ cm}^{-3}$ were used for Zn diffusion experiments. Ga–Zn alloys with 2–20 at% Zn were made by annealing Zn (99.9999%) with Ga (99.9999%) at 750°C for 2 days in evacuated ampoules. Prior to the diffusion anneal, rectangular samples of approximately 15 mm^2 GaSb were cleaned first with organic solvents, followed by a 30 s HCl etch and a 10 s HF etch. Samples were sealed in quartz ampoules with base pressures of below 2×10^{-5} Torr along with approximately 5 mg of Ga–Zn alloy as Zn source. The samples were annealed in a resistively heated furnace where the temperature can be controlled to $\pm 2 \text{ K}$. Termination of the annealing process was carried out through quenching the ampoule in water at room temperature.

Cross-sectional transmission electron microscopy (TEM) was performed at the National Center for Electron Microscopy at the Lawrence Berkeley National Laboratory.

Secondary ion mass spectrometry (SIMS) with a Cameca IMS-3f was used to measure elemental profiles. A Cs^+ ion beam with energies of 2–3 keV was used to obtain the diffusion profiles of ^{64}Zn while monitoring ^{69}Ga to assure a constant etch rate in the matrix. In order to achieve good depth resolution, only those samples having a specular surface after annealing were used for the SIMS analysis. Crater depth measurements were done using a surface profilometer with an accuracy of 5%. Secondary ion counts were converted into concentrations using a Cz-grown Zn doped GaSb wafer from University Wafer with a bulk Zn concentration of $1\text{--}2 \times 10^{18} \text{ cm}^{-3}$.

3. Experimental results

SIMS depth concentration profiles of Zn were obtained showing two characteristic shapes. Fig. 1 gives examples of both the kink and tail and box type diffusion profiles. The kink and tail profiles are clearly identifiable by their kink located behind the diffusion front while this characteristic is missing in the box profiles. The kink and tail profiles were observed in all samples showing Zn surface concentrations in excess of 10^{20} cm^{-3} while box profiles were observed in all samples showing surface concentrations below 10^{20} cm^{-3} .

Fig. 1. Two examples each of kink and tail and box shaped Zn diffusion profiles in GaSb as measured by SIMS. Annealing schedules and Zn sources are as follows: 4% Zn/96% Ga source, 30 min at 640°C (\times); 4% Zn/96% Ga source, 114 min at 638°C ($+$); 20% Zn/80% Ga source, 60 min, 550°C (\bullet); 3% Zn/39% Ga/58% Sb source, 917 min at 576°C (\blacktriangle).

Cross-sectional TEM was carried out on representative samples showing box as well as kink and tail profiles to determine the presence of any extended defects which would make the samples unsuitable for these diffusion studies. The box shaped diffusion profiles were all found to be free of extended defects in the area of diffusion, while a loose network of dislocations coincident with the high concentration kink was observed in the kink and tail samples. An example of this can be seen in Fig. 2 where the SIMS profile and TEM are overlaid with matching depth axes for comparison. Two defective regions are clearly visible in the TEM, the first being approximately 450 nm below the surface, and the second near 800 nm. The defect band at 800 nm is formed by $\frac{1}{2}\langle 110 \rangle$ type dislocations.

4. Discussion

The presence of extended defects in the samples with kink and tail profiles made them unsuitable for this diffusion study. The observation that the deeper defect band coincides nearly exactly with the kink suggests that they are directly interrelated. No kink and tail type profiles were used in any of our modeling.

Extensive modeling was carried out on a number of profiles showing the box shape. In all models, it is assumed that Zn diffuses interstitially as a singly positively charged specie, while being present as a

Fig. 2. Composite SIMS profile and TEM micrograph with common depth axis of a sample annealed at 550 °C for 60 min using a 20% Zn/80% Ga source. SIMS clearly shows a kink and tail diffusion profile while the TEM shows two defective regions approximately 450 and 800 nm from the surface.

singly ionized acceptor in the Ga substitutional position. Accurate modeling of the box profiles is achieved within the Ga interstitial controlled mode of Zn diffusion via the kick-out mechanism. For surface concentrations of $1\text{--}2 \times 10^{19} \text{ cm}^{-3}$, very good fits are obtained assuming that neutral Ga interstitials are the mediating defects. Hence the reaction considered for modeling these Zn profiles reads

For surface concentrations exceeding $2 \times 10^{19} \text{ cm}^{-3}$, reaction (1) does not ensure an accurate fit to the Zn distribution at the diffusion front. Examples of these two conditions can be seen in Fig. 3. At the higher surface concentration we believe that the Fermi level drops low enough to ionize the neutral Ga interstitials into a singly positively charged donor state via the following reaction:

The kick-out reaction is thus no longer described only by (1), but by a combination of (1) and the following reaction

The shallower diffusion front observed for these samples is very likely related to a lower effective rate constant for the Zn_i to Zn_{Ga} exchange active at this doping level.

Diffusivity data can be extracted directly from the accurate fittings achieved in the surface concentration range of $1\text{--}2 \times 10^{19} \text{ cm}^{-3}$. Reduced Zn diffusivity data (Zn concentration independent) were used to calculate D_0 and Q for Zn diffusion under intrinsic conditions as $1.4 \times 10^{10} \text{ cm}^2/\text{s}$ and 4.3 eV, respectively. The fitting also yielded data for the Ga interstitial contribution to Ga self-diffusion. The I_{Ga}^0 contribution equals the directly measured Ga self-diffusion under Ga-rich conditions [2]

Fig. 3. SIMS profiles (□, +) and fits (solid lines) based on neutral Ga interstitial controlled mode of the kick-out mechanism. The samples were annealed at 609 °C for 500 min (□) and 561 °C for 921 min (+) using a 2% Zn/98% Ga source.

within a factor of 2. This indicates that Ga self-diffusion is very likely mediated by neutral Ga interstitials. The Zn and Ga diffusion data is summarized in Fig. 4. At this time we cannot completely exclude that singly positively charged Ga interstitials also contribute to Zn diffusion at Zn doping levels of $1\text{--}2 \times 10^{19} \text{ cm}^{-3}$. More extensive modeling of Zn diffusion must be performed to determine the contributions of reactions (1) and (3) to Zn diffusion and thereby the individual contributions of neutral and singly positively charged Ga interstitials to Ga self-diffusion.

Fig. 4. Ga and Zn diffusion data extracted from Zn diffusion profiles. Contribution of neutral Ga interstitial to Ga self-diffusion (●) as extracted from box profile diffusion profiles compared to directly measured Ga self-diffusion data [2] (solid line). Reduced Zn diffusivity (□) and best fit using exponential form (dashed line).

The deviation from Arrhenius behavior observed in the diffusivity data can be explained by the limited accuracy of the Zn surface concentration. All values determined for the effective diffusivity of I_{Ga}^0 and the reduced Zn diffusivity are reduced by the equilibrium concentration of Zn adjusted at the surface. Hence the accuracy of the diffusivity data depends on an accurate determination of the Zn surface concentration.

5. Conclusion

Kink and tail Zn diffusion profiles in GaSb are shown to correlate with the presence of a dislocation network behind the diffusion front for Zn surface concentrations exceeding 10^{20} cm^{-3} . Defect-free samples with box shape diffusion profiles are found for Zn surface concentrations below 10^{20} cm^{-3} . Accurate modeling of the box shaped diffusion profiles is only achieved with the kick-out mechanism for Zn diffusion. Neutral Ga

interstitials are considered to mediate Zn diffusion for Zn surface concentrations of $1\text{--}2 \times 10^{19} \text{ cm}^{-3}$, while singly positive charged Ga interstitials begin to contribute at concentrations above $3 \times 10^{19} \text{ cm}^{-3}$. The deduced contribution of neutral Ga interstitials to Ga self-diffusion equals the directly measured Ga self-diffusion within a factor of 2, indicating that Ga self-diffusion is very likely mediated by the neutral Ga interstitial.

Abstract

InP:C layers grown by metal organic vapour phase epitaxy at 500°C and doped with CCl₄ remain semi-insulating following anneals up to 700°C. The compensation of grown-in C_P acceptors ([C_P] ~ 5 × 10¹⁸ cm⁻³) is attributed to the presence of C–C deep donor defects, revealed by Raman scattering. [C_P] and the concentration of grown-in C_P–H pairs both decrease with increasing temperatures. C_{In}, V_{In}H₄ or P_{In} shallow donors are not detected. Reductions in the internal random electric fields upon annealing lead to narrowing of the C_P localised vibrational mode. Samples annealed at 800°C become lightly n-type (~ 10¹⁶ cm⁻³). © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Semi-insulating layers of carbon-doped InP can be grown on (100) InP substrates by metal organic vapour phase epitaxy (MOVPE) at 500°C, using PH₃ and In(CH₃)₃ precursors and CCl₄ as the dopant source [1,2]. We shall discuss measurements made on such layers with a thickness of 8 × 10⁻⁴ cm and an incorporated carbon concentration, [C] ~ 10¹⁹ cm⁻³, determined by secondary ion mass spectrometry (SIMS). These measurements also reveal hydrogen concentrations [H] ~ 5 × 10¹⁸ cm⁻³ but the concentrations of all other elements are much smaller [2]. The strengths of infrared (IR) active localised vibrational modes (LVMs) originating from the layers confirm the SIMS data since we find [H–C] = 5.4 × 10¹⁸ and [C] = 5.8 × 10¹⁸, assuming the two unknown calibration factors, (*f*), to be similar to those for the corresponding centres in GaAs. The separation of the LVM frequencies of the ¹²C and ¹³C

(1.1% naturally abundant) modes is incompatible with an assignment to C_{In} donors but is consistent with the interpretation of C_P acceptors [2]. Three other modes were assigned to H–¹²C_P pairs by comparing their dispositions and relative strengths with the modes of H–C_{As} pairs in GaAs [3]. This assignment is now confirmed by demonstrating correlations of the line strengths in InP samples following anneals at temperatures up to 800°C, that lead to reductions of [C_P] and the complete loss of [H–C_P] pairs.

There has been an outstanding need to identify the incorporated donors or traps that compensate C_P acceptors in the InP epitaxial layers. LVMs from V_{In}H₄ defects (2316 cm⁻¹) were present in the as-grown substrates [4] but any additional V_{In}H₄ absorption (not detected) from the epitaxial layer was smaller by a factor of at least 10² than that required to effect compensation: our measurements do not reveal LVMs of P_{In} antisite defects or C_{In} centres. However, we now show that Raman scattering measurements reveal high frequency modes, analogous to those of deep donor di-carbon pair defects (C–C), present as dumbbells occupying As lattice sites in highly carbon-doped GaAs and AlAs [5,6]. Anneals lead to increases of [C–C] in InP as [C_P] and [H–C_P] decrease.

Fig. 1. Profiles of the $^{12}\text{C}_\text{P}$ IR LVM, after growth, *a*, and following anneals at increasing temperatures, *b*, *c*, *d*, *e*, at 500°C, 600°C, 700°C and 800°C.

The $^{12}\text{C}_\text{P}$ and $^{13}\text{C}_\text{P}$ LVMs are located in a gap in the density of two-phonon states of InP, so that decay of their excitations must involve the formation of three (or more) InP lattice modes [2]. Their linewidths Δ were expected to be small ($\sim 0.1\text{ cm}^{-1}$) but the observed profiles for $^{12}\text{C}_\text{P}$ show a very sharp central peak with two 'shoulders' (Fig. 1). The splitting of the three-fold degenerate first excited vibrational state of ionised acceptor carbon atoms is caused by internal electric fields that have random strengths and orientations, arising from all other incorporated acceptors and donors [7,8]. There are no mobile electrons to effect screening since the material is semi-insulating. We show that reductions of $[\text{C}_\text{P}]$ in annealed samples leads to reduced LVM linewidths as the strength of the internal fields decreases, probably with decreases of strain.

2. Experimental details

Details of as-grown samples (see [2]) have been outlined in Section 1. These samples were then subjected to rapid transient anneals for 5 min at 500°C, 600°C, 700°C or 800°C in flowing argon, leading to changes in $[\text{C}_\text{P}]$ and $[\text{H-C}_\text{P}]$ (Table 1). The samples were coated with a thin layer of SiO_2 from a plasma source to prevent destruction of the epitaxial InP:C layers during the anneals and the SiO_2 was subsequently removed with HF acid. IR measurements were made with a Bruker IFS 120 HR spectrometer operated at a spectral resolution of 0.02 cm^{-1} and a sample temperature of $\sim 10\text{ K}$. Raman measurements were made from the (100) growth surface of samples cooled to 77 K. The back scattering geometry was used and the scattered light from a Kr^+ ion laser with $h\nu_\text{L} = 3.00$ or 3.05 eV was analysed with a triple spectrometer and a charge coupled detector array for the spectral ranges between

Table 1

Values of $[\text{C}_\text{P}] \times 10^{18}\text{ cm}^{-3}$ and $[\text{H-C}_\text{P}] \times 10^{18}\text{ cm}^{-3}$ using IR calibration factors $f(\text{C}_\text{P}) = 7 \times 10^{15}\text{ cm}^{-1}$ and $f(\text{H-C}_\text{P}) = 2 \times 10^{15}\text{ cm}^{-1}$, respectively [2], and the parameter, γ , following heat treatments of samples [10]

Anneal <i>T</i> (°C)	$[\text{C}_\text{P}]$ 546.9 cm^{-1}	$[\text{H-}^{12}\text{C}_\text{P}]$ 2703 cm^{-1}	γ (cm^{-1})
As-grown	5.8	5.4	0.07
500°C	6.6	4.6	0.08
600°C	5.3	2.6	0.06
700°C	2.5	0.7	0.04
800°C	1.3	0.0	0.04

$60\text{--}2200$ and $3000\text{--}4500\text{ cm}^{-1}$: the partial breakdown of selection rules implies some roughening of the sample surfaces. Hall measurements were made at room temperature using the van der Pauw geometry with indium dot contacts made at a temperature below 350°C.

3. IR and Raman measurements of the modes of isolated carbon atoms and H-C_P pairs

Increases of $[\text{C}_\text{P}]$ and decreases of $[\text{H-C}_\text{P}]$ in samples heated at 500°C (the growth temperature) are attributed to out-diffusion of hydrogen (Table 1). At higher temperatures, there are systematic reductions of both $[\text{C}_\text{P}]$ and $[\text{H-C}_\text{P}]$, implying a loss of carbon acceptors from substitutional sites and further out-diffusion of H-atoms.

Three of the four IR-active modes of the H-C_P centres are detected for samples annealed at temperatures up to 700°C, namely the A_1^- -anti-symmetric stretch mode at 2703.3 cm^{-1} , the A_1^+ -symmetric stretch mode at 413.5 cm^{-1} and the transverse *E*-mode (also identified by Raman scattering) at 521.1 cm^{-1} with dominant carbon vibrational displacements. The second *E*-mode, with dominant H-displacements, is not detected but the corresponding line in GaAs is also very weak [3]. The measurements establish the correlation of the three lines (Fig. 2), supporting the assignment of paired substitutional carbon atoms to phosphorus lattice sites. Weak satellite lines detected at 2756 and 2818 cm^{-1} are tentatively attributed to centres with a hydrogen atom paired to two adjacent substitutional carbon atoms (cf. data for highly carbon-doped GaAs [9]). The samples remain semi-insulating after anneals at 600°C and 700°C, but an anneal at 800°C leads to low conductivity with $n \sim 10^{16}\text{ cm}^{-3}$ that is two orders of magnitude smaller than the remaining $[\text{C}_\text{P}] = 1.3 \times 10^{18}\text{ cm}^{-3}$. Related Raman scattering measurements of C_P and H-C_P pairs are discussed elsewhere [10].

Of greater importance is the presence of lines at 1785 and 1814 cm^{-1} detected by Raman scattering from

Fig. 2. Correlations of the IR strengths (integrated absorption IAs) of the LVMs at 521 cm^{-1} (squares, E -mode) and 414 cm^{-1} (diamonds, A_1^- -mode) as a function of the IA of the LVM at 2703 cm^{-1} (A_1^- stretch mode) for as-grown and annealed samples: additional points are for other samples with $[C_P] = 2.5 \times 10^{18}$ and $[H-C_P] = 1.4 \times 10^{18}\text{ cm}^{-3}$ [10]. The dashed (solid) line is a fit to the square points (diamonds) with a gradient of 0.150 (0.134).

Fig. 3. Raman spectra from as-grown and annealed InP:C samples with lines due to carbon complexes marked by arrows and where $a\text{-C}$ denotes scattering from amorphous carbon. The spectral resolution was 7 cm^{-1} .

as-grown samples (Fig. 3). The strengths of these modes increase with a constant ratio following anneals at 500 and 600°C and a small third line at 1764 cm^{-1} emerges and becomes stronger. Another line at 1558 cm^{-1} also appears, together with a broad band, centred at 1580 cm^{-1} with $\Delta \sim 70\text{ cm}^{-1}$, characteristic of precipi-

tated amorphous carbon. Similar scattering occurs in samples that were etched to remove the surface of the epitaxial layer, demonstrating that precipitation of carbon occurs in the InP bulk. There are no significant changes following the 700°C anneal but the lines discussed are no longer resolved after the 800°C anneal because of strong background scattering and/or luminescence in the range $1000\text{--}2000\text{ cm}^{-1}$. Raman scattering from hydrogen (H_2) is not detected in the frequency range $3000\text{--}4500\text{ cm}^{-1}$.

The structure of the C_P LVM (Fig. 1) can be fitted to theoretical profiles [7,8] that predict the sharp central feature to be logarithmically divergent in the absence of strain. In practice, all of the sharp lines that go together to form the profile are broadened by inhomogeneous strain from point defects and dislocations, limited instrumental resolution and three-phonon decay. This broadening is characterised by a half width at half height, γ . The reductions in γ that follow sample anneals (Table 1) are attributed to reductions of $[C_P]$ and $[H-C_P]$, with the implication that the resulting C–C defects and amorphous carbon produce smaller strains. We note that the smallest value of $\gamma = 0.04\text{ cm}^{-1}$ (Table 1) is not limited by the IR resolution of 0.02 cm^{-1} , (corresponding to $\gamma = 0.01\text{ cm}^{-1}$).

4. Discussion and conclusions

The assignment of Raman LVMs lines in the range $1763\text{--}1814\text{ cm}^{-1}$ to $(^{12}\text{C}\text{--}^{12}\text{C})_P$ pairs in InP:C is inferred by comparisons with corresponding lines observed in annealed GaAs:C and AlAs:C. Two sets of transitions, each showing $^{12}\text{C}\text{--}^{12}\text{C}$, $^{12}\text{C}\text{--}^{13}\text{C}$ and $^{13}\text{C}\text{--}^{13}\text{C}$ pairs, are observed in GaAs that contains $[^{12}\text{C}_{\text{As}}] = [^{13}\text{C}_{\text{As}}]$ [5]. Theory shows that the two types of (C–C) pairs, labelled T1 and T2 (also observed in AlAs), are both deep donors that occupy vacant As-lattice sites but with two nonequivalent molecular orientations [5]. The two Raman transitions have separations of 87 and 96 cm^{-1} for GaAs and AlAs, respectively, and a common mean frequency of 1800 cm^{-1} ; for comparison, the two strong lines in InP:C at 1784.9 and 1814.0 cm^{-1} have a smaller separation of 25 cm^{-1} but the same mean frequency of 1800 cm^{-1} . We therefore attribute the compensation of the carbon acceptors in epitaxial InP layers predominantly to H–C pairs and to di-carbon deep donors occupying P-lattice sites. During anneals substitutional carbon atoms must jump to interstitial sites and diffuse to form di-carbon defects [11] and larger amorphous carbon precipitates. The continued loss of C_P atoms with the formation of $(\text{C}\text{--}\text{C})_P$ donors is expected eventually to cause the samples to become lightly n-type when an excess of the defects occurs. The possibility that some C_{In} and P_{In} donors are present is not ruled out as their LVMs may be obscured by strong intrinsic

absorption and/or scattering from the InP lattice (the frequencies are not known): we state only that there is no evidence for their presence. Additionally, phosphorus vacancies are expected to be deep hole traps but they have not been detected.

In conclusion, our analyses now lead to significant steps in understanding the semi-insulating property of the InP layers that may have future technological applications [1].

Abstract

The motion of Mu^+ defect centers is investigated in heavily Zn-doped p-type GaAs, GaP, and GaSb using zero-field muon spin depolarization. Hop rates extracted from dynamic Kubo–Toyabe relaxation functions show activated motion above 200 K and changes in site or dynamics within 50 K of the onset. Barrier energies are extracted for the mobile centers. A second Mu^+ state at T_v sites is suggested by these results. Additional diamagnetic states are present implying interactions with Zn acceptors involving mobile states, Mu_T^0 at low T and Mu^+ at high T . © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

The effectiveness of hydrogen passivation reactions in semiconducting materials depends to a large extent on properties of the isolated hydrogen precursors. Hydrogen is ordinarily a deep compensating defect, thus, the equilibrium charge state for an isolated hydrogen is appropriate for a Coulomb interaction with the dominant dopant leading to hydrogen passivation. Thus, at ordinary temperatures where dopants are ionized, the mobility of oppositely charged hydrogen impurities may control the reaction rates.

Much of the experimental information on isolated hydrogen impurities has come from investigations of its muonium counterpart (Mu) formed when positive muons are implanted into a semiconductor. Muonium

forms defect states very similar to those of hydrogen, and although care must be taken when inferring motional properties of H from measurements on Mu due to the factor of nine mass difference, the dynamics of Mu^\pm states can serve as a qualitative guide to behavior of H^\pm centers. Preliminary data [1] on Mu^+ and Mu^- in GaAs showed the onset of motion for Mu^+ near 200 K and that Mu^- remains stationary to 500 K, consistent with drift properties inferred for hydrogen in GaAs [2–5]. Subsequently, we obtained a barrier of 0.7 eV for motion of Mu^- [6]. However, the neutral Mu_T^0 center is several orders of magnitude more mobile than either charged state [7], and we concluded that diffusion of H is controlled by transitions into and out of this highly mobile state [6].

We recently examined the motion of Mu^- in p-type Zn-doped GaAs and demonstrated trapping of Mu^+ at the Zn acceptor above room temperature [8]. In that work we characterized the motion of Mu^+ as hops among bond-center (BC) sites with barrier of 0.15 eV.

However, more detailed examination of the data strongly suggests that the motion is not a simple activated process, and that a change in dynamics occurs about 50 K above the onset. In the present contribution, we pursue details of these data for p-type GaAs and examine two other Ga-based materials to understand general features of H^+ dynamics in III–V compounds as elucidated by changes to muon depolarization associated with Mu^+ motion.

Before examining the data and results, we point out a few qualitative features pertinent to Mu^+ motion. First, the BC structure for Mu in a III–V compound is asymmetric in both the positive and neutral charge state [9]. For Mu^+ , this asymmetry and the weakly ionic nature of the host bonds imply that, the bond with Ga should be weaker than that with the Group-V element. Consequently, the lowest temperature motion is likely to be among four BC sites with the Mu^+ staying attached to a single Group-V atom. Second, bond ionicity implies that the tetrahedral site with group-V neighbors (T_V) is negatively charged and thus attractive for Mu^+ . At elevated temperatures a metastable T_V region could serve as the main Mu^+ location during diffusion, which would likely proceed through BC. Alternatively, and at lower temperatures, global motion may be BC-to-BC through an off-center site within T_V regions [9]. Zero-point motion will centralize Mu^+ at T_V if it remains in that general region for any length of time, although it might not do so for H^+ [10]. Furthermore, lattice dynamics can shift stability from BC to a T site [11]. These features suggest the possibility of three distinctly different types of motion for Mu^+ as a function of increasing temperature: local hops among four BC sites, BC-based diffusion, and perhaps eventually T_V -based diffusion.

2. Zero-field data and analysis

Fig. 1 shows typical zero-field depolarization data used in the present study, specifically from p-type Zn-doped GaP, analyzed as either one or two dynamic Kubo–Toyabe (KT) relaxation functions. Our standard procedure was to initially fit each curve as a single dynamic KT signal with all parameters free, then to fix the width parameter Δ_{KT} to an average over the region where these fits imply a “static” center (see later discussion) and perform a second round of fits to obtain good hop rates. In some circumstances, as for 230 K in Fig. 1, a single dynamic KT function fails to produce a good fit; in which case a second static KT component was added, followed by freeing the second hop rate if required. This procedure yields very good fits, but may not give a unique component separation.

Figs. 2 and 3, along with Table 1, summarize the results of this analysis. The temperature-dependent amplitudes of component signals for GaP are displayed

Fig. 1. Zero-field muon spin depolarization curves at selected temperatures for p-type GaP:Zn offset for clarity. Fits are for two Kubo–Toyabe signals, except for Mu_{BC}^+ alone at 150 K. Dashed line for 230 K is a Mu_{BC}^+ fit for comparison.

Fig. 2. Amplitudes for the different zero-field signals in GaP. State assignments are in Table 1.

Fig. 3. Hop rates extracted for Mu^+ in GaAs with BC (squares) and T_V (triangles) as separate signals. Fitted energies are in Table 1.

Table 1

Assignment of states to static KT widths within the model presented, and the motion-related parameters obtained for Mu^+ in Ga-based III–V compounds

State and parameter	GaAs	GaP	GaSb
Mu_{BC}^+ state:			
Static width, Δ_{BC} (kHz)	199(3)	217(4)	231(3)
Tunneling rate, ν_0 (kHz)	68(27)	262(15)	63(8)
Hop barrier, E'_{BC} (meV)	222(8)	215(14)	330(50)
Hop prefactor, ν'_{BC} (MHz)	3×10^4	3×10^5	2×10^5
Mu_{TV}^- state:			
Static width, Δ_{TV} (kHz)	122(4)	112(2)	150(30)
Hop barrier, E'_{TV} (meV)	260(30)		
Hop prefactor, ν'_{TV} (MHz)	2×10^5		
Low- T Mu–Zn pair:			
Static width, Δ_{Zn} (kHz)		270	
High- T Mu–Zn pair:			
Static width, Δ'_{Zn} (kHz)	87(1)		63(6)

in Fig. 2. A second signal, tentatively assigned to a Mu^+ at a T_{P} site, is definitely required above 220 K. For GaAs a second signal is also suggested by a small change in barrier energy near 230 K when a single KT signal is used [8]. Hop rates for Mu^+ states in GaAs from a two signal analysis up to 320 K are shown in Fig. 3. The GaSb data do not show a second isolated Mu^+ state quite as convincingly, and Mu_{T}^0 ionizes at approximately the same temperature increasing the mobile Mu^+ amplitude.

3. Discussion

As indicated in the introduction, III–V bonding properties and structural asymmetry of BC states suggest a second site and three distinct motions for Mu^+ in zincblende materials. The most straightforward interpretation of the GaAs results presented here support that picture of the dynamics; however, several caveats need to be stated. We have used the Kubo–Toyabe relaxation function in its static form as characteristic of a stationary Mu_{BC}^+ center. This function assumes that a large number of nuclear moments contribute equally to local magnetic fields at the muon location. In reality, these fields are dominated by the two nearest neighbors for a BC site, giving a slightly different functional form [12]. The slow hop rates found at low temperatures might simply represent these differences; and, although very high-statistics data could answer that question, we currently have no points with the necessary statistics. If one accepts the static KT function as properly characterizing a stationary Mu_{BC}^+ , the low- T hop rates imply temperature-independent

dynamics. This is typical of a tunneling process and consistent with expectations for low- T hops among four BC orientations around a central atom. In this picture, the onset of activated dynamics represents detachment from the central atom and global hopping motion among BC sites, and the additional change in dynamics signals the switch to T-site based diffusion. The state labels in Table 1 are based on this model of Mu^+ behavior. Conversion to T-site motion in this analysis starts by 225 K and is nearly complete by 300 K. If the low- T dynamics are incorrect, an alternative is that the 200 K onset represents thermally assisted local tunneling, with the additional change in dynamics assigned to diffusive motion.

A second complication is that an increase in depolarization rates is observed above 300 K for p-type GaAs and GaSb (the high- T data do not yet exist for GaP). Such increases may signal either muonium charge-state cycling or trapping of the mobile state. In GaAs, where we have extensively investigated the high- T behavior, Mu^+ traps at an ionized Zn^- and we obtained $\Delta_{\text{KT}} = 86.5(\pm 8)$ kHz for the complex. This value differs considerably from that assigned to the second Mu^+ state for 220–300 K (Table 1). Furthermore, the hop rates are too small for Mu^+ to encounter an acceptor on average over much of this range: evidence of the trapped state is present only above 290 K in the current analysis. We therefore discount interaction with another impurity as the explanation of changes occurring just above the onset of activated dynamics.

Formation of a different state immediately above the onset of motion was also observed [13] in p-type InP, where the new state was interpreted as Mu^- in the T_{P} interstitial cage based on observed Δ_{KT} values compared to local fields expected for various sites. The present data for GaP yield a value for Δ_{KT} almost identical to that for InP, lending additional credence to the T_{V} site interpretation. The difference between results for InP and GaP compared to GaAs is that this state is mobile from its initial formation in GaAs. Additional support for two sites comes from $\text{Mu}^0 \leftrightarrow \text{Mu}^-$ charge-cycle data in semi-insulating GaAs [14] which also suggests two different Mu^+ states.

Finally, we turn to the additional low- T state in p-type GaP. A similar situation is seen in n-type GaP and reported [15] for n-type GaAs as well. In the latter case, Mu_{T}^- QLCR spectra are seen only above 150 K and low- T depolarization rates imply interaction of the mobile Mu_{T}^0 with donors, leading to a Mu–donor complex. We suggest that a similar low- T charge-exchange interaction and formation of a Mu–acceptor complex is present for p-type GaP. The reaction we envision is $\text{Mu}^0 + \text{A}^0 \rightarrow \text{Mu}^+ + \text{A}^-$ with the final state most likely a bound complex. The rate of this reaction would be reduced when the acceptors thermally ionize, roughly consistent with the results in Fig. 2.

In conclusion, we have presented zero-field muon spin depolarization data related to Mu^+ defect centers in GaAs, GaP and GaSb which support the possibility of a second Mu^+ site and three distinctly different types of motional dynamics. In addition, interactions are inferred for mobile Mu_T^0 centers with neutral acceptors at low temperatures and mobile Mu^+ centers with ionized acceptors at elevated temperatures, both of which can lead to formation of Mu–acceptor complexes in analogy to hydrogen passivation.

Substitutional incorporation of arsenic from GaAs substrates into MOVPE grown InSbBi thin films

M.C. Wagener, J.R. Botha, A.W.R. Leitch*

Department of Physics, University of Port Elizabeth, P.O. Box 1600, Port Elizabeth 6000, South Africa

Abstract

The substitutional incorporation of As from the GaAs substrate during the MOVPE growth of InSbBi layers has been verified by resonant Raman scattering measurements. The anticipated reduction in the energy gap was also confirmed by infrared spectroscopy. The detection of an In–As LO phonon mode, as well as the absence of an In–Bi phonon mode, established that no Bi was substitutionally incorporated into the layers and that the previously observed lattice contraction and band gap reduction are entirely attributed to As incorporation. © 2001 Published by Elsevier Science B.V.

Keywords: InSbBi; Arsenic; Raman scattering

1. Introduction

The III–V compound $\text{InSb}_{1-x}\text{Bi}_x$ has received attention as a candidate for infrared detectors operating in the 8–14 μm wavelength range [1–4]. The band gap of InSbBi can in principle be reduced from that of InSb (0.167 eV at 300°C) to that of the semi-metal InBi (–1.5 eV at 300°C). Although only a small concentration of Bi is required to decrease the band gap into the desired range, the large miscibility gap of the material has necessitated the use of non-equilibrium growth techniques. A recent series of papers by Lee et al. [3,5] demonstrated the low pressure MOVPE growth of InSbBi at 456°C. Seventy-seven Kelvin photoconductive spectral response measurements clearly indicated an extension of the absorption edge from that of InSb (5.5 μm) to 9.3 μm for layers grown on GaAs substrate. A peculiarity of these results was the observed lattice contraction of the InSbBi epilayers, instead of the expected lattice dilation [6]. This was tentatively attributed to a cubic-to-tetragonal phase transformation as Bi incorporates into the lattice.

In a report by Wagener et al. [4], the crystalline properties of InSbBi layers grown on GaAs substrates were shown to dramatically differ from layers grown on InSb substrates. The observed lattice contraction observed for layers grown on GaAs substrates was attributed to the incorporation of As from the substrate during growth. The incorporation of As was found to be directly attributed to the interaction between Bi and the GaAs substrate. The concentration of As incorporated into the epilayers also increased with the increased availability of Bi in the reactor, with concentrations as high as 35 mol% InAs being incorporated. Besides causing lattice contraction, the presence of As was also anticipated to dramatically alter the optical properties of the material. In this paper, the incorporation of As in these layers has been investigated by infrared absorption and Raman spectroscopy.

2. Experimental

The InSbBi layers were grown in a horizontal MOVPE reactor at atmospheric pressure. TMSb, TMIIn and TMBi were used as precursors. Layers were grown on both InSb and GaAs substrates (orientated 2° off the (100) towards <110>) at a temperature of 455°C.

E-mail address: phaaw@upei.ac.za (A.W.R. Leitch).

A 0.5 μm thick InSb buffer layer was grown before introducing TMBi into the reactor. The layers were grown at a rate of 2.1 $\mu\text{m}/\text{h}$, with the total epilayer thickness of approximately 2.6 μm . The TMIn flow rate was maintained at 5.6 $\mu\text{mol}/\text{min}$ and the Bi to group V ratio in the vapour (Bi/V) was varied between 0 and 0.1. The infrared absorption edges of the layers were determined by Fourier transform infrared spectroscopy using a Nicolet Magma 550 spectrometer. Resonant Raman scattering measurements of the near-surface region were also obtained using a Jobin–Yvon T640000 Raman spectrometer and CCD detector. The acquisition optics was configured in the triple subtractive mode, giving a resolution of roughly 1 cm^{-1} . The 647.1 nm line of a Kr^+ -ion laser was used in the backscattering configuration. The particular incident photon energy was chosen since it coincides with the second direct critical point, the E_1 energy gap = 1.86 eV [7]. The resulting resonance effect was found to greatly enhance the Raman scattering signal. The laser spot size was roughly 2 μm in diameter, with the incident power maintained at 590 mW (measured at the laser).

3. Results and discussion

If As is incorporated substitutionally on the group V lattice sites of InSb, additional phonon modes, related to the In–As bond, are expected. Fig. 1 depicts the Raman scattering spectra of InSbBi layers grown with a V/III = 2 and a Bi/V ratio = 0.1. Fig. 1(a) shows the expected LO-phonon peak at 190.2 cm^{-1} and TO-phonon mode at 183.3 cm^{-1} for layers grown on InSb substrates. Except for the peaks at 72 and 99 cm^{-1} , the spectrum is essentially the same as for an InSb layer grown on InSb substrate [7]. This agrees with previous

X-ray diffraction (XRD) measurements [4], which showed that layers grown on InSb substrates contained no substitutional Bi. The Raman scattering spectrum for the InSbBi layer grown on GaAs substrate (Fig. 1(b)) has, however, an additional peak at roughly 211 cm^{-1} . Since As is expected to be present in these layers, the extra peak is ascribed to the In–As vibrational mode. Although the ν_{InAs} TO phonon mode for bulk InAs is $218.6 \pm 0.2\text{ cm}^{-1}$ [8], the presence of Sb neighbouring atoms in the InAsSb alloy is expected to shift the InAs-phonon modes towards lower frequencies.

A Raman study by Li et al. [9] revealed that $\text{InAs}_{1-x}\text{Sb}_x$ displays a two-mode behaviour over the entire composition range, with the InAs-like LO phonon frequency having a composition dependence of $\nu_{\text{InAs}} (\text{cm}^{-1}) = 238 - 32x$. An InAs-like LO mode at 211 cm^{-1} would then correspond to a composition of roughly 16 mol% InAs, significantly less than the concentration of 36 mol% InAs measured by XRD. Although less pronounced, the InSb-like LO phonon mode also has a linear dependence on composition, with $\nu_{\text{InSb}} (\text{cm}^{-1}) = 177 + 12x$. For a composition of 16 mol% InAs, the InSb-like LO mode is therefore expected to decrease by only 1.9 cm^{-1} . Due to the high absorption coefficient of InSb at 647.1 nm, the observed scattering originates from a region extending roughly 500 Å below the surface. The expected decrease in the As concentration towards the surface [4], together with the high vapour pressure of As, will produce a near-surface As concentration notably lower than that measured by XRD. Based on the above discussion, the peaks measured in Fig. 1(b) at 190.0 and 182.8 cm^{-1} are labelled with the InSb-like LO and TO phonon modes, respectively, and the peak at 211 cm^{-1} with the InAs-like LO phonon mode.

The InAs-like LO peak position showed a very weak dependence on the Bi/V ratio and consequently the As concentration. Fig. 2 shows the Raman spectra for layers grown with significantly different Bi/V ratios (and hence As concentrations) on GaAs substrates. The As concentrations determined by XRD were 11 and 36 mol% InAs for Figs. 2 (a) and (b), respectively. The similarity of the InAs-like LO peak positions is probably due to similar As concentrations in the near-surface region, as well as a slight insensitivity to changes in composition. The InSb-like TO mode was also found to be enhanced with higher Bi/V ratios (or As concentrations). This can either be attributed to a deterioration in crystallinity, since increased Bi/V ratios produced broader XRD peaks [4], or to the presence of alloy disorder with the addition of a second group V atom [9].

The LO and TO vibrational modes for InBi are 161 and 155 cm^{-1} , respectively [10]. No phonon mode was, however, observed in this region. This, therefore, clearly illustrates that the lattice contraction related to growth on GaAs substrates only requires that Bi be present

Fig. 1. Room temperature Raman spectra of an InSbBi epilayer grown on (a) InSb and (b) GaAs substrate. The epilayers were grown with a V/III = 2 and a Bi/V ratio = 0.1.

Fig. 2. Room temperature Raman spectra of an InSbBi epilayer grown on GaAs substrate with a V/III = 2 and a Bi/V ratio of (a) 0.01 and (b) 0.1. The deconvolution of the spectra has been obtained by fitting three Lorentzian functions.

Fig. 3. Room temperature infrared transmittance curves of 2.1 μm thick $\text{InAs}_{1-x}\text{Sb}_x$ layers resulting from As incorporation from the GaAs substrate. The compositions have been determined by XRD.

during the growth, with Bi having no direct influence on the epitaxial properties of the epilayers. The two extra peaks shown in Figs. 1 and 3 (positioned at 72 and 99 cm^{-1}) were measured in only two of the samples. The Raman spectrum of Bi has a prominent mode at 141 cm^{-1} [10]. It is, therefore, unlikely that the two peaks are attributed to Bi precipitates within the material [4]. Since the two peaks have been detected in layers grown on both InSb and GaAs substrates, it is also unlikely that they are related to the incorporation of As or Ga. Their origin therefore remains unclear.

The Raman scattering measurements clearly corroborate the incorporation of As into the epilayers, which

was inferred from the lattice contraction measured by XRD [4]. Besides lattice contraction, the substitutional incorporation of As is also expected to alter the energy gap of the material: the 300 K energy gap decreases with increasing As concentrations, reaching a minimum of 0.12 eV (absorption edge of roughly 12 μm) at 35 mol% InAs. The epilayers in which As has been incorporated are therefore capable of having significantly increased absorption cut-off wavelengths. Fig. 3 shows the room temperature transmittance spectra of InAsSb layers resulting from As incorporation from the GaAs substrate. The layers were grown with different V/III and Bi/V ratios. The compositions, which were determined by XRD, increased from 9.2 to 36 mol% InAs as the Bi/V ratio was increased from 4.4×10^{-4} to 0.1. The high surface roughness of these layers produced significant photon scattering. As a result, it was not possible to calculate sensible values for the absorption coefficient. What is clear, however, is that the absorption edge of the InAsSb layers shifts to lower energies (longer wavelengths) as the As concentration increases. The overall reduction in transmittance with increasing composition is ascribed to the increased surface roughness of the layers. The sharp drop in transmittance below 0.07 eV is due to the low response of the IR detector in this wavelength region.

4. Conclusions

Even though the original objective was to reduce the energy gap by incorporating Bi into the InSb lattice, no direct evidence of substitutional Bi could be found. Instead, a reduction in the energy gap was achieved by the interaction of Bi with the GaAs substrate, which consequently led to the substitutional incorporation of As into the layers. This was successfully verified by the observed In-As vibrational mode, as well as by the extension of the absorption edge to longer wavelengths. Care should, therefore, be taken with growth studies involving Bi, as well as possibly other heavy metals, i.e. thallium, with special attention given to variations in the properties of layers grown on different substrates.

Deep-level defects in MBE-grown Ga(As,N) layers

P. Krispin^{a,*}, S.G. Spruytte^b, J.S. Harris^b, K.H. Ploog^a

Abstract

Deep levels are examined in the whole band gap of strained Ga(As,N) with 3% GaN composition by deep-level transient Fourier spectroscopy on as-grown as well as annealed GaAs/Ga(As,N)/GaAs heterojunctions grown by molecular beam epitaxy. In the lower half of the band gap, there are only hole traps, which are not associated with nitrogen-related defects. For n-type structures, we find in as-grown samples a huge concentration of an electron trap at $E_C - 0.25$ eV, which is most likely connected with the nitrogen split interstitial defect (N–N)_{As}. The concentration of this giant trap can be strongly reduced by rapid thermal annealing. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: MBE-grown Ga(As,N); Hole and electron traps; Post-growth treatment

1. Introduction

Group-III-arsenide-nitrides grown on GaAs substrates are promising materials for optoelectronic devices. Ga(As,N) layers are of special interest, because the band gap decreases drastically with increasing GaN composition [1–3]. In contrast to the optical properties, the electrical characteristics of Ga(As,N) layers have been hardly studied. We have recently shown that p-type GaAs/Ga(As,N) interfaces exhibit a very small valence band offset ΔE_V [4]. For a GaN composition of 3%, ΔE_V values of (11 ± 2) meV have been determined. For the same composition, the conduction band offset ΔE_C has been found from n-type GaAs/Ga(As,N) heterostructures to be $-(400 \pm 10)$ meV [5]. Thus, the Ga(As,N)/GaAs heterointerface is definitely of type I, in accordance with first principle calculations [6].

Crystal quality and luminescence efficiency of Ga(As,N) layers deteriorate unfortunately for larger GaN mole fractions. Both can be remarkably improved by postgrowth heat treatment [7]. The degradation and anneal mechanisms are still controversially discussed. The presence of N-related deep-level defects has been often postulated, but not explored yet. We therefore use

deep-level transient Fourier spectroscopy (DLTFS) [8] on p- and n-type GaAs/Ga(As,N)/GaAs heterojunctions grown by molecular beam epitaxy (MBE) to examine the spatial distribution of hole and electron traps in as-grown as well as annealed structures. The main hole traps in as-grown and annealed Ga(As,N) layers with a GaN mole fraction of 3% are due to Cu and Fe impurities with concentrations in the 10^{15} cm⁻³ range. For as-grown, n-type Ga(As,N), substantial densities above 10^{17} cm⁻³ are estimated for an electron trap at about 0.25 eV below the conduction band edge E_C . The corresponding defect is of intrinsic origin and probably associated with nitrogen split interstitials (N–N)_{As}. Its concentration can be drastically reduced by rapid thermal annealing (RTA).

2. Experimental details

p- and n-type GaAs/Ga(As,N)/GaAs heterostructures were grown by elemental source MBE on p⁺- and n⁺-type GaAs(001) substrates, respectively. Dimeric arsenic and atomic nitrogen were provided by a thermal cracker and a radio frequency (RF) nitrogen plasma cell, respectively. Details of the growth [7] and of the carrier distribution [4,5] in the investigated heterostructures have been published previously. Deep-level spectra were

measured with a computer-controlled Bio-Rad DL8000 system based on the DLTFs technique [8]. For this paper, temperature scans of the first sine coefficient b_1 were evaluated with a period of 1 s. RTA was performed after growth for 60 s at 760°C with a GaAs proximity cap under N_2 atmosphere.

3. Results and discussion

3.1. p-type GaAs/Ga(As,N)/GaAs structures

For an as-grown, p-type GaAs/Ga(As,N)/GaAs structure, deep-level spectra are shown in Fig. 1 as relative capacitance changes $\Delta C/C$ vs. temperature under various bias conditions. Fig. 1 exhibits a sequence of distinct peaks labeled Hk1 to Hk5, which are observed in all as-grown heterostructures. Their respective thermal activation energies are found to be about 0.17, 0.39, 0.36, 0.55, and 0.69 eV. The peak heights strongly change with bias. Since different bias conditions lead to deep-level responses from different depths below the MS contact, Fig. 1 shows that the concentration of all hole traps strongly varies with position. A further striking property of the level responses concerns the

shift of the DLTFs peak temperatures. For example, the signal of the hole trap Hk4 is observed in the lower bias range (curves 3 and 4) at 260 K. This peak shifts at intermediate bias values towards 250 K (curves 5 and 6) and then back to 260 K at sufficiently high reverse biases (curves 7 and 8). Such a behavior is characteristic for a defect with composition-dependent features. Very small differences of the thermal activation energy E_{th} are expected for hole traps linked to the same defect in GaAs and in Ga(As,N), because the band offset ΔE_V is only 11 meV [4]. For level Hk4, the DLTFs peaks in Fig. 1 at low, intermediate, and high reverse biases can be associated with the same defect in the upper GaAs, the Ga(As,N), and the bottom GaAs layers, respectively. Detailed depth profiles of the level concentration (not shown) emphasize that the switch from one to the other peak position occurs for all hole traps at the GaAs/Ga(As,N) interfaces.

Levels Hk2 and Hk5 are identical to the well-known hole traps A and B, which are the dominant levels in GaAs grown by liquid phase epitaxy [9]. They originate from the Ga_{As} antisite defect [9,10]. In particular, the hole trap Hk5 is observed in this study being spatially localized at the surface of the GaAs top layer (see curves 1–3 in Fig. 1). It is a general phenomenon that Ga_{As} antisite defects are formed during epitaxial GaAs growth near the p-type surface [11], because the defect formation energy, which depends strongly on the position of the Fermi level [12], becomes smaller at the surface.

The levels Hk3 and Hk4 exhibit properties identical to those well-known hole traps in GaAs, which are associated with Cu and Fe atoms on Ga sites, respectively [13,14]. Their occurrence in Ga(As,N) is apparently linked with the operation of the RF plasma source or the nitrogen purity. All dominant hole traps can be removed by annealing.

3.2. n-type GaAs/Ga(As,N)/GaAs structures

For an as-grown, n-type GaAs/Ga(As,N)/GaAs structure, deep-level spectra are plotted in Fig. 2 for varying bias conditions. The presence of a giant electron trap labeled Ek1 is obvious below 200 K. Its peak position is constant at low reverse biases (curves 1–3) and shifts to higher temperatures for higher reverse biases. The thermal activation energy E_{th} of this dominant level changes from 0.25 (curve 1) to 0.49 eV (curve 7). At higher reverse biases, level Ek1 disappears, and three minor electron traps Ek2, Ek3, and Ek4 emerge with energies of about 0.60, 0.67, and 0.75 eV, respectively. They disappear for even higher reverse biases (curve 10 in Fig. 2).

To determine the location of measured DLTFs responses, depths are commonly determined from the voltage-dependent capacitance of the MS contact

Fig. 1. Deep-level spectra for an as-grown, p-type heterostructure. The spectra 1–8 correspond to increasing reverse biases. The pulse height was 0.5 V. For the hole traps Hk1 to Hk5 in Ga(As,N) and GaAs, the temperature positions of the DLTFs peaks are marked by dashed and solid lines, respectively.

Fig. 2. Deep-level spectra for an as-grown n-type heterostructure. The spectra 1–10 correspond to increasing reverse biases. Curves 1 and 10 were measured at -2 and -6.5 V, respectively. The pulse height was 0.5 V.

including the λ -effect [15]. We, however, find for n-type heterostructures an admittance dispersion (see Ref. [5]). The capacitance therefore depends additionally on frequency and temperature (not shown). This admittance dispersion is due to the diffusion barrier at the GaAs/Ga(As,N) interfaces, which originates from the relatively large conduction band offset of 400 meV [5]. The potential distribution around the Ga(As,N) layer is illustrated in Fig. 3. Dots in Fig. 3 mark for each bias the thickness obtained from the capacitance.

In the bias range between -2 and -3 V, the peak position of the trap Ek1 remains at 170 K (curves 1–3 in Fig. 2), and the capacitance is dominated by electrons in the Ga(As,N) layer (cf. Fig. 3). However, there is a further (smaller) contribution to the capacitance at the edge of the depletion layer in GaAs close to the Ga(As,N)-on-GaAs interface (see, vertical dashed line at 725 nm in Fig. 3). The signal of the electron trap Ek1 is related to this part of the measured capacitance. Including the band offset, the λ -correction for the level Ek1 is about 200 nm (double arrow in Fig. 3). We can therefore conclude that the giant trap Ek1 is located in the Ga(As,N) layer. Its concentration is estimated to be above $1 \times 10^{17} \text{ cm}^{-3}$.

As long as the capacitance is dominated by the electrons in Ga(As,N), the Ek1 signal originates from

Fig. 3. Band diagram of investigated n-type GaAs/Ga(As,N)/GaAs structures as obtained from solutions of the Poisson equation for several reverse biases. The Fermi level for each bias is given by a horizontal dashed line. Dots mark for each bias the thickness obtained from the capacitance. The edge of the depletion layer in the bottom GaAs layer is marked by the vertical dashed line at 725 nm. For level Ek1, the λ value is indicated by a double arrow.

the Ga(As,N) layer. Its peak position and height remain constant with increasing reverse bias (curves 1–3 in Fig. 2). In the bias range from -3 to -5 V, the capacitive contribution of the electrons in the Ga(As,N) layer becomes weaker and the capacitance is more and more governed by the depletion layer edge in the bottom GaAs layer (dashed line at 725 nm in Fig. 3). Under these conditions, the DLTS peaks of the electron trap Ek1 are due to the interface region, where the GaN mole fraction decreases with increasing reverse bias. We observe a shift of the DLTS peak to higher temperatures and a decrease of the trap concentration (curves 4–7 in Fig. 2). The level Ek1 in the Ga(As,N) band gap reflects the increase of the conduction band edge energy with decreasing GaN composition. The electron trap Ek1 is probably associated with the split interstitial defect $(\text{N-N})_{\text{As}}$. As-grown Ga(As,N) layers contain a significant concentration of interstitial nitrogen [16], in agreement with the theoretical prediction that nitrogen split interstitials are the dominant defects in Ga(As,N) [17].

Deep-level spectra of the same GaAs/Ga(As,N)/GaAs structure after annealing are displayed in Fig. 4. The concentration of the electron trap Ek1 in Ga(As,N) is drastically reduced by RTA. We believe that the underlying defect is annihilated by reactions between

Fig. 4. Deep-level spectra for the same n-type heterostructure as in Fig. 2, but after annealing. The spectra 1–9 correspond to increasing reverse biases. Curves 1 and 9 were measured at -2 and -6 V, respectively. The pulse height was 0.5 V.

intrinsic defects. It is obvious that all partners, which are desired for the complete recombination, are available in the Ga(As,N) region. An additional level with an energy below 100 meV appears after annealing under certain bias conditions (peak at 100 K in Fig. 4). By heat treatment, the traps Ek2 and Ek4 are additionally generated in the GaAs top layer (see, curves 2 and 3 in Fig. 4). The level Ek3 is missing after annealing.

4. Conclusions

Deep levels have been examined in the whole band gap of strained Ga(As,N) with 3% GaN composition. In the lower half of the band gap of MBE-grown material, there is no indication for hole traps, which could be

associated with nitrogen-related defects. For n-type structures, we find in as-grown samples, however, a very high concentration of an electron trap at $E_C - 0.25$ eV, which is most likely connected with a nitrogen split interstitial defect on As site. According to thermodynamic calculations, this interstitial defect is dominant in Ga(As,N) [17]. However, the calculated trap level is 0.66 eV below the conduction band, in contrast to the experimental value of 0.25 eV. The concentration of this giant trap can be strongly reduced by annealing. Since the capture cross section of this level is about 10^{-17} cm², it cannot be the recombination center, which causes the degradation of the luminescent properties of Ga(As,N) at higher GaN compositions.

Effects of structural defects on the activation of sulfur donors in $\text{GaN}_x\text{As}_{1-x}$ formed by N implantation

J. Jasinski^{*1}, K.M. Yu, W. Walukiewicz, Z. Liliental-Weber, J. Washburn

Materials Science Division, Lawrence Berkeley National Laboratory, 1 Cyclotron Road, MS 62-203, Berkeley, CA 94720, USA

Abstract

The effects of structural defects on the electrical activity of S-doped $\text{GaN}_x\text{As}_{1-x}$ layers formed by S and N co-implantation in GaAs are reported. S and N ions were implanted to the depth of about $0.4\text{ }\mu\text{m}$. Electrochemical capacitance voltage measurements on samples annealed at 945°C for 10 s show that in a thin ($<0.1\text{ }\mu\text{m}$) surface layer the concentration of active shallow donors is almost an order of magnitude larger in S and N co-implanted samples than in samples implanted with S alone. The activation efficiency of S donors also shows a broad minimum at a depth of about $0.2\text{ }\mu\text{m}$ below the surface. The results of these electrical measurements are correlated with the distribution of structural defects revealed by transmission electron microscopy (TEM). The TEM micrographs show that in addition to a band of dislocation loops commonly found in ion implanted GaAs, an additional band of small voids is observed in samples co-implanted with S and N. The location of this band correlates well with the region of reduced electrical activation of S donors, suggesting that the formation of the voids through N accumulation results in a lower concentration of “active”, substitutional N atoms. Published by Elsevier Science B.V.

Keywords: $\text{GaN}_x\text{As}_{1-x}$; TEM; Microstructure; Implantation

Incorporation of a small amount of N (up to $\sim 5\%$) into III-V semiconductors leads to a dramatic reduction of the energy gap of the resulting group III-N_x-V_{1-x} alloys. The effect has been observed experimentally in a large variety of III-N-V alloys including GaNAs [1–4], GaInNAs [3,5], GaNP [6,7], InNP [8,9], and AlGaInAs [10]. The issue of the N-induced band gap reduction has been addressed by a number of recent theoretical studies [3,5–8]. It has been shown, based on the band anticrossing model [11,12], that the N-induced downward shift of the conduction band edge and a large increase in the electron effective mass lead to great improvements in the electrical activation of group VI donors [13]. The enhanced electrical activation was observed in the as-grown selenium-doped GaInNAs [14] as well as in sulfur implanted $\text{GaN}_x\text{As}_{1-x}$ [15]. A large increase in the

electrical activation of sulfur (S) co-implanted with nitrogen in GaAs has also been observed [16]. In the case of N and S co-implanted GaAs, however, the increase in the electrical activation of sulfur donors was measured only in the near-surface region. In order to understand the mechanism leading to such a behavior, we performed detailed structural studies using transmission electron microscopy (TEM) to make it possible to correlate the structural defect distribution with depth profiles of electrical measurements.

In this study we used two GaAs wafers. The first one was implanted only with S and the second was co-implanted with S and N. Multiple energy ion implantation was used in both cases, resulting in $\sim 0.4\text{ }\mu\text{m}$ thick layers with $\sim 3.3 \times 10^{20}\text{ 1/cm}^3$ of N and $\sim 0.2\text{ }\mu\text{m}$ thick layers with $\sim 6 \times 10^{19}\text{ 1/cm}^3$ of S. After implantation, wafers were covered by other GaAs wafers (in order to prevent As outdiffusion) and annealed at 945°C for 10 s by rapid thermal annealing (RTA) in a flowing N_2 ambient. Cross-sectional TEM specimens were prepared by the standard method of mechanical thinning followed

by ion milling. TEM studies were carried out using a TOPCON 002B microscope operated at 200 kV.

TEM studies performed on these wafers showed the presence of subsurface layers of post-implant damage. The distribution of structural defect present in these layers studied using bright field TEM images of both materials is shown in Fig. 1. In the sample implanted with S only [see Fig. 1(a)], a highly defective layer containing stacking faults, a dislocation network and small angle grain boundaries was observed below the surface. The thickness of this layer varied within the range: $\sim 0.05\text{--}0.10\text{ }\mu\text{m}$. Below this layer to a depth of $\sim 0.2\text{ }\mu\text{m}$ a high quality crystal layer was observed. However, in the middle of this layer at a depth of about $0.13\text{ }\mu\text{m}$ below the surface, a narrow band of tiny defects was present. High resolution electron microscopy studies suggested that they were stacking fault tetrahedra. Such defects have been previously reported in implanted GaAs [17,18]. The main structural feature visible in this sample was a band of defects present in a layer at a depth from ~ 0.2 to $\sim 0.3\text{ }\mu\text{m}$ below the surface. These defects were the dislocation loops with an average size of $\sim 10\text{ nm}$, located on $\{111\}$ planes surrounding extrinsic stacking faults. Such a band of dislocation loops is a typical feature in the implanted and then annealed GaAs.

TEM studies of the S and N co-implanted samples [see Fig. 1(b)] showed different structural features compared to those observed in the sample implanted with S only. The only similarity was the presence of the band of dislocation loops at the depth of $\sim 0.2\text{--}0.3\text{ }\mu\text{m}$ below the surface. This band was slightly narrower and the loops were larger (with an average size of $\sim 15\text{ nm}$) than in the sample implanted only with S. There were pits observed at the surface of the sample co-implanted with N and S, probably originating from very high annealing temperature or stacking fault formation. In this sample, a broad layer containing a high density of small voids (of an average size of about $4\text{--}5\text{ nm}$) was observed. They were located mostly in a layer extending

from $\sim 0.1\text{ }\mu\text{m}$ to $\sim 0.3\text{ }\mu\text{m}$ below the surface. Their concentration rapidly decreased outside this area.

The observed distribution of structural defects correlated well with electrical measurements performed on these samples. Depth profiles of free electron concentration obtained for these materials by electrochemical capacitance voltage (ECV) are shown in Fig. 2. The calculated distributions of implanted species are also shown in this figure. One can observe from these results that the electron concentration profile measured for the sample implanted only with S differs drastically from that obtained for the one co-implanted with S and N. For both samples, these line profiles have a qualitatively similar shape. In the near-surface region for a thickness of about $0.1\text{ }\mu\text{m}$ there is a maximum of electron concentration. Then as the distance from the surface increases this concentration rapidly decreases, resulting in a characteristic dip visible on these profiles. Despite these qualitative similarities there is a significant difference between the two profiles. In the co-implanted sample, the density of free electrons in the near-surface region is almost an order of magnitude higher than in the sample implanted with S only. On the other hand, the depth of the dip measured for the co-implanted sample is much larger than in the sample with S only. In addition, this dip is much broader ($0.2\text{ }\mu\text{m}$ compared to $0.1\text{ }\mu\text{m}$) in the co-implanted sample.

Fig. 1. TEM micrographs of GaAs samples implanted with S (a), and co-implanted with S and N (b).

Fig. 2. ECV measured net donor concentration profiles for the GaAs samples implanted with S alone and S+N after RTA at 945°C for 10 s. The calculated atomic depth profiles for both S and N are also shown.

A comparison of the measured free electron concentration profiles with structural defect distributions shows a correlation between these results. In the sample implanted only with S, the dip in the electrical profile correlates well with the location of the band of dislocation loops. It is likely that a significant fraction of the S implanted into this region becomes inactive by accumulating around the dislocation cores. This mechanism is probably also partially responsible for the reduced electrical activation of S in the co-implanted sample. However, it seems that in this case the presence of voids is an even more important mechanism for reducing the electrical activity of S. These voids were most likely formed as agglomerates of vacancies filled with N and acted as defect centers compensating for electrical activity of S donors. This argument is supported by the observed very large activation efficiency of S donors in the void-free region within the $\sim 0.1 \mu\text{m}$ layer near the surface, where N is incorporated into the As sublattice forming a layer of $\text{GaN}_x\text{As}_{1-x}$ alloy.

In summary, structural defect distributions, observed by TEM in GaAs implanted with S and co-implanted with S and N, were correlated with electrical measurements performed on the same samples. It was found in the co-implanted sample that besides the typical implantation induced structural defects, voids are formed in the material. We believe that these voids were filled with N and were responsible for the reduced activation of S donors. On the other hand, experimental results indicate that large N-induced enhancement of the donor activation efficiency can only be realized in the void-free region, where $\text{GaN}_x\text{As}_{1-x}$ alloy was formed.

Abstract

InGaAsN layers grown by molecular beam epitaxy were investigated using Fourier transform infrared absorption spectroscopy. The nitrogen-related local mode at 471 cm^{-1} is used as a quantitative tool to assess the substitutional nitrogen fraction. Evidence is presented that nitrogen in the quaternary alloy is bonded only to gallium atoms as in GaAsN. No change in the local environment of nitrogen is observed after annealing. From nuclear reaction analysis of GaAsN under channeling conditions it is confirmed that the major fraction of nitrogen atoms ($>95\%$) is localized on string positions. © 2001 Elsevier Science B.V. Keywords: InGaAsN; Nitrogen; FTIR; NRA

1. Introduction

Adding of a small amount of nitrogen to GaAs during epitaxial growth leads to a large shrinkage of the band gap of about 100 meV per percent of nitrogen [1]. Contrary to the low concentrations of nitrogen found in bulk GaAs, being even in polycrystalline material in the lower 10^{16} cm^{-3} range at a maximum [2], alloy compositions of $\text{GaAs}_{1-x}\text{N}_x$ layers with x up to several percent can be grown by molecular beam epitaxy (MBE) as well as metalorganic vapor phase epitaxy (MOVPE). The simultaneous addition of indium, leading to the quaternary system InGaAsN, further reduces the band gap. Therefore optical emission in the $1.3\text{--}1.55\text{ }\mu\text{m}$ range, most interesting for optical fiber-based communication systems, can be expected [3]. Several groups reported recently on the observation of long-wavelength laser activity in such layers [4–6], culminating in the first vertical-cavity surface-emitting laser (VCSEL) working under CW conditions at room temperature [7].

In spite of this rapid technological progress, the theoretical understanding of the remarkable effects of nitrogen in these ternary and quaternary dilute alloy systems is still under debate [8–12]. Partly, this is related to the fact that it is experimentally not clear whether a true random alloy exists or some nitrogen-related ordering occurs, especially in the case of the quaternary InGaAsN. Experimental methods typically used for characterization are mass spectrometry, photoluminescence (PL) or X-ray diffraction (XRD). These methods are not selective with respect to the nitrogen species of interest, which is nitrogen on the anion site. Fourier transform infrared (FTIR) absorption spectroscopy can provide valuable information in this context. It is known that nitrogen in GaAs gives rise to a local vibrational mode (LVM) at 471 cm^{-1} which is due to isolated substitutional nitrogen, N_{As} [13]. The frequency of a LVM is a sensitive tool for the environment of a defect as it is dependent on the bond strength and the mass of the nearest neighbors [14]. It is the purpose of this paper to use FTIR absorption spectroscopy in combination with nuclear reaction analysis (NRA) under channeling conditions to resolve microscopic details of the local environment of nitrogen in these diluted alloys.

2. Experimental

GaAs_{1-x}N_x and In_yGa_{1-y}As_{1-x}N_x layers were grown by solid-source MBE on semi-insulating GaAs (001) substrates. A radio frequency-coupled plasma source was used to generate the reactive nitrogen species from N₂. Ternary alloys were grown up to 3 μm thick. Quaternary alloys were produced as multiple-quantum-well (MQW) structures with up to 5 quantum wells of up to 10 nm thickness. The nitrogen content *x* was between 0.003 and 0.027 (according to X-ray diffraction [1]), the indium content *y* between 0.3 and 0.4. Standard annealing was performed in situ at 750°C, for comparative purposes some of the samples were annealed ex situ under similar conditions. InAs wafers of low conductivity were implanted with 3-MeV singly charged nitrogen ions. Three different sets of samples were generated: (i) 2×10^{16} ¹⁴N⁺/cm², (ii) 2×10^{16} ¹⁵N⁺/cm², (iii) 1×10^{16} ¹⁴N⁺/cm² + 1×10^{16} ¹⁵N⁺/cm².

FTIR measurements were carried out with a vacuum instrument (Bruker IFS 113v) using a globar source and a tri-glycine sulphate (TGS) detector. Due to the pronounced features of the two-phonon absorption in the GaAs substrate, subtraction of the spectrum of a reference sample was necessary. GaAsN layers were investigated by NRA under channeling conditions. The normalized yield of the ¹⁴N(*d,x*)¹²C nuclear reaction was measured as a function of the angle of incidence. The deuteron energy was 1.4 MeV.

3. Results and discussion

A typical low-temperature (77 K) FTIR absorption difference spectrum of an In_yGa_{1-y}As_{1-x}N_x MQW structure (*x* = 0.018, *y* = 0.35) with 5 quantum wells of a thickness of 10 nm each is shown in Fig. 1. A sharp band is found at 471.4 cm⁻¹. The band position is identical to the N-related LVM in bulk GaAs [2]. By implantation of ¹⁴N and ¹⁵N it has been proved that this band is due to the isolated nitrogen impurity on the anion lattice site, N_{As} [13]. The FWHM of about 3.0 cm⁻¹ is smaller than in the ternary alloy GaAsN and not much larger than in bulk crystals (2.0 cm⁻¹). This is indicative for the high quality of the MBE layer. After annealing no change is observed neither in the strength nor in the position of the band. This is in contrast to the behavior reported for InGaAsN layers grown by MOCVD [15]. The effect of annealing is, as usually observed, a large increase of the PL intensity. Evidently, this enhancement is not related to a substantial redistribution of the substitutional nitrogen fraction itself, but probably is caused by annealing of nonradiative recombination centers [16]. It should be mentioned that the 471 cm⁻¹ band was also detected by Raman spectroscopy [17,18].

For different in situ or ex situ annealed In_yGa_{1-y}As_{1-x}N_x MQW structures (0.3 ≤ *y* ≤ 0.4), the area under the absorption band, the integrated absorption (IA), is plotted versus the nitrogen content as determined by XRD on GaAsN layers produced by similar MBE growth conditions (Fig. 2). For *x* ≤ 0.02 reasonable agreement is found with the calculated IA

Fig. 1. Low-temperature FTIR absorption spectra of an In_yGa_{1-y}As_{1-x}N_x MQW structure with *y* = 0.35 and *x* = 0.018 before and after (ex situ) annealing. The reference spectrum has been subtracted. The spectrum of annealed sample has been displaced vertically for clarity. The inset shows the N_{As} LVM of a nitrogen-rich GaAs bulk crystal for comparison.

Fig. 2. IA of the 471 cm⁻¹ band in different In_yGa_{1-y}As_{1-x}N_x MQW structures (0.3 ≤ *y* ≤ 0.4) as a function of the nitrogen content determined by XRD. The straight line is calculated using the calibration factor derived from mass spectrometry in bulk GaAs crystals (Ref. [2]). The inset shows the lateral variation of the IA along the (100) direction of a 75-mm wafer (sample with full circle in the main graph).

based on the IR calibration factor of $7.4 \times 10^{15} \text{ cm}^{-1}$ derived from mass spectrometry on nitrogen-rich bulk GaAs crystals [2]. For higher x values considerable deviations exist, as previously observed in GaAsN layers [13]. It should be noted that recently also deviations were reported from Vegard's law, which is the basis for the XRD determination of the nitrogen content, for $x > 0.015$ in $\text{GaAs}_{1-x}\text{N}_x$ [19]. We found no dependence of the N content on the In content in the limited variation range for the In content ($0.3 \leq y \leq 0.4$). This is in agreement with the conclusions drawn by other groups for MBE material [20]. In any case, the FTIR method provides a sensitive tool to assess quantitatively the substitutional nitrogen content in MBE MQW structures. For the first time, it could be proved directly that, up to moderate x values of about 0.02, nitrogen is incorporated predominantly on the anion lattice site.

This picture is corroborated by the NRA investigation on selected $\text{GaAs}_{1-x}\text{N}_x$ layers produced by similar MBE growth conditions. In Fig. 3 the result is shown for a layer with a thickness of $0.35 \mu\text{m}$ and a total chemical nitrogen content of 0.6%. The normalized yield of the $^{14}\text{N}(d,\alpha)^{12}\text{C}$ nuclear reaction was measured as a function of the angle of incidence. Using a kinematical model for the reaction between deuterons and nitrogen atoms, the area projection of the N concentration in the GaAs lattice was calculated. N is predominantly localized on string positions. However, the half width of the distribution is larger than the thermal oscillation amplitude of the matrix atoms ($\langle u_{\text{th}} \rangle \approx 0.1 \text{ \AA}$). The

fraction of nitrogen atoms on interstitial sites is estimated to be less than 5%.

Using Monte Carlo simulations for the quaternary system InGaAsN, it was predicted that nitrogen should bond preferably with In atoms [21]. The argument is that the low-strain configuration N-In is energetically more favorable than N-Ga, in spite of the fact that the N-Ga bond energy is higher. Also experimentally some indications were presented that local correlations between nitrogen and indium occur [15,22]. Our FTIR results do not support such a behavior. The LVM frequency of N_{As} in InGaAsN is the same as in pure GaAs (Fig. 1). For nitrogen surrounded by indium a considerable lowering of the LVM frequency is expected. First indication is the LO phonon frequency being in InAs only 254 cm^{-1} compared to 296 cm^{-1} in GaAs. The so-far unknown frequency of the corresponding N_{As} LVM in InAs was studied by implantation of ^{14}N and ^{15}N into bulk crystals (Fig. 4). The result is similar to the same experiment in GaAs [13]. Two LVMs are observed at 443 ± 0.5 and $429 \pm 0.5 \text{ cm}^{-1}$ being due to ^{14}N and ^{15}N , respectively. The close correspondence to the same experiment in GaAs leaves no doubt that these bands are the LVMs of $^{14}\text{N}_{\text{As}}$ and $^{15}\text{N}_{\text{As}}$ in InAs, respectively. The frequency lowering amounts to 6.3% relative to GaAs. Cluster calculations have shown that already the inclusion of nearest neighbors leads to a very good approximation of the true LVM frequency [23]. Therefore a NIn_4 complex in InGaAsN should show a LVM frequency which is close to the frequency of N_{As} in bulk InAs. In a random

Fig. 3. Area projection of the ^{14}N content derived from NRA. The $\text{GaAs}_{1-x}\text{N}_x$ layer investigated has a thickness of $0.35 \mu\text{m}$ and a total chemical nitrogen content of 0.6%. The half width of the distribution is larger than the thermal oscillation amplitude of the matrix atoms ($\langle u_{\text{th}} \rangle \approx 0.1 \text{ \AA}$; indicated by white circle).

Fig. 4. FTIR absorption spectra of nitrogen-implanted InAs samples. The difference spectra shown were obtained after subtraction of the reference spectrum and a flat baseline. The inset shows from bottom to top the uncorrected spectra of unimplanted reference sample, the ^{14}N -, $^{14}\text{N}/^{15}\text{N}$ -, and the ^{15}N -implanted sample.

alloy with $y = 0.35$, the probability that 0, 1, 2, 3, and 4 nearest-neighbor indium atoms surround a nitrogen atom on the anion site, is 0.179, 0.384, 0.311, 0.111, and 0.015, respectively. From theory, these complexes have 9 different LVM frequencies which are essentially spread between the LVM frequencies of NGa_4 and NIn_4 [24]. No such bands are observed. Therefore, it is concluded that in the MBE grown InGaAsN MQW structures investigated nitrogen is surrounded only by nearest-neighbor gallium atoms.

4. Conclusion

Independent from the indium content, nitrogen in $\text{In}_y\text{Ga}_{1-y}\text{As}_{1-x}\text{N}_x$ layers grown by MBE is incorporated predominantly as substitutional N_{As} for $x < 0.02$. No redistribution or precipitation is found after annealing. Contrary to theoretical predictions, the local environment is determined by 4 nearest-neighbor gallium atoms.

Partly filled impurity band formation in compensated InP : Mn

S.B. Mikhlin*, K.F. Shtel'makh

*Experimental Physics Department, Saint Petersburg State Technical University, Russian Federation, Politechnicheskay 29,
195251 St. Petersburg, Russia*

Abstract

In this work, we present the results of the study of a compensated InP slightly doped with manganese. In this material, a large drop of resistivity (more than 10^4) with temperature decrease (120–100 K) has been observed. In order to clarify the mechanism of this effect we have undertaken the following: Hall effect and magneto-resistance measurements; magnetic susceptibility measurements; measurements of EPR and NMR; and optical absorption measurements. The main results of our investigations are (1) a peculiarity of NMR results corresponds with that of the Hall effect data and (2) non-paramagnetic behavior of an ^6S -state ESR signal in the temperature region 30–300 K. The main idea that explains these results exploits the non-symmetrical character of the manganese d^4 state. The impurity subband formation is due to the electron tunneling between the neutral non-relaxed manganese centers at temperatures below 120 K. We present some ideas in order to observe this effect in other A^3B^5 semiconductors doped with manganese. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: InP : Mn; Conductivity; NMR; ESR; Impurity subband

1. Introduction

Manganese in A^3B^5 compounds is one of the most interesting impurities. Many unusual effects have been observed in heavy doped materials [1–2], and mostly, they are due to the interactions of the d-shells of the manganese impurities. Commonly, the lesser the d-element concentration we have in samples, the weaker effects we observe. The particular effect for such compounds is observed in the slightly doped samples of InP : Mn. A giant resistivity drop has been observed [3] under the temperature decrease in the slightly doped highly compensated samples. In this work, we continue the investigation of this phenomenon paying special attention to (a) the results obtained by EPR and (b) the comparison of the Hall effect data with NMR data.

2. Sample preparations

The InP : Mn single crystals grown by a liquid encapsulated Chochralsky method have been used. Manganese has been added to the melt under the growth of the crystals. The very beginning of the ingot of n-type, the middle part of the ingot and its end have the conductivity of p-type (the distribution coefficient of $Mn < 1$). The total Mn content estimated by spectrochemical analysis has been varied over the range $5 \times 10^{16} - 2 \times 10^{17} / \text{cm}^3$ for samples having an unusual conductivity. The non-controlled donor concentration was about $2 \times 10^{16} / \text{cm}^3$, the sample contacts were made by In–Ni(3%) alloy.

3. Experimental results

The results of Hall effect measurements for two samples are shown in Fig. 1. The manganese acceptor ionization energy, defined by $n(T)$ curve in the temperature range from 300 to 160 K, is $E_{IH} = (200 \pm 5) \text{ meV}$. The same energy determined by the $\rho(T)$ curve is equal

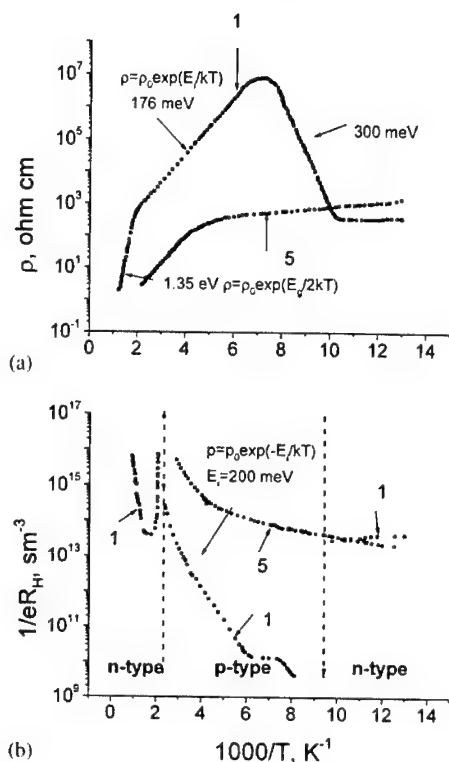

Fig. 1. Temperature dependencies of resistivity (a) for InP samples doped with different Mn concentrations: sample 1– $5 \times 10^{16}/cm^3$, sample 5– $5 \times 10^{17}/cm^3$, and carrier concentrations (b) for the same samples. Dashed lines show n–p–n conversion with temperature.

to 180 and 157 meV for the samples 1 and 5, respectively. The activation energy (1.35 eV) defined from $\rho(T)$ curve over the temperature range from 500 to 800 K correlates well with the forbidden gap energy E_g . A giant exponential drop of resistivity in the temperature range from 120 to 100 K has an activation energy of 300 ± 2 meV. In spite of p→n conversion, the carrier mobility changes the value from $70 cm^2/Vs$ only to 450 – $2500 cm^2/Vs$. It should be noted that the difference in electron mobility for the subband ($T < 100$ K) 450 – $2500 cm^2/Vs$ is much less than the corresponding value known for n-InP (77 K) $40,000 cm^2/Vs$. The magneto-resistivity has not changed significantly demonstrating a weak linear dependence in the temperature range from 200 to 77 K.

The optical absorption was measured at 300 K and the results were described well by Lukovsky's formula with the threshold $E_{i0} = 249 \pm 6$ meV. So, we have observed the difference $E_{i0} - E_{iH} \cong 50$ meV.

The results of EPR studies obtained for the temperature range 3.8–150 K are shown in Fig. 2. At low temperatures, the EPR spectrum consists of one broad line having the unresolved super fine

Fig. 2. The dependence of the relative magnetisation (circles) and the linewidth (triangles) on temperature for sample 1.

Fig. 3. The temperature dependence of the relaxation time T_1 for samples 1 and 5.

structure ($g = 1.99 \pm 0.03$). The relative magnetization which is proportional to a magnetic state population in 4–110 K temperature range increases exponentially with the activation energy $\Delta E = 22$ meV. This increase is defined mainly by the temperature variation of the linewidth. The shift of the spectrum to the range of lower magnetic fields has been observed for the temperature interval from 30 to 110 K (the g factor is 2.07 ± 0.03). The Curie-Weiss-law behavior with $\theta = -1.9 K$ has been observed for the magnetic susceptibility.

The temperature dependences of NMR relaxation time T_1 for two samples [4] are shown in Fig. 3. The NMR measurements were carried out on ^{115}In nucleus at 8 MHz. The value of T_1 has been varied as $T^{3.4}$ dependence for both samples (1 and 5) in the temperature range from 250 to 200 K. It is important to note that in the temperature range from 185 to 160 K the differences between the two samples have been revealed:

Fig. 4. An illustration of electron and hole transport in InP:Mn at different temperatures: 300 K—a (all manganese acceptors are ionized); 150 K—b (a part of manganese acceptors are ionized, the others are not) and 120 K—c.

for the heavy doped sample, T_1 continues to decrease, while for the low doped sample the value of T_1 increases as $T^{-8.3}$. For the last sample at temperatures less than 140 K, we have $T_1 \sim T^{-1.36}$. For temperatures less than 120 K we have observed the resonance frequency shift up to 1 G at 100 K which indicates the change of the relaxation mechanism [5].

4. Discussion

In contrast to the Mn impurity center in GaAs [6] for the similar center in InP we see quite significant Stocks shift. This clearly shows the non-central character of neutral Mn state (d^4 or $d^5 + \text{hole}$; the profile of Mn potential is shown by solid line in the central part of Fig. 4). We can explain the transport effects by the model which is illustrated in Fig. 4. At room temperature, all manganese centers are ionized (Fig. 4a) and there is no possibility for electron tunneling between them. With the temperature decrease up to ~ 150 K (Fig. 4b) one part of the Mn centers is ionized owing to the presence of the non-controlled shallow donors; the other part of the Mn centers is not ionized (strongly compensated samples have approximately equal

amounts of different Mn states; the compensation ratio $\alpha = \text{Nd}/\text{Na}$ is about 0.5). At this temperature (150 K), after the electron tunneling into non-central quantum well the d^4 Mn center relaxes into the state having the energy minimum produced by the d^5 state. The lattice relaxation is fast enough for the tunneling through the relaxed states produced under a strong phonon interaction. The further temperature decrease up to 100 K (Fig. 4c) leads to slowing down the processes of relaxation (Fig. 3) which in turn causes the electron tunneling between the non-relaxed Mn centers. The possibility exists whether the minimum of ^6S (d^5) state (dashed lines in Fig. 4) is above or coincides with the local maximum of d^4 state. The effect might be observed in GaAs:Mn having lower Mn concentration (10^{15} – $10^{16}/\text{cm}^3$) and the compensation ratio of about 0.5.

The conductivity at low temperatures (below 120 K), as a whole, exhibits an electron transport over the partly filled impurity subband. The electron mobility in the subband depends on the compensation ratio α (Nd/Na).

Abstract

The effects of mid-infrared (MIR) radiation on the photoluminescence (PL) of Yb^{3+} in p-type InP have been investigated in the wavelength range of 7–17 μm . It has been found that effective quenching of the luminescence intensity can be observed during the 4 μs length of the MIR pulse. The effect is explained by an Auger process of energy transfer between the Yb^{3+} excited state and free holes that are ionized from the acceptors in the host. From the dependence of the luminescence quench amplitude on the MIR wavelength, the acceptor is identified as Zn, which is the residual acceptor in the investigated sample. © 2001 Elsevier Science B.V. 1. Introduction

Rare-earth (RE) doped semiconductors show sharp and temperature-stable luminescence due to the RE intra-4f-shell transitions. These properties are attractive for fabricating light-emitting devices that are insensitive to the host environment. However, the luminescence efficiency rapidly decreases at elevated temperatures, the effect known as thermal quenching. A good understanding of the luminescence mechanisms and the excitation pathways of the RE ions in semiconductor hosts is necessary to overcome this problem.

The Yb-doped InP has been widely used to investigate the excitation and de-excitation processes of the REs in semiconductors, because the Yb ions in the InP form a single kind of luminescence center and have only one excited state. It is believed that the Yb ion gives rise to an acceptor-like electron (AE) trap at 30 meV below the conduction band [1]. The recombination energy of an electron localized at the AE trap with a free hole can be

transferred to the 4f-shell of ytterbium, which excites the ion from the $^2\text{F}_{7/2}$ to the $^2\text{F}_{5/2}$ state.

The majority of information currently available on the excitation and de-excitation mechanisms of the REs in semiconductors is based on results obtained from temperature quenching of photoluminescence (PL) intensity and the decay characteristics of the excited state. However, processes governed by larger activation energies can only be observed at higher temperatures and, therefore, lower PL intensity. Two-beam experiments, with an intense mid-infrared (MIR) beam operating parallel to an above-band-gap photoexcitation, can be used to avoid this problem and study selectively energy transfer processes at low temperature, where the PL intensity is still high [2].

2. Experiment

The experiments were performed at the free-electron-laser (FEL) users facility in Nieuwegein, the Netherlands. The samples under investigation were grown by liquid phase epitaxy (LPE). The InP:Yb layer was grown in a graphite sliding-boat system by a super-cooling process at high growth temperatures of up to

E-mail address: mklik@science.uva.nl (M.A.J. Klik).

800°C [3]. The Yb-concentration in the In growth melt was 0.2 percent mole fraction. The crystal exhibited p-type conductivity with a carrier concentration of $p = 7 \times 10^{16} \text{ cm}^{-3}$ at 300 K, with Zn being the residual acceptor. The samples were mounted inside an Oxford Instruments flow-cryostat and cooled down to 4.2 K. For band-to-band excitation, the samples were illuminated with the second harmonic (532 nm) of a Nd:YAG laser with a repetition rate of 5 Hz and a pulse length of 100 ps. A MIR ‘macropulse’ from the FEL provided the secondary excitation of a 4–6 μs length and an (adjustable) wavelength of 7–17 μm . The time delay between the Nd:YAG and the MIR pulses can be varied from –90 to +90 ms. A 7 μm cut-off filter was placed in the MIR beam to avoid penetration of shorter wavelengths from higher harmonics in the FEL. Both beams illuminated an area circular in shape and with a diameter of $\sim 5 \text{ mm}$. The emerging PL was gathered using a single grating monochromator and a near-infrared photomultiplier tube with a flat response from 300 to 1600 nm.

3. Results and discussion

Time-resolved measurements of the intra-4f-shell PL of Yb have been performed for various delay times Δt between the Nd:YAG pulse and the onset of the FEL pulse. Both enhancement and quenching of the PL signal could be observed, depending on Δt being positive (FEL before YAG) or negative.

3.1. Quench of luminescence

Fig. 1 shows the effect of the FEL pulse (depicted for reference at the lower part of the image) on the Yb^{3+} luminescence signal for a delay time of $\Delta t = -1, 2$ and

4 μs . It can be seen that quenching of the PL only occurs during the FEL pulse. This observation excludes thermal heating of the crystal lattice, which has a relaxation time of milliseconds, as a possible explanation for this intensity quenching effect. The ratio of the PL intensity observed with and without the FEL pulse, hereafter called the ‘quenching ratio’, is constant for all positive delay times for a given photon flux and a fixed wavelength of the MIR pulse. From this, we conclude that the quenching amplitude is proportional to the number of excited Yb^{3+} ions. The possible mechanisms that can explain this dependence are an optically induced back-transfer [4] effect and an Auger process, involving energy transfer from the excited Yb^{3+} ions to free or bound carriers. However, a back-transfer mechanism should not show saturation with the FEL photon-flux, as observed in our experiments. A localized Auger effect has been proposed as a PL quenching mechanism for the n-type InP:Yb as follows [5]. After excitation of the 4f-shell of Yb^{3+} by the recombination of the electron–hole pair, the AE trap becomes empty. These empty traps can again capture electrons from distant shallow donors. The energy of the excited 4f-shell can now be used to bring this electron to the conduction band in a localized Auger process, de-exciting the Yb^{3+} ion. This mechanism was used to explain the initial fast non-exponential decay observed in the InP:Yb intra-4f-shell luminescence in samples with high shallow donor concentrations [6]. For p-type materials, a similar model was proposed to explain the temperature quenching which involves holes captured at the acceptors receiving the relaxation energy of the 4f-shell. Similar to thermal ionization, the holes on these acceptors in the InP host can also be ionized by the MIR radiation. Therefore, the concentration of the bound holes will decrease with increasing FEL photon-flux. Taking into account our observation of an increase of PL quenching with increasing FEL photon-flux, it is more probable that a free-hole Auger process is responsible for the observed effect. It is reasonable to assume that a steady free-hole concentration exists during the FEL pulse, even at low temperatures. This concentration p will depend on the photon flux of the MIR pulse, the ionization cross-section of the shallow acceptor centers for a particular FEL wavelength and the shallow acceptor concentration in the sample. The intensity of the Yb^{3+} intra-4f-shell luminescence during the Auger quenching process can be described by

$$Y^*(t) = Y(t_1) \exp\left(\left(-\frac{1}{\tau} + C_A p\right)t\right)$$

$$\text{for } t_1 < t < t_2,$$

where t_1 and t_2 denote the time during which the FEL is on, $Y(t_1)$ is the luminescence intensity at time t_1 , τ is the effective lifetime of the Yb^{3+} excited state and C_A

Fig. 1. The quenching of the Yb^{3+} PL observed under Nd:YAG excitation for three different delay times of the MIR pulse. The relative position at $t = 0$ is indicated in the inset.

the Auger coefficient describing the energy transfer to the ionized holes p . Calculating the ratio between the integrated 4f-shell luminescence for a luminescent transient with and without the FEL, we find

$$\ln \frac{Y^*(t)}{Y(t)} = -C_A p(t_2 - t_1) \quad \text{for } t > t_2.$$

The dependence of the quenching on the MIR photon-flux is depicted in Fig. 2. For two different wavelength settings of the FEL, the dependencies can be fitted with an exponentially decaying curve with an offset of 0.29, meaning that the quenching saturates when 71 percent of the signal has disappeared. Following the assumed mechanism, this saturation appears as a result of the exhaustion of holes bound to the acceptors. As can be seen from the picture, the photon-flux dependence of the quenching effect can be described with a single exponentially decaying curve for a low photon flux. Therefore, we can calculate the expected dependence of the quenching ratio $Q(t) = Y^*(t)/Y(t)$ on the FEL wavelength:

$$Q(\lambda) = \exp(-C_A P(\lambda) N_A \sigma(\lambda) \tau_H (t_2 - t_1)) \quad \text{for } t > t_2,$$

with $P(\lambda)$ the photon flux of the FEL at wavelength λ , $\sigma(\lambda)$ the ionization cross-section of the acceptor as a function of the FEL wavelength, N_A the number of acceptors and τ_H the effective lifetime of a hole. Fig. 3a shows this dependence for a value $\sigma(\lambda)$ that is taken to be constant over the wavelength range of the scan (black) and the measured dependence (gray). The value of $\sigma(\lambda)$ can now be calculated as follows:

$$\sigma(\lambda) = -\frac{\ln Q(\lambda)}{C_A P(\lambda) N_A \tau_H (t_2 - t_1)}.$$

This is shown in Fig. 3b, with the curve normalized to the value at $\lambda_{\text{FEL}} = 11 \mu\text{m}$; we conclude a clear

Fig. 2. The quenching ratio as a function of the MIR pulse photon flux for two different MIR wavelengths. The dependence of the photon flux of the MIR pulse on the wavelength is depicted in the inset.

Fig. 3. (a) Calculated (black) and measured (gray) wavelength dependence of the quenching effect as a function of the MIR wavelength. (b) Ionization cross-section of the shallow acceptors as a function of the MIR wavelength. The data can be fitted with a curve corresponding to a trap characterized by a Coulomb potential and ionization energy of 70 meV.

dependence on the FEL wavelength, which has a maximum corresponding to an optical quantum energy of ~ 100 meV.

It has been shown that the photoionization cross-section of a trap can be described as [7]

$$\sigma = m \frac{(h\nu - E_D)^{3/2}}{(h\nu)^{3+2\gamma}},$$

with m a constant and $h\nu$ and E_D the energy of the ionizing beam and the trap ionization energy, respectively. The parameter γ depends on the form of the binding potential, and has a value between 0 (δ -like potential) and 1 (Coulomb potential). As illustrated in the figure, experimental data are best fitted to the ionization of a trap characterized by a Coulomb potential and (optical) ionization energy of $E_D \approx 70$ meV. This value is in good agreement with the position of the Zn acceptor as determined from the donor-acceptor/free-to-bound recombination observed in the same sample at 902 nm. It is therefore highly likely that in the present experiment, the MIR induced ionization of the Zn acceptor is observed.

For the regime where the quenching is saturated to 71 percent, we can estimate the hole concentration to be equal to that at room temperature. From the sample parameters of $2 \times 10^{20} \text{ cm}^{-3}$ for the Yb concentration and $7 \times 10^{16} \text{ cm}^{-3}$ for the free-hole concentration, we calculate an Auger coefficient value for the energy transfer to free holes of $C_A \approx 3 \times 10^{-12} \text{ cm}^{-3} \text{ s}^{-1}$.

3.2. Enhancement of luminescence

A considerable enhancement of the Yb^{3+} PL was found when applying the FEL before the band-to-band excitation with the Nd:YAG laser. The enhancement

effect was present for delay times up to -15 ms, which suggest a process with a long relaxation time. This could be due to the lattice heating and will not be discussed here.

A more complete treatise of the enhancement effect will be published elsewhere [8].

4. Conclusion

Two effects of the MIR radiation on the intra-4f-shell luminescence of the Yb in p-type InP have been investigated. It was found that an intense pulse of a FEL with a photon energy corresponding to 70–170 meV applied before the above-band excitation induced an enhancement of the intra-4f-shell PL intensity, most probably due to heating of the crystal matrix. Applying the FEL after the above-band excitation was found to quench the PL luminescence up to 70

percent. The observations were explained as a free-hole Auger process, for which we calculated an Auger coefficient of $3 \times 10^{-12} \text{ cm}^{-3} \text{ s}^{-1}$. The dependence of the quenching effect amplitude on the FEL wavelength suggests that the FEL induced ionization of the dominant acceptor Zn provides free holes participating in the Auger energy transfer.

Abstract

Acceptor atoms are experimentally observed to accumulate in the low bandgap layers of III–V heterostructures while being depleted from the high bandgap layers. Such acceptor segregation can be explained by considering the space charge neutrality condition in conjunction with hole segregation across the heterointerface. This approach reveals that the acceptor concentration ratio varies exponentially with valence band offset across the heterointerface, and further demonstrates that such acceptor segregation is suppressed by counterdoping the high bandgap layer with donor atoms. The same model can be used to explain enhanced acceptor solubility and suppressed acceptor diffusion in uniform composition samples that are counterdoped with donors. In each of these cases, the dopant concentrations (and hence dopant diffusion) are determined by the thermal equilibrium requirement that the Fermi energy be spatially invariant. © 2001 Elsevier Science B.V. Keywords: Acceptor diffusion; Acceptor segregation; Counterdoping

1. Introduction and experiment

Although III–V semiconductors offer extensive design flexibility compared to Si based devices, the benefits of III–V devices are often compromised by the rapid diffusion of p-type dopants, which makes p–n junction placement difficult to control. The present understanding of this rapid acceptor diffusion is based upon the charge states of the interstitial and substitutional acceptor atoms, and upon the native defects (group III self interstitials, III_i^0 , or group III vacancies, III_v^0) and free holes, h^+ , that mediate the exchange of acceptor atoms between interstitial and substitutional sites [1].

Since the diffusion rate of the interstitial group II atom, A_i^+ , is assumed to far exceed that of the substitutional group II atom, A_s^- , acceptor diffusion is thought to

occur through the conversion of group II atoms from substitutional sites to interstitial sites. Given the assumption that acceptors diffuse as interstitial atoms, Eqs. (1) and (2) demonstrate the dependence of acceptor diffusion on the hole (acceptor) concentration. In fact, it can be shown from Eqs. (1) and (2) that the acceptor diffusion coefficient varies as the square of the acceptor concentration. In contrast to this rapid acceptor diffusion, donors are thought to diffuse by a different mechanism in III–V semiconductors, resulting in a linear dependence of donor diffusion coefficient on donor concentration [2].

While the above discussion explains rapid acceptor diffusion in III–V semiconductors, a variety of related, yet less understood phenomena have been reported in the literature. These observations include acceptor segregation in III–V heterostructures, where acceptors diffuse from regions of low concentration into regions of high concentration [2–6], as well as reduced acceptor diffusion and enhanced acceptor incorporation in the presence of donor species [4,7–9]. While the effect of such donor species on acceptor diffusion in III–V semiconductors is clear due to its impact on the hole

E-mail address: pat.grillot@lumileds.com (P.N. Grillo).

concentration, its impact on acceptor incorporation is more subtle. We believe that this effect is fundamentally related to acceptor segregation, however, and it is our intent to demonstrate this connection in this paper.

To investigate these effects, six double heterostructure $(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$ samples were fabricated as described elsewhere [6]. These samples consisted of an n-type $\text{Al}_{0.5}\text{In}_{0.5}\text{P}$ lower confining layer, an $(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$ active layer (AL), and a p-type $(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$ upper confining layer (CL) all grown lattice matched on GaAs. Two different AL compositions (7% and 28% Al) and three different CL compositions (40%, 60%, and 100% Al) were used in this sample set. $(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$ is an ideal choice for such acceptor segregation studies since it is lattice matched to GaAs, and has a valence band energy that varies linearly with Al composition, x .

$$E_V(x) = E_V(0) - 0.241x. \quad (3)$$

2. Results

Various acceptor species, including Mg, Zn, Be, and Mn have previously been shown to segregate across a heterointerface in $(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}/\text{GaAs}$ samples, similar to that shown in Fig. 1 for the six AlGaInP samples described above [2,6]. Note that the extent of this Mg segregation increases with increasing change in Al composition, dx , across the AL/CL interface. This Mg segregation can be understood by considering the segregation of free holes in such heterostructures. In a uniform composition, non-degenerate semiconductor, the free hole concentration is given by

$$p = N_V \exp[-(E_F - E_V)/kT]. \quad (4)$$

These holes will segregate across a heterointerface, however, and accumulate in the layer of lowest hole energy. Using the thermal equilibrium requirement that $E_{\text{FAL}} = E_{\text{FCL}}$, it is straightforward to show that the hole concentration ratio between layers AL and CL is given by

$$p_{\text{AL}}/p_{\text{CL}} = (m_{\text{hAL}}^*/m_{\text{hCL}}^*)^{3/2} \exp(\Delta E_V/kT), \quad (5)$$

where m_{hAL}^* and m_{hCL}^* are the hole effective masses in the AL and CL, respectively, and $\Delta E_V = E_{\text{VAL}} - E_{\text{VCL}}$. From the space charge neutrality condition, $p + N_D^+ = n + N_A^-$, it is apparent that the spatial separation of the positively charged holes and negatively charged acceptors will give rise to an electric field across the heterointerface, and given sufficient thermal energy for the acceptors to diffuse, the acceptors should achieve a similar segregation ratio. In fact, for a p-type semiconductor where $p \gg n$, the space charge neutrality condition reduces to $p = N_A^- - N_D^+$, which implies that

$$N_A^- - N_D^+ = N_V \exp[-(E_F - E_V)/kT]. \quad (6)$$

Under the additional condition that $N_A^- \gg N_D^+$, the ratio of Eq. (6) for layers AL and CL gives

$$N_{\text{AAL}}^-/N_{\text{ACL}}^- = (m_{\text{hAL}}^*/m_{\text{hCL}}^*)^{3/2} \exp(\Delta E_V/kT). \quad (7)$$

For the case in Fig. 1, where both the AL and CL are p-type, and $N_A^- \gg N_D^+$, the acceptor concentration ratio at the AL/CL interface should obey Eq. (7). Using the compositional dependence of m_{h}^* for $(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$, the results of Eq. (7) and Fig. 1 are compared in Fig. 2.

$$m_{\text{h}}^*(x) = (0.62 + 0.05x)m_0. \quad (8)$$

This comparison in Fig. 2 reveals close agreement between experiment and theory, thus indicating that Eq. (7) accurately describes the acceptor segregation that has been reported in the literature by numerous authors [2–6]. This acceptor segregation can be suppressed, however, if the p-type CL is counterdoped with a donor species, as in Fig. 3. Such reduced acceptor

Fig. 1. Mg segregation in six $(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$ heterostructures with various compositional offsets, $dx = x_{\text{CL}} - x_{\text{AL}}$, across the AL/CL heterointerface.

Fig. 2. Comparison of the Mg segregation ratio from Eq. (7) and from Fig. 1.

Fig. 3. Counterdoping the p-type CL with a donor species (O or S) reduces acceptor segregation.

segregation in the presence of compensating donor species is similar to previous reports of reduced acceptor diffusion and increased acceptor incorporation in III–V semiconductors that are simultaneously doped with both a donor species and an acceptor species. The key to understanding these three effects (enhanced acceptor incorporation, reduced acceptor diffusion, and reduced acceptor segregation) is apparent from Eqs. (6) and (7), in conjunction with the acceptor solubility equation,

$$[A_S^-] = C_0 \exp[(E_F - E_A)/kT], \quad (9)$$

where E_A is the ionized acceptor energy level and C_0 is the acceptor solubility when $E_F = E_A$ [10]. For example, counterdoping a p-type semiconductor with donors tends to increase $E_F - E_A$ in Eq. (9), which increases the solubility of the substitutional acceptor, $[A_S^-]$, and hence increases acceptor incorporation. This increase in the solubility of the substitutional acceptors will decrease the conversion of group II atoms from substitutional sites to interstitial sites, however, thus reducing acceptor diffusion. For the case in Fig. 3, where the CL is doped with both donors and acceptors, while the AL is doped only with acceptors, the donors will reduce acceptor segregation since they will not diffuse during thermal processing. This effect can be quantified by revisiting Eq. (7), where N_{AAL}^-/N_{ACL}^- must now be replaced by $N_{AAL}^-/(N_A^- - N_D^-)_{CL}$. While the theoretical basis for this technique is therefore quite simple, counterdoping is useful in helping to control both acceptor segregation and p–n junction location. A heterointerface is not necessary for this discussion to apply, however, as can be seen by setting $\Delta E_V = 0$ and $m_{hAL}^* = m_{hCL}^*$ in Eq. (7). Thus, one obtains $N_{AAL}^- = (N_A^- - N_D^-)_{CL}$. In thermal equilibrium, space charge neutrality thus requires that a sudden increase

in donor concentration must result in a sudden increase in acceptor concentration, i.e., enhanced acceptor incorporation. Hence, the equilibrium requirement of spatially invariant E_F explains reduced acceptor diffusion and enhanced acceptor incorporation in both uniform composition and heterostructure III–V semiconductors that are counterdoped with donors. The same effect of enhanced acceptor incorporation and suppressed acceptor diffusion can thus be achieved either by using spatially varying composition, or spatially varying doping compensation.

3. Conclusions

Acceptor segregation in semiconductor heterostructures was shown to depend exponentially on the valence band offset at the heterointerface, as explained by the space charge neutrality condition in conjunction with hole segregation across the heterointerface. This model also explains reduced acceptor diffusion, reduced acceptor segregation, and enhanced acceptor incorporation in the presence of compensating donor species. Thus, donor counterdoping is a useful technique to help control p–n junction location in both uniform composition and heterostructure III–V devices.

Abstract

Er,O-codoped GaAs/GaInP double heterostructures (DHS:Er,O) were grown by organometallic vapor phase epitaxy and the intra-4f shell transitions of Er ions were investigated by photoluminescence (PL) measurements. Er,O-codoping was carried out with trisdipivaloylmethanatoerbium ($\text{Er}(\text{DPM})_3$) as an Er source and an addition of O_2 diluted with Ar to a reactor. Er,O-codoped GaAs (GaAs:Er,O) and GaInP layers were all grown at 550°C. In-depth profiles showed a uniform distribution of Er and O along the growth direction in the GaAs:Er,O active layer. The Er concentration in the GaAs:Er,O active layer was evaluated to be about $5 \times 10^{17} \text{ cm}^{-3}$. In 4.2 K PL measurements, DHS:Er,O sample exhibited Er–2O lines and the intensity was approximately three times stronger than that of GaAs:Er,O sample. This suggests that photoexcited carriers confined in the GaAs:Er,O active layer contribute effectively to excitation of Er. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Recently, there has been a wide scientific and technological interest in semiconductors doped with rare-earth (RE) impurities. RE isoelectronic impurity incorporated into semiconductors shows sharp and temperature-stable intra-4f-shell luminescence. This stability occurs because the filled outer 5s and 5p electron shells screen transitions within the inner 4f electron shell from interaction with the host. These properties are attractive for fabricating optical devices such as semiconductor lasers and optical amplifiers.

Special attention has been paid to Er ions in III–V semiconductors. Er doping in III–V semiconductors produces sharp luminescence at around 1.54 μm due to

intra-4f-shell transition from the first excited state ($^4\text{I}_{13/2}$) to the ground state ($^4\text{I}_{15/2}$) of Er ions. The emission is coincident with the minimum loss wavelength region of silica-based fibers. However, it has been found that Er ions doped in semiconductors show various fine structures, depending on doping conditions. This indicates that various kinds of Er centers with different atom configurations are formed simultaneously in a semiconductor because the fine structures of photoluminescence (PL) spectra reflect atomic configurations around Er ions. Selective formation of highly efficient Er centers for luminescence has been strongly desired for applications of Er-related luminescence to light-emitting devices.

Oxygen (O) has been found to play an important role in the production of efficient Er-related luminescent centers in GaAs. Er,O-codoped GaAs (GaAs:Er,O) produces a strong emission intensity and simple PL spectrum predominantly from one kind of Er center [1]. The Er center has been identified as an Er atom located

E-mail address: koizumi@mercury.numse.nagoya-u.ac.jp (A. Koizumi).

at the Ga sublattice with two adjacent O atoms (Er–2O center) [2]. The dependence of the PL spectra on growth temperature revealed the existence of a threshold growth temperature between 560°C and 580°C for Er incorporation into GaAs [3].

For optical device applications, Er should be introduced in confinement structures such as double heterostructures (DHS). In these structures, a GaAs:Er,O layer should be sandwiched between layers of a different semiconductor. The growth of $\text{Ga}_{0.51}\text{In}_{0.49}\text{P}$ (hereafter GaInP) is very attractive as an aluminum-free alternative to the conventional $\text{Al}_x\text{Ga}_{1-x}\text{As}$ -based materials. The aluminum-free GaAs/GaInP material system has advantages over the GaAs/ $\text{Al}_x\text{Ga}_{1-x}\text{As}$ material system, such as the low reactivity of GaInP to O.

In this paper, we report the results on fabrication of GaAs:Er,O/GaInP double heterostructures (DHS:Er,O) grown by organometallic vapor phase epitaxy (OMVPE) and its luminescence properties.

2. Experimental

GaAs:Er,O and DHS:Er,O samples used in this study were fabricated by a low-pressure growth system with a cold-wall quartz 4-barrel reactor [4]. The reactor pressure was 0.1 atm. The substrates were semi-insulating and Si-doped GaAs was oriented in the (100) direction. Triethylgallium (TEGa), trimethylindium (TMIn), tertiarybutylarsine (TBAs) and tertiarybutylphosphine (TBP) were used as sources. Er doping was carried out with trisdipivaloylmethanatoerbium ($\text{Er}(\text{C}_{11}\text{H}_{19}\text{O}_2)_3$, $\text{Er}(\text{DPM})_3$) as an Er source which was introduced into the reactor by a H_2 flow through the Er source cylinder. The rate of the H_2 flow was kept at 125 sccm. Ar gas with 38.4 ppm of $^{18}\text{O}_2$ was used as an additional O_2 source [3]. The O_2 content in growth ambient was set at 0.2 ppm.

Growth sequence for GaAs–GaInP interface used in this work is as follows. At the beginning of the layer growth, group-V gas was switched on first for 1 s and then group-III gas was switched on. At the end of layer growth, the group-III gas was switched off and growth was interrupted under the group-V gas to change TEGa flow rate and substrate temperature. In the growth of GaAs/GaInP DHS, we used two growth sequences (sequences A and B). Variations of gas flow and growth temperature for the sequences are schematically drawn in Fig. 1. In sequence A, GaInP and GaAs layers were grown at 580°C and 540°C, respectively. The temperatures were optimum growth temperatures for GaInP and GaAs:Er,O, respectively. In sequence B, GaAs and GaInP layers were all grown at 550°C. The crystal quality of the DHS was characterized by PL measurements at 77 K using the DHS having 200 nm-thick GaAs without Er,O-codoping and 200 nm-thick GaInP cladding layer.

Fig. 1. Variations of gas flow and growth temperature for (a) sequence A and (b) sequence B. In sequence A, GaInP and GaAs layers were grown at 580°C and 540°C, respectively. In sequence B, on the other hand, these layers were all grown at 550°C.

The measurements were carried out with a 514.5 nm beam of Ar-ion laser and an Si-type detector cooled by dry ice.

The structure and growth conditions of DHS:Er,O samples are as follows. All the samples were initiated by the growth of a 150 nm thick GaAs buffer layer at 610°C. Then, 1 μm -thick GaInP cladding layer, 1 μm -thick GaAs:Er,O active layer and 0.6 μm -thick GaInP cladding layer were grown with sequence B. These thicknesses were evaluated using undoped GaAs/GaInP DHS samples by a scanning electron microscope (SEM). As a reference sample, GaAs:Er,O was grown under the same doping conditions as the active layer of DHS:Er,O.

PL measurements of Er-related luminescence were carried out mainly with the samples directly immersed in liquid He at 4.2 K. The photoexcitation source was a CW-mode semiconductor laser diode, operating at 660 nm, with an incident power of 30 mW. The photon energy is below the band-gap of the GaInP cladding

layer, which enabled us to excite the GaAs active layer directly. The luminescence of the sample was dispersed using a 0.91 m grating monochromator and detected with a liquid nitrogen-cooled Ge p-i-n photodiode using a chopper and a lock-in technique.

For measurements of concentration profiles by secondary ion mass spectroscopy (SIMS), an O^+ ion and a Cs^+ ion were used as primary ions for Er and O, respectively.

3. Results and discussion

3.1. PL characterization of undoped GaAs/GaInP DHS

It is well known that making a high-quality GaInP–GaAs interface is very difficult via OMVPE growth because of the problems in As–P substitution and indium memory effects in reactor gas switching [5–13]. Characteristics of GaInP–GaAs interface strongly depend on the growth sequence for the interface. Fig. 2(a) shows 77 K PL spectrum of undoped DHS grown with sequence A. The spectrum has one peak at wavelength of 884 nm with the full-width at half-maximum (FWHM) of 54 meV. The wavelength of 884 nm is longer than those of the near-band-edge emissions from GaAs. Several researchers have also reported a similar broad peak at wavelengths between 850 and 930 nm in low-temperature PL spectra of GaAs/GaInP heterostructures [10,12].

Fig. 2(b) shows PL spectrum of a sample grown with sequence B. The spectrum is dominated by a peak

Fig. 2. 77 K PL spectra in undoped GaAs/GaInP DHS grown with (a) sequence A and (b) sequence B. An interface-related peak at 884 nm disappears in the sample grown with sequence B.

corresponding to the near-band-edge emission from GaAs. Also, a broad peak is weakly observed at 850 nm. This result suggests that photoexcited carriers injected in GaAs active layer recombine effectively in GaAs layer. Therefore, we can conclude that samples grown with sequence B have good quality of GaAs–GaInP interface compared with sequence A.

3.2. SIMS profiles in DHS:Er,O sample

DHS:Er,O samples were prepared with sequence B. In-depth profiles of Er, O, Ga and As for DHS:Er,O are shown in Fig. 3. For the DHS:Er,O sample, a distinct GaAs/GaInP DHS is seen in the SIMS profile. The profile reveals a uniform distribution of Er and O along the growth direction in the GaAs:Er,O active layer. Furthermore, in GaInP cladding layers, Er concentration is below the SIMS detection limit and O concentration is at the background level. Er concentration in GaAs:Er,O active layer, calibrated by using an Er-implanted GaAs sample, was evaluated to be about $5 \times 10^{17} \text{ cm}^{-3}$. This Er concentration was the same as GaAs:Er,O reference sample.

Fig. 3. In-depth profiles of Er, O, Ga and As for DHS:Er,O. Er and O are introduced selectively in the GaAs:Er,O active layer.

Fig. 4. 4.2 K Er-related PL spectra in (a) DHS:Er,O and (b) GaAs:Er,O. As shown by arrows, the spectrum is dominated by the Er-2O lines, indicating that an Er-2O center is selectively formed in GaAs:Er,O active layer of DHS:Er,O.

3.3. Er-related luminescence in DHS:Er,O

In Fig. 4, the 4.2 K $^4I_{13/2} \rightarrow ^4I_{15/2}$ Er-related luminescence from DHS:Er,O sample is compared with the luminescence from the GaAs:Er,O reference sample. The spectrum of DHS:Er,O shows identical positions of Er-related PL lines as in the GaAs:Er,O. Vertical arrows denote the Er-2O lines. This indicates that Er-2O centers are selectively formed in GaAs:Er,O active layers of DHS:Er,O. The intensity of the Er-related luminescence is approximately three times stronger than that of GaAs:Er,O sample. These results suggest that carriers photoexcited in the GaAs:Er,O region contribute effectively to excitation of Er because GaInP cladding layers confine the carriers and eliminate the surface recombination.

4. Conclusion

We have successfully grown Er,O-codoped GaAs/GaInP double heterostructures. In-depth profiles of Er and O exhibited a uniform distribution along the growth direction in the GaAs:Er,O active layer. The Er-related luminescence indicated that Er-2O centers

are selectively formed in GaAs:Er,O active layer. The intensity of Er-related luminescence was about three times higher than the GaAs:Er,O sample grown under the same doping conditions and Er concentration as in the GaAs:Er,O active layer of DHS:Er,O. These results are interpreted easily by the advantage of the DHS: confinement of photoexcited carriers and elimination of surface recombination.

Abstract

We investigated diffusion of Zn into GaP for P-rich conditions between 803°C and 1097°C to obtain information about the diffusion mechanism and the participating native point defects. Extremely diluted Zn sources were employed so as to avoid the formation of microstructural defects during diffusion. Penetration profiles measured by secondary ion mass spectroscopy and electrochemical capacitance–voltage profiling are in mutual accordance. The profiles are well described within the framework of interstitial-substitutional diffusion yielding not only Zn diffusion coefficients but also transport coefficients for the Ga-related native point defects involved. The latter data are compared with self-diffusion data related to the Ga sublattice in GaP. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

For GaAs there has been considerable recent progress in the understanding of diffusion processes [1] whereas diffusion in GaP is still poorly investigated. The progress for GaAs resulted to a large extent from experiments with hybrid impurities such as Cd [2] and N [3] which interchange between interstitial and substitutional sites under participation of native point defects. For obtaining quantitative information about the native-defect transport coefficients it proved to be advantageous when the hybrid impurity diffusion takes place under conditions virtually free of microstructural defects acting as sinks or sources for vacancies and self-interstitials.

In the present GaP study, Zn was chosen as hybrid impurity interacting with the Ga sublattice. Virgin GaP was exposed to Zn in diluted form so as to avoid

extreme diffusion-induced deviations from point-defect equilibria leading to agglomeration and precipitation processes [4,5].

2. Experimental

As base material we used $\langle 100 \rangle$ -oriented, nominally undoped GaP with a negligibly low density of dislocations and other extended defects. Samples of typically $6 \times 6 \text{ mm}^2$ were cut from 1 mm thick wafers and, after etching and cleaning, enclosed in Ar-flushed, evacuated quartz ampoules of about 3.5 cm^3 inner volume. Crushed Zn-diffusion-doped GaP was included as diffusion source while elemental phosphorus ($\approx 3 \text{ mg}$) was added to establish a P_4 partial pressure close to 1 atm. The ampoules were inserted into a pre-heated resistance furnace, isothermally annealed, and water quenched.

Zn depth profiles were monitored by secondary ion mass spectroscopy (SIMS) in a Cameca ims-6f instrument using O_2^+ primary ions and the state-of-the-art procedures characteristic of an in-depth analysis mode.

Conversion of mass counts to Zn concentration was based on calibration with a GaP:Zn implantation standard. The penetration depth scale was calibrated within about 5% error by measuring the SIMS crater depth with a surface profilometer. In each case, the Zn-induced hole distribution was analysed on a second GaP sample originating from the same diffusion ampoule by using a Biorad electrochemical capacitance–voltage (ECV) profiler.

Depth profiling was accompanied by transmission electron microscope (TEM) examination of a third, identically treated sample in a Philips CM30 instrument at 300 kV. Electron-transparent sample cross-sections were prepared using mechanical thinning followed by ion-beam thinning, thus allowing for the microstructural characterisation of the Zn-diffused regions.

3. Results

The TEM investigations showed the Zn-diffused samples to be free of crystal defects like the original GaP wafer material. This strongly supports the view that the diffusion proceeded under virtually ideal conditions in which only the sample surface acts as source or sink for point defects.

Figs. 1 and 2 show depth profiles arising from SIMS and ECV analysis after diffusion at 1097°C and 803°C, respectively. It is seen that the ECV-resolved hole concentration closely follows the SIMS-resolved Zn concentration. Within error tolerances this is consistent with the view that every Zn atom accommodated by the Ga sublattice (Zn_{Ga}^-) generates one electronic hole, and moreover, that the concentrations of interstitial Zn, i.e., Zn_{i}^+ , and the native point defects are negligibly small with respect to the Zn_{Ga}^- concentration.

Fig. 1. SIMS depth profile of Zn in GaP after diffusion at 1097°C and corresponding hole distribution from ECV analysis. Solid-lines fits are based on Eqs. (1)–(3).

Fig. 2. Similar to Fig. 1 but after diffusion at 803°C.

At the highest temperature investigated, i.e. 1097°C, the Zn profile reveals two distinct steps (Fig. 1). With decreasing temperature the near-surface profile step increases relative to the great-depth profile step, so that finally at 803°C, the latter is hardly visible anymore (Fig. 2). The varying 'kink-and-tail' profile shape is reproduced by an interstitial-substitutional (i-s) diffusion model involving Ga-related point defects as documented by the solid lines in Figs. 1 and 2. The same model also describes Zn diffusion into GaAs [6].

4. Modeling

The simplest i-s diffusion model which accounts for all relevant features of the measured profiles as well as for earlier data on Zn in GaP [7,8] involves neutral Ga interstitials (I_{Ga}^0) in addition to neutral and singly positively charged Ga vacancies ($\text{V}_{\text{Ga}}^0, \text{V}_{\text{Ga}}^+$), i.e.,

Electronic holes h participate in these quasi-chemical reactions in order to maintain local charge neutrality under the extrinsic doping conditions in the Zn-diffused region. Profiles were simulated by solving the partial differential equations based on Eqs. (1)–(3). In the actual simulation, reaction (3) was replaced by $\text{Zn}_{\text{i}}^- + \text{V}_{\text{Ga}}^+ \rightleftharpoons \text{Zn}_{\text{Ga}}^- + 3\text{h}$ being the 'sum' of Eqs. (2) and (3), i.e., for computational reasons. This does not affect the numerical results, provided that all reactions rates are chosen sufficiently large to virtually maintain local equilibrium among the point defects in terms of the mass action law. On the other hand, equilibrium and starting concentrations of the native defects were taken

low enough so that they do not explicitly enter the calculations. In this limiting case, the profiles are exclusively diffusion controlled.

In fitting the Zn_s profiles to the SIMS measurements (see solid lines in Figs. 1 and 2) we also obtained the depth distributions of the other species involved. This is illustrated in Fig. 3 for the 1097°C case. The vacancy annihilation and the self-interstitial generation by the Zn_i -to- Zn_s exchange leads to in-diffusion of V_{Ga}^0 , V_{Ga}^+ and out-diffusion of I_{Ga}^0 , respectively. This is also evident from Fig. 4 displaying the self-interstitial supersaturation ($S > 1$) and the corresponding vacancy undersaturation ($S < 1$). Here the local supersaturation parameter $S = C(x)/C^{eq}[p(x)]$ accounts for the dependence of the point-defect equilibrium concentration C^{eq}

Fig. 3. Point-defect profiles associated with the Zn_s solid-line fit in Fig. 1.

Fig. 4. Diffusion-induced super- or undersaturation of point defects associated with the Zn_s solid-line fit in Fig. 1.

on the local hole concentration $p(x)$ which, in turn, is practically equal to the Zn_s concentration C_s .

5. Diffusion coefficients

Fig. 5 exhibits the Zn-related diffusivity resulting from profile fitting in comparison to earlier data on GaP [4,7,8] and to similar data for GaAs [9]. Within the i-s diffusion model this 'effective' diffusivity is a complex quantity which comprises the individual diffusivity of Zn_i and the ratio of mobile (Zn_i) to immobile (Zn_s) atoms [2,4]. For the sake of comparability all data have been reduced to electronically intrinsic conditions ($p = n_i$) and a standard P_4 partial pressure of 1 atm [2,4]. Zn diffusion in intrinsic GaP is much slower than in p-type crystals (Fermi-level effect) while for the present 'P-rich' data the normalisation to standard pressure only leads to corrections of less than 15%. Altogether a fair agreement among the various GaP : Zn data is observed in Fig. 5, at least at the higher temperatures.

Fig. 6 compares the Ga-defect-related transport coefficients obtained in this work with the Ga tracer diffusivity D_{Ga}^T measured on GaP isotope heterostructures [10]. For instance, the I_{Ga}^0 -related data are given by the product of the I_{Ga}^0 diffusivity and the I_{Ga}^0 equilibrium concentration normalised to the Ga lattice-site density [2,4]. This represents the I_{Ga}^0 component of the ('overall') Ga tracer diffusivity (neglecting minor geometrical correlation effects). Fig. 6 reveals that the I_{Ga}^0 -related Ga diffusivity is not far from D_{Ga}^T but in any case below D_{Ga}^T , as it should be for a partial component. In contrast, the V_{Ga}^0 and V_{Ga}^+ components lie distinctly above D_{Ga}^T . This clearly violates the consistency among the different sets of data, which should

Fig. 5. Zn diffusion coefficient in GaP as a function of inverse temperature. Solid-line fit of present data: $9.5 \exp(-4.08 \text{ eV}/k_B T) \text{ cm}^2 \text{ s}^{-1}$.

Fig. 6. Ga diffusivity components of various native point defects in GaP deduced from Zn diffusion profiles in comparison with Ga tracer data D_{Ga}^{T} (solid line).

be all representative for intrinsic GaP under P-rich conditions.

6. Conclusions and outlook

The present work represents the first study of Zn diffusion in GaP under well-established defect-free conditions. A good description of the measured 'kink-and-tail' profiles is obtained within an i-s diffusion model involving I_{Ga}^0 , V_{Ga}^0 , and V_{Ga}^- . Profile fitting yields the Ga self-diffusion components related to these native point defects. However, a discrepancy with existing Ga tracer diffusion data becomes manifest. This discrepancy gives rise to the following questions: (i) Does the presently chosen diffusion conditions allow for thermal equilibrium among the various atomic species and point

defects to be established near the surface of heavily Zn-doped GaP? (ii) Does the Ga tracer data from the epitaxially grown isotope heterostructures correspond to the assumed equilibrium conditions? (iii) Are more complex mobile defects like e.g. $V_{\text{Ga}}-V_{\text{P}}$ divacancies involved in the diffusion process? These open questions will stimulate further research on diffusion in GaP and other III-V compounds.

Defect analysis and engineering in ZnO

Chris G. Van de Walle*

Xerox Palo Alto Research Center, 3333 Coyote Hill Road, Palo Alto, CA 94304, USA

Abstract

Zinc oxide has numerous applications in electronic and optoelectronic devices. Progress is currently hampered by a lack of control over electrical conductivity: ZnO is typically n-type conductive, the cause of which has been widely debated. A first-principles investigation, based on density functional theory, shows that native defects are unlikely to be the cause of the unintentional n-type conductivity. Detailed results for the oxygen vacancy show that it is a *deep* donor, and that its paramagnetic state is metastable. An investigation of likely donor impurities reveals that hydrogen acts as a shallow donor. Experimental results are discussed in the light of these new insights. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: ZnO; Doping; Native defects; Hydrogen

1. Introduction

Zinc oxide is a wide-band-gap semiconductor with numerous technological applications. Its strongly non-linear resistance makes it useful for varistors, its large piezoelectric constants enable applications in transducers, and its luminescence is used in phosphors. The properties of ZnO surfaces are sensitive to the presence of adsorbates, allowing applications as sensors. ZnO also exhibits large optical nonlinearities that can be exploited in optical devices, and a high thermal conductivity that makes it suitable as a substrate for growth of other materials, including GaN. ZnO has a band gap of 3.4 eV, very close to that of GaN. It thus lends itself to similar applications as GaN in optoelectronics, i.e., light emitting diodes and lasers in the blue and UV region of the spectrum. Efficient excitonic emission should be possible at room temperature due to the large exciton binding energy (60 meV). For comparison, the exciton binding energy in GaN is 25 meV. Optically pumped lasing has already been reported in ZnO platelets [1], thin films [2], clusters consisting of ZnO nanocrystals [3], and ZnO nanowires [4].

ZnO can be grown with a variety of techniques, including vapor-phase transport [5], hydrothermal growth [6], chemical vapor deposition (MOCVD) [7], laser ablation [8] and sputtering [9]. Most of these growth techniques produce ZnO that is highly n-type. This high level of n-type conductivity is very useful for some applications, such as transparent conductors—but in general, it would be desirable to have better control over the conductivity. In particular, the ability to reduce the n-type background and to achieve p-type doping would open up tremendous possibilities for device applications, in general, and for light-emitting diodes and lasers, in particular.

Because of its widespread occurrence, the unintentional n-type conductivity has conventionally been attributed to native defects. In particular, zinc interstitials (Zn_i) and oxygen vacancies (V_O) are expected to act as donors, and have frequently been invoked as the source of high carrier concentrations. Recent first-principles investigations [10,11], however, have revealed that none of the native defects exhibits characteristics consistent with a high-concentration shallow donor. Zinc interstitials have high formation energies and low diffusion barriers; they are thus unlikely to be incorporated in a stable fashion. As to oxygen vacancies, the main problem is that they are *deep* rather than shallow donors. We will discuss their electronic and structural

(C.G. Van de Walle).

properties in more detail in Section 3. Our numerical results on native defects are very similar to those of Zhang et al. [12], but we differ in the interpretation of those results.

Having concluded that native defects are *not* the cause of n-type conductivity, we must turn to extrinsic sources, i.e., impurities that are unintentionally incorporated. We have proposed that hydrogen is an excellent candidate for such an impurity [13]. Hydrogen is ubiquitous and very difficult to remove from the crystal growth environment. It also forms a strong bond with oxygen, providing a powerful driving force for its incorporation in the ZnO crystal. The resulting O-H bonding unit can, in fact, be regarded as a new type of dopant atom, the addition of the proton turning the oxygen into an element behaving more like fluorine. Details of the behavior of hydrogen in ZnO are discussed in Section 4. We will discuss experimental evidence for this proposal, including some very recent results for muonium, a pseudo-isotope of hydrogen [14,15].

2. Methods

Our first-principles calculations are based on density-functional theory (DFT) within the local density approximation (LDA) [16,17] and the pseudopotential plane-wave method [18]. We have studied both the zinc-blende (ZB) and the wurtzite (WZ) structure; the latter is the stable phase for ZnO. Properties of native defects and impurities are very similar in both phases; unless specifically mentioned, the results below are for WZ. Our defect and impurity studies were carried out in supercells containing up to 96 atoms for the WZ structure and up to 64 atoms for the ZB structure, using 2 or 3 special k-points in the irreducible part of the Brillouin zone. Effects of the Zn 3d states were included using the nonlinear core correction (nlcc) [19], using an energy cutoff of 40 Ry. Test calculations with explicit inclusion of the Zn 3d electrons as valence electrons (with a 70 Ry cutoff) confirmed the validity of the conclusions obtained with the nlcc.

Formation energies are foremost among the quantities that can be derived from the first-principles calculations. In equilibrium, the formation energy E^f determines the concentration c of the impurity in the semiconductor through the expression

$$c = N_{\text{sites}} \exp(-E^f/kT), \quad (1)$$

where N_{sites} is the number of sites in the lattice where the impurity can be incorporated, k is Boltzmann's constant, and T is the temperature. The formation energy of a hydrogen interstitial in charge state q is defined as

$$E^f(H^q) = E^{\text{tot}}(H^q) - E^{\text{tot}}(\text{bulk}) - \mu_{\text{H}} + qE_{\text{F}}, \quad (2)$$

where $E^{\text{tot}}(H^q)$ is the total energy derived from a supercell calculation for the hydrogen interstitial, and $E^{\text{tot}}(\text{bulk})$ is the total energy for a supercell containing only bulk ZnO. μ_{H} is the hydrogen chemical potential, i.e., the energy of the reservoir with which H atoms are exchanged. For presentation purposes, we will fix the value of μ_{H} to half the energy of an H_2 molecule. E_{F} , finally, is the Fermi level, i.e., the chemical potential of the reservoir with which electrons are exchanged.

Defects and impurities often introduce levels in the band gap; these *transition levels* can be obtained based on our calculated total energies. The transition level $\epsilon(q+1/q)$ is defined as the Fermi-level position for which the formation energies of charge states $q+1$ and q are equal. It is well known that DFT produces band gaps significantly smaller than experiment. When performing calculations for defects and impurities, the band-gap error introduces uncertainty in the position of the transition levels. We have addressed this uncertainty by comparing results obtained with the nlcc approach with those including full treatment of the 3d states. Such a comparison highlights the systematics in the behavior of the defect levels.

3. Oxygen vacancies

Our calculations show that the defects that are favored by Zn-rich conditions (V_{O} , Zn_i , and Zn_{O}) all behave as donors. Among these, the oxygen vacancy has the lowest formation energy. The oxygen vacancy has frequently been invoked as the source of n-type conductivity in ZnO. Our results indicate that this assignment cannot be correct. First of all, the formation energy of V_{O} is quite high under n-type conditions, even under Zn-rich conditions. More importantly, however, the oxygen vacancy is a *deep* rather than a *shallow* donor. Our calculated energies for the various charge states of V_{O} are shown in Fig. 1.

We find that the oxygen vacancy is a "negative- U " center, implying that $\epsilon(2+/+)$ lies above $\epsilon(+/0)$ in the band gap. As the Fermi level moves upward, the charge-state transition is thus directly from the $2+$ to the 0 charge state, at an energy about 2.7 eV above the valence band. It is clear that the oxygen vacancy cannot provide electrons to the conduction band in a stable manner, and therefore it cannot be a source of n-type conductivity.

An alternative way to express the negative- U behavior of V_{O} is to say that V_{O}^- is always higher in energy than either V_{O}^{2-} or V_{O}^0 , for any Fermi-level position. The positive charge state is thus never thermodynamically stable. This is an important finding, because it is the positive charge state, with its unpaired electron, that is detectable by magnetic resonance techniques. We thus

Fig. 1. Relative formation energies of various charge states of oxygen vacancies in ZnO as a function of Fermi level, obtained from DFT-LDA calculations. The formation energy of the neutral charge state is chosen as the reference, and the zero of Fermi energy is chosen at the top of the valence band. Transition levels and the value of U are indicated.

do not expect to observe an electron paramagnetic resonance (EPR) signal associated with V_O under thermodynamically stable conditions. It is, of course, possible to create oxygen vacancies in the + charge state in a metastable manner, for instance by excitation with light. Once generated, V_O^+ does not immediately decay into the 2+ or 0 charge state because of energetic barriers. These barriers are associated with the large lattice relaxations that occur around the oxygen vacancy; these relaxations are very different for the different charge states. We thus expect that at low enough temperatures EPR signals due to V_O^+ may be observed upon excitation, but if the excitation is removed and the temperature is raised, these signals will decay.

These theoretical results shed light on a rather confused situation in the experimental literature, which contains numerous reports of EPR measurements on oxygen vacancies. Space does not permit to provide a comprehensive list of references here, but the observations fall into two broad categories: those with g values ≈ 1.96 , and those with $g \approx 1.99$. In our opinion, it is the $g \approx 1.99$ signal that corresponds to V_O . Smith and Vehse [20] reported that the $g \approx 1.99$ center is light sensitive, and they also observed hyperfine interactions with the Zn neighbors of the vacancy. Similar hyperfine structure was observed by Gonzalez et al. [21]. Soriano and Galland [22] subsequently showed that illumination is necessary to observe the $g \approx 1.99$ line, and measured its decay after illumination is turned off. The light sensitivity and metastability are consistent with our results for the oxygen vacancy.

With regard to the $g \approx 1.96$ signal, a table with reported results up to 1970 can be found in Ref. [23].

Numerous authors have attributed the $g \approx 1.96$ line to oxygen vacancies; however, the evidence for this was much less convincing than in the case of the $g \approx 1.99$ line. It is much more likely that the $g \approx 1.96$ signal is associated with electrons in the conduction band or in a donor band, as originally proposed by Müller and Schneider [24].

4. Hydrogen in ZnO

The behavior of hydrogen in ZnO is highly unusual. In all other semiconductors studied to date, hydrogen has been found (theoretically as well as experimentally) to act as an *amphoteric* impurity [25,26]: in p-type material, hydrogen incorporates as H^+ , and in n-type material as H^- , always counteracting the prevailing conductivity of the material. This amphoteric behavior precludes hydrogen from acting as a dopant, i.e., from being a *source* of conductivity of the material. In ZnO, however, we find that hydrogen occurs exclusively in the positive charge state, i.e., it always acts as a donor.

The calculated formation energy for H in ZnO is displayed in Fig. 2. The lowest energy position for H^+ is at the bond-center (BC) site, with the antibonding (AB_O) position slightly higher in energy. H^0 and H^- are never stable in ZnO. We obtained this result by carefully checking the nature of the energy level in the band structure that is occupied with one or two electrons in the H^0 and H^- calculations. When H is at the AB_{Zn} site, the corresponding state is indeed localized near the H atom; but at this site, the energies of H^0 and H^- are always higher than that of H^+ , for all Fermi-level positions. When H is at the BC or AB_O sites, the occupied state turns out to be an *extended* state. Correct calculations for H^0 and H^- should therefore *not* place

Fig. 2. Formation energy of interstitial hydrogen in ZnO as a function of Fermi level, obtained from DFT-LDA calculations and referenced to the energy of a free H_2 molecule. Zero-point energies are included. The zero of Fermi energy is chosen at the top of the valence band.

electrons in this state—the actual hydrogen-induced energy level occurs higher in the band structure. When these considerations are taken into account, AB_O and BC are found to be even higher in energy than AB_{Zn} for both H^0 and H^- .

Coming back to the positive charge state, we note that H^+ prefers sites where it can strongly bind to an oxygen atom, forming an O–H bond with a length of 0.99–1.01 Å. Large lattice relaxations occur around the hydrogen interstitial; in particular, for the BC configuration the Zn atom moves outward over a distance equal to 40% of the bond length (0.8 Å), to a position slightly beyond the plane of its nearest neighbors. Simultaneously, the O atom moves outwards by 11% of the bond length. For the AB configuration, the relaxation of both Zn and O amounts to about 20% of the bond length.

Interestingly, such large relaxations are not unique to hydrogen. We have performed calculations for fluorine in ZnO, which we find to be a shallow donor, in agreement with experiment [27]. For F^+ , we find a large displacement of one of the neighboring Zn atoms away from the F atom, by 25% of the bond length; the F atom itself moves outward by 12% of the bond length. The bond between the F atom and one of its Zn neighbors is thus effectively broken. Such large relaxations are usually thought of as giving rise to deep (localized) states, but here we find that F still behaves as a shallow donor.

Hydrogen is, of course, a very plausible impurity to be unintentionally incorporated during growth or processing. Hydrogen can indeed be present in all of the growth techniques mentioned in Section 1. Experimental indications for hydrogen's behavior as a donor in ZnO were reported in the 1950s [28–30]. ZnO was, in fact, the first semiconductor in which the properties of hydrogen were systematically studied. Those results, however, went largely unnoticed during the upsurge in research activity on hydrogen in semiconductors that started about 30 years later. Thomas and Lander [29] observed an increase in n-type conductivity when H diffuses into ZnO. They actually used the measured conductivity as a function of temperature to derive the solubility of H in ZnO, and found the heat of the reaction $H_2 \times (\text{gas}) \rightarrow 2H^+ + 2e^-$ to be 3.2, or 1.6 eV per hydrogen. This value should correspond (within small correction terms) to the formation energy for H^- in ZnO as defined above and plotted in Fig. 2. For $E_F = E_c$, this formation energy is 1.56 eV, in very good agreement with the experimental value.

More recent experiments have also proved consistent with the nature of hydrogen as a donor. An increase in conductivity upon exposure to H_2 was observed by Baik et al. [31], and by Kohiki et al. [32] who introduced hydrogen by proton implantation followed by annealing at 200°C.

Finally, we mention the very recent results obtained with the muon spin rotation technique [14,15]. Muonium is a pseudo-isotope of hydrogen and is expected to exhibit a very similar electronic structure. Muonium in ZnO was observed to exhibit all characteristics of a shallow donor (including ionization behavior consistent with a level close to the conduction band, and a delocalized wave function), confirming the model that H acts as a shallow donor.

Controlling the background n-type conductivity is an essential first step towards achieving p-type doping. Nitrogen seems to be a good candidate acceptor, and, interestingly, the simultaneous incorporation of hydrogen may actually be beneficial for achieving p-type doping. As previously discussed in the context of p-type doping of GaN [33], hydrogen has the beneficial effect of increasing acceptor solubility and suppressing compensation by native defects. Whether this type of dopant engineering also works in the case of ZnO will depend on the binding and dissociation energies of N–H complexes, and on the barriers that need to be overcome to remove H from the vicinity of the acceptors during a post-growth anneal.

5. Conclusions

We have reported first-principles results for native defects and for hydrogen in ZnO. We argue that native defects do not provide a consistent explanation for the observed n-type conductivity, pointing towards an extrinsic impurity as the cause. In particular, we note that the oxygen vacancy is a *deep* acceptor, with metastable behavior consistent with the experimentally observed $g \approx 1.99$ EPR center. As to the nature of the unintentional impurity, we propose that hydrogen is a plausible candidate.

Electronic structure and ferromagnetism of transition-metal-impurity-doped zinc oxide

K. Sato*, H. Katayama-Yoshida

Department of Condensed Matter Physics, The Institute of Scientific and Industrial Research, Osaka University, 8-1 Mihogaoka, Ibaraki, Osaka 567-0047, Japan

Abstract

The ferromagnetism in ZnO-based diluted magnetic semiconductors (DMSs) is investigated based on the first principles calculations. The electronic structure of a ZnO-based DMS is calculated using the Korringa–Kohn–Rostoker method combined with the coherent potential approximation based on the local density approximation. The stability of the ferromagnetic state compared with that of the spin-glass state is systematically investigated by calculating the total energy difference between them. It is found that the ferromagnetic state is more stable than the spin-glass state in V-, Cr-, Fe-, Co- or Ni-doped ZnO without any additional carrier doping treatments. In the case of the Mn-doped ZnO, the spin-glass state is stable at a carrier concentration of 0%, but the ferromagnetic state is stabilized by the hole doping treatment. Analyzing the calculated density of states, it is proposed that the origin of the stabilization of the ferromagnetism is a double-exchange mechanism. © 2001 Elsevier Science B.V. 1. Introduction

Since the successful synthesis of ferromagnetic (In, Mn)As and (Ga, Mn)As, diluted magnetic semiconductors (DMSs) have been studied extensively to realize semiconductor spin electronics (spintronics) [1]. From the industrial viewpoint, it is indispensable to fabricate a ferromagnetic DMS whose Curie temperature (T_C) is higher than the room temperature. Recently, some new high- T_C DMSs were proposed based on experimental [2–4] and theoretical [5–9] studies. However, in order to develop spintronics as a practical technology, it is still necessary to explore a new candidate of functional DMS whose magnetic property is controllable by changing the external field or carrier concentration.

In this paper, the magnetism of (Zn, TM)O, where TM is one of the 3d-transition metals, is investigated

based on the first principles calculations [6–9], and a materials design of new ferromagnetic ZnO-based DMSs is proposed. Recently, ZnO attracted much attention because of its low cost, abundance and being environmentally friendly. Besides, ZnO has a wide band-gap energy of 3.3 eV and a large exciton binding energy of 60 meV, so it is one of the most promising substances for optoelectronics. Jin et al. experimentally showed that 3d-TM was soluble up to several tens (%) in ZnO [10]. Moreover, Joseph et al. successfully prepared p-type ZnO thin films by using the codoping method [11]. Therefore, it is worth investigating the carrier-induced ferromagnetism in the ZnO-based DMSs.

2. Calculation

The electronic structure of the TM-doped ZnO is performed based on the local spin density approximation with the parameterization by Moruzzi et al. [12]. The relativistic effect is taken into account by the scalar

relativistic approximation. We employ the muffin-tin approximation to describe the crystal potential, and the wave functions in each muffin-tin sphere are expanded with real harmonics up to $l = 2$, where l is the angular momentum defined at each muffin-tin sphere. Throughout the present calculations, lattice constants of doped ZnO are fixed to those of pure ZnO, which are $a = 3.24950 \text{ \AA}$, $c = 5.2069 \text{ \AA}$ and the internal coordinate $u = 0.345$ [13]. These lattice constants lead to muffin-tin radii of 0.941 and 0.855 \AA for the Zn and O, respectively, to touch muffin-tins with each other. Fifty-two independent k -points in the first Brillouin zone are used in the calculations.

ZnO-based DMSs are described within the framework of the coherent potential approximation to take disorder into account [14]. Owing to this treatment, it is possible to simulate the random distribution of the TM-impurities in an *ab initio* manner. In ZnO, the TM impurity has almost saturated magnetic moment. In this case, there are two directions of the magnetic moment along the quantization axis, i.e., up and down directions. Consequently, there are two self-consistent solutions for the electronic structure of the ZnO-based DMS. One is the ferromagnetic state in which all of the magnetic moments are parallel with each other. This is written as $(\text{Zn}, \text{TM}_x^{\text{up}})\text{O}$, where x is the concentration of the TM. The other is the spin-glass state in which the magnetic moments are pointed randomly at each other, therefore, the system has no magnetization. This is written as $(\text{Zn}, \text{TM}_{x/2}^{\text{up}}, \text{TM}_{x/2}^{\text{down}})\text{O}$. Comparing the total energy of the ferromagnetic state with that of the spin-glass state, it is possible to judge which state is more stable. Naively, the total energy difference between these two states corresponds to T_C .

3. Results and discussion

3.1. Chemical trend

First, the chemical trend in the magnetic states of the ZnO-based DMSs is investigated. The stability of the ferromagnetic state in $(\text{Zn}, \text{TM})\text{O}$ is studied as a function of atomic number of the TM impurity without any additional carrier doping treatments. V, Cr, Mn, Fe, Co and Ni are chosen as TM impurities. Calculated energy differences per one formula unit are shown in Fig. 1. The TM concentrations are 5%, 10%, 15%, 20% and 25%. As shown in the figure, $(\text{Zn}, \text{TM})\text{O}$ is ferromagnetic except for Mn, and the ferromagnetic states are very much stable. For example, in 25% V-doped ZnO, an energy difference of 1.36 mRy is expected. This is larger than the energy difference of 0.12 mRy in 5% Mn-doped GaAs. Taking into account that the T_C of 5.5% Mn-doped GaAs is 110 K [15], it is suggested that the ZnO doped with V, Cr, Fe, Co or Ni

Fig. 1. The stability of the ferromagnetic states in ZnO-based DMSs. V, Cr, Mn, Fe, Co or Ni is doped as a magnetic impurity. The vertical axis is the energy difference per one formula unit between the ferromagnetic and the spin-glass state. A positive energy difference indicates that the ferromagnetic state is more stable than the spin-glass state.

is a candidate for high- T_C ferromagnetic DMS. It has been shown experimentally that TM-doped ZnO is transparent with visible ray [10], therefore, a material design of transparent ferromagnets with ZnO-based DMSs is proposed based on the present calculations.

Recently, some experiments have been performed to confirm the present materials design, and the ferromagnetic behavior was reported in $(\text{Zn}, \text{Co})\text{O}$ [16] and $(\text{Zn}, \text{Ni})\text{O}$ [17] above room temperature. On the other hand, the ferromagnetic interaction was not detected by the magneto-optical experiment [18]. Further experimental efforts are needed to make the magnetism in the ZnO-based DMSs clear.

In order to elucidate the mechanism underlying the ferromagnetism in the ZnO-based DMSs, density of states (DOS) of the ZnO-based DMS is calculated. In Fig. 2, the total DOS per unit cell and partial DOS of 3d-states per atom at each TM site in the ferromagnetic state are shown. The TM atoms are doped up to 25%. The host valence band consists of Zn-3d bands, which appear at approximately 0.5 Ry below the Fermi level (E_F) as a peak whose width is 0.15 Ry, and O-2p band, which distributes from -0.4 to -0.2 Ry. Between the valence band and the conduction band, there are impurity-3d states. These impurity states show large exchange splitting, and they are gradually occupied as increasing the atomic number of impurity. Since the exchange splitting is larger than the crystal field splitting, all the TMs are in high spin states. In particular, the half-metallic DOS are realized in the V-, Cr-, Fe-, Co- and Ni-doped ZnO.

In Fig. 2(c), it is shown that the Mn impurity has d^5 electron configuration due to the substitution of Zn^{2+} by Mn^{2+} . In this case, it is suggested that the anti-ferromagnetic super-exchange interaction between the Mn ions stabilize the spin-glass state. On the other hand, V^{2+} , Cr^{2+} , Fe^{2+} , Co^{2+} and Ni^{2+} have d^3 , d^4 , d^6 , d^7

Fig. 2. Total DOS per unit cell (solid line) and partial density of d-states per TM atom at the TM site (dotted line) in (a) (Zn, V)O, (b) (Zn, Cr)O, (c) (Zn, Mn)O, (d) (Zn, Fe)O, (e) (Zn, Co)O and (f) (Zn, Ni)O in the ferromagnetic state. The TM atoms are doped up to 25%. The energy is relative to the Fermi energy.

and d^8 electronic configurations, respectively, therefore, 3d-band of the up- or the down-spin states are not fully occupied. In these cases, the 3d-electron in the partially occupied 3d-orbitals of the TM is allowed to hop to the 3d-orbitals of neighboring TM, if neighboring TM ions have parallel magnetic moments. As a result, the d-electron lowers its kinetic energy by hopping in the ferromagnetic state. This is the so-called double-exchange mechanism. Akai had already pointed out this mechanism in his paper on the magnetism in the (In, Mn)As [19]. From this point of view, the magnetism in ZnO-based DMSs is well-understood [6–9].

3.2. Carrier-induced ferromagnetism

In this section, the magnetism in the ZnO-based DMSs under carrier doping treatment is investigated [6,7]. Fig. 3 shows energy difference per one unit cell (two formula units) between the ferromagnetic and the spin-glass state in the Mn-doped ZnO as a function of the carrier concentration. In the (Zn, Mn)O, the spin-glass state is realized because there is no itinerant carrier and there is no contribution of the double-exchange interaction with the ferromagnetism. While increasing the hole concentration by N-doping, the ferromagnetic state is stabilized as shown in Fig. 3, namely, it is suggested that the carrier-induced ferromagnetism will be observed in the (Zn, Mn)O as is in the (Ga, Mn)As. Moreover, energy difference is large compared with that of the (Ga, Mn)As and a high- T_C is expected. On the contrary to the hole doping, electron doping does not stabilize the ferromagnetic state as shown in Fig. 3. The Zn atoms are substituted by Ga atoms to dope electrons. Due to the large hybridization of the N-2p states with

Fig. 3. Stability of the ferromagnetic state in Mn-doped ZnO-based DMSs as a function of the carrier concentration. The vertical axis is the energy difference between the ferromagnetic and the spin-glass state per two formula units. A positive energy difference indicates that the ferromagnetic states are more stable than the spin-glass state. The horizontal axis is the concentration of the holes or electrons.

the Mn-3d states, holes are itinerant in keeping with its d-character, therefore the kinetic energy is lowered so efficiently that the ferromagnetic state is stabilized by the double-exchange mechanism. On the other hand, the doped electrons never go into the Mn-3d states but into the host conduction band, therefore, the double-exchange mechanism does not work to stabilize the ferromagnetism.

The magnetism of the (Zn, Fe)O, (Zn, Co)O and (Zn, Ni)O under carrier doping treatment is also investigated [7]. In these systems, the ferromagnetic states are stabilized much more by electron doping. Considering that the n-type ZnO is easily available and the intrinsic defects such as the O-vacancies and Zn-interstitials work as a donor, it is concluded that the (Zn, Fe)O, (Zn, Co)O and (Zn, Ni)O are promising

candidates for high- T_C ferromagnets. It is also suggested that the (Zn,Mn, Fe)O, (Zn,Mn,Co)O or (Zn, Mn,Ni)O may show carrier-induced ferromagnetism under electron doping by adjusting the ratio of Mn to Fe, Co or Ni. It is strongly encouraged to perform the first principles materials design along this idea.

4. Conclusion

In this paper, the magnetism in ZnO-based DMSs is investigated by the first principles calculations. It is proposed that high- T_C ferromagnetic DMSs are available in V-, Cr-, Fe-, Co- and Ni-doped ZnO-based DMSs. As for controlling the magnetism of the ZnO-based DMSs, it is shown that the Mn-doped ZnO changes its magnetic states from the spin-glass state to the ferromagnetic state with increasing hole concentration. It is also shown that it is possible to raise the T_C of Fe-, Co- and Ni-doped ZnO by electron doping. Analyzing the calculated DOS, it is proposed that the mechanism to stabilize the ferromagnetic state is the double-exchange mechanism. We believe that new ideas which contribute to the spintronics will be triggered under the guidance of the present materials design.

I. Physikalisches Institut, Justus-Liebig-Universität, Heinrich-Buff-Ring 16, D-35625 Giessen, Germany

Abstract

Optically detected magnetic resonance shows that a broad, green emission band in ZnO at 2.45 eV originates from a spintriplet-recombination characterised by $g_{||c} = 1.984$ and $g_{\perp c} = 2.025$ (parallel and perpendicular to the crystallographic c -axis, respectively) and a zero-field splitting of $D = 260 \times 10^{-4} \text{ cm}^{-1}$. These parameters and the polarisation properties of the emission are very similar to the anion vacancies in CaO but not compatible with the Zeeman results on ZnO:Cu. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: ZnO; Optically detected magnetic resonance; Anion vacancies

1. Introduction

The recently reported ability to dope ZnO p-type has stimulated renewed interest in this material system as it opens novel possibilities for opto-electronic emitters in the blue spectral range [1]. Successful doping typically requires a detailed knowledge on the presence of residual impurities as well as on the formation of intrinsic defects because in many cases these defects counteract in the desired conductivity type or have severe influence on the optical properties of the material. For ZnO an emission in the green spectral range is commonly reported, but the responsible defects are not identified. Cu present in ZnO as a residual impurity was shown to create an emission in the green spectral range. The Cu related emission band exhibits a pronounced LO-phonon structure [2] and detailed structural information is available from Zeeman experiments [3]. But more frequently a broad emission is observed without any phonon structure, and intrinsic defects such as O- or Zn-vacancies are discussed as the origin of this recombination [4].

We used nominally undoped ZnO crystals and Cu doped ZnO crystals for our optically detected magnetic resonance (ODMR) investigation and will show that the origin of the unstructured green emission band in the undoped crystals is a spintriplet system with properties similar to the anion vacancies in CaO and MgO.

2. Experimental details

For our photoluminescence (PL) and ODMR experiments we used undoped n-type ZnO single crystals, which are commercially available from Eagle-Picher. The electrical properties are very similar to the samples investigated by Look et al. [5] which originates from the same supplier. The total shallow donor concentration is about $1 \times 10^{17} \text{ cm}^{-3}$. The ODMR measurements were carried out with a 24 GHz microwave bridge with 200 mW maximum output power. The sample is placed in a TE₀₁₁ resonator immersed in liquid helium at 1.5 K being part of a 4 T superconducting magnet system. The luminescence is excited by a HeCd laser (325 nm, 35 mW) and analysed by a 1/4 m monochromator in connection with a photomultiplier tube. A photo-elastic modulator (PEM) operating at 42 kHz in connection with a linear-polarizer allows to measure the difference of the left- and right-circular polarized components of the emitted light, i.e. the magnetic circular polarisation of the emission

(MCPE). Either, the frequency of the PEM or the amplitude modulation frequency of the microwave power served as the reference for lock-in detection.

3. Results

Fig. 1a shows the low temperature PL spectra of the undoped ZnO sample. At high energies bound exciton emissions are dominating, followed by LO-phonon replica. In the spectral range below 2.75 eV the unstructured “green” emission is visible. The intensity maximum of the emission is at 2.45 eV and its full width at half maximum is 320 meV. For comparison we show in Fig. 1b the emission of a Cu doped ZnO sample in this spectral range. Although the emission maximum of the Cu related band is almost the same as that observed in the undoped sample its LO-phonon structure is clearly visible and gives evidence that the two emissions are of different origin.

Following the temperature dependence of the green emission in undoped ZnO (Fig. 2) we find that it maintains its peak position up to 300 K, while the excitonic recombination follows the shrinkage of the bandgap of ZnO. This is a typical feature of a recombination within a localised defect, i.e. the ground and excited states are only very weakly coupled to the band properties of the host crystal.

In order to get further insight in the nature of the green emission in the undoped samples we performed ODMR. From ODMR experiments monitoring the emission intensity and modulating the microwave power spectra such as shown in Fig. 3a are obtained. In phase with the microwave modulation frequency two resonances are observed which enhance the emission

Fig. 1. Photoluminescence spectrum of undoped ZnO (spectrum (a)), the arrow indicates the peak position of the green emission on which the ODMR results were obtained. Spectrum (b) shows the phonon structured emission observed in Cu doped ZnO samples (5 K, 325 nm HeCd laser).

Fig. 2. Dependence of the peak position of the donor bound exciton (D^0X) and the 2.45 eV emission on temperature. The D^0X follows the shrinkage of the bandgap (drawn line), while the 2.45 eV emission maintains its peak position.

Fig. 3. (a) Optically detected magnetic resonance spectra measured on the 2.45 eV emission: (I) “in phase” with the microwave pulses, (II) “90° phase”. (b) Angular dependence of the ODMR signals ($0^\circ: B_0 \parallel c$, $90^\circ: B_0 \perp c$).

intensity of the order of 1% (spectrum I), while with a 90° phase shift a third signal is detected (spectrum II). This behaviour is observed independent of the microwave modulation frequency which could be set in the range from 30 Hz to 5 kHz.

These observations indicate that the two signals are of different origin. This is also evident from the orientation dependence of the resonances in respect to the magnetic field (B_0) (Fig. 3b). The small signal is isotropic and the corresponding g -value is $g=1.956$, i.e. the g -value of shallow donors in ZnO [6]. The reported small anisotropy of the signal originating from the wurtzite crystal structure of ZnO is not resolvable in our ODMR experiments. The two intense resonances show the characteristic angular dependence of a spin-triplet system ($S=1$). The orientation dependence is explained

by the solution of the spin Hamiltonian:

$$H = \mu_B \mathbf{B}_0 g \mathbf{S} + D[S_z^2 - 1/3S(S+1)] \quad (1)$$

with $g_{\parallel} = 1.984$ and $g_{\perp} = 2.025$, and a fine-structure splitting D of $D = 260 \times 10^{-4} \text{ cm}^{-1}$.

It was proven that the triplet resonances are detectable only in the energy range of the green emission. The shallow donor is also detectable in the excitonic range, but as an emission enhancing signal. This indicates that the shallow donor signal appears in the green emission by a spin dependent energy transfer process.

Further proof for the triplet nature of the recombination were obtained from ODMR experiments monitoring the MCPE (Fig. 4). The MCPE intensity shows the expected increase with increasing magnetic field, and the two triplet related resonances (marked by arrows) are now observed as MCPE enhancing and decreasing signals. At low magnetic fields an additional resonance is seen (labeled Level Anti-Crossing (LAC)). It is observable even without applying any microwaves during the measurement. The sign of the triplet resonances and the appearance of the LAC signals are fully explained by the level scheme shown in the inset of Fig. 4. The circular polarised components of the emission arise from the magnetic sublevels $| -1 \rangle$ and $| +1 \rangle$. Due to the selection rules for dipole transitions we can expect the $| 0 \rangle$ state to have the highest population, between the $| -1 \rangle$ and $| +1 \rangle$ levels we assume a thermalised population. The latter is justified by the intensity dependence of the MCPE in respect to B_0 , which follows the expected Brillouin-function behaviour for an $S = 1$ system. For the ODMR transition equalising the population differences between the $| +1 \rangle$ and $| 0 \rangle$ levels we thus expect a decrease of the MCPE and for the $| -1 \rangle$ to $| 0 \rangle$ an enhanced MCPE intensity. The LAC signal is caused by the "crossing" of the $| 1 \rangle$ with the $| 0 \rangle$ state and is a direct measure of fine

Fig. 4. Optically detected magnetic resonance spectrum detected on the magnetic circular polarisation emission (MCPE) of the 2.45 eV recombination in undoped ZnO. The inset shows the level scheme of the triplet explaining the magnetic resonance positions.

Fig. 5. Recombination model for the 2.45 eV recombination in undoped ZnO. For details see text.

structure splitting D . Further the observation of the LAC in connection with the sign of the ODMR resonances allows to determine the sign of D which is positive in our case. Remarkable is the strong influence of the shallow donor resonance on the MCPE of the triplet recombination. It gives further evidence that the population of the $| \pm 1 \rangle$ sublevels of the triplet is strongly dependent on the population of the magnetic sublevels of the shallow donor, i.e. a spin dependent energy transfer process.

Discussing the origin of the triplet emission we find similarities to the anion vacancies (F-centres) in CaO and MgO [7]. The ground state of the centre is a singlet state with two electrons, the neutral oxygen vacancy. Excitation with light leads to an excited singlet state, from which the electrons can relax into the triplet $S = 1$ state, causing the ODMR signals (see Fig. 5). The optical cycle is closed by radiative recombination back to the $S = 0$ groundstate. Such a cycle also explain our ODMR results as well as the constant emission energy of the green band with temperature. Above bandgap excitation seems to excite simultaneously the excitonic and the oxygen vacancy recombinations.

It should be noted that we failed to detect any ODMR signals on the LO-phonon structured emission in the Cu doped samples and that the ground and excited state g -values obtained by Zeeman spectroscopy for the green Cu emission are incompatible to the results obtained here.

In summary, our experimental results on the green unstructured emission band at 2.45 eV observed in undoped ZnO show that it is a spintriplet recombination with properties very similar to anion vacancies in ionic crystals. We thus conclude that it originates from the oxygen vacancy in ZnO.

First-principles study of the compensation mechanism in N-doped ZnO

Eun-Cheol Lee, Y.-S. Kim, Y.-G. Jin, K.J. Chang*

Department of Physics, Korea Advanced Institute of Science and Technology, 373-1 Kusung-dong Yusung-Ku, Taejeon 305-701, South Korea

Abstract

Based on first-principles electronic structure calculations for N-related and native point defects in Zinc Oxide (ZnO), we propose a mechanism for the compensation of N acceptors. As compared to a normal N_2 source, the use of an active plasma N_2 gas generally increases the N solubility limit, because the N chemical potential is enhanced. However, whenever a pure N source is used, N acceptors are greatly compensated by donor defects, which may explain the difficulty in achieving low-resistance p-type ZnO. Major compensating donors for N acceptors are found to be different at low and high N doping levels, and also depend on the type of N_2 gas source. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: ZnO; Nitrogen; Compensation

Very recently, zinc oxide (ZnO) has attracted much attention because of its wide applications for various optoelectronic devices. This material has a direct band gap of 3.3 eV and a large exciton binding energy of 60 meV, and efficient excitonic UV laser actions have been demonstrated at room temperature [1]. In addition, ZnO has been shown to be ferroelectric or antiferromagnetic by doping Li or Mn impurities [2,3]. For practical applications for optoelectronic devices based on p–n junctions such as laser diodes, both n- and p-type ZnO are needed. Undoped ZnO exhibits intrinsic n-type conductivity, and low-resistance n-type doping with electron concentrations as high as 10^{21} cm^{-3} was achieved [4]. However, it is very difficult to dope p-type in ZnO like other wide band-gap semiconductors, ZnSe and GaN. Although N is considered to be a good shallow p-type dopant among group IV acceptors [5], p-type doping in ZnO have been failed using a pure nitrogen source, while acceptor concentrations as high

as 10^{18} cm^{-3} have been obtained for ZnSe using an N_2 plasma source [6]. Thus, it appears that N acceptors are more strongly compensated in ZnO, compared with ZnSe. On the other hand, it has been reported that ZnO can be p-type by codoping N with H or Ga impurities [7,8].

In this work, we investigate the electronic structure of various defects including point defects and N-related defect complexes in ZnO using a first-principles pseudo potential method within the local-density-functional approximation (LDA). To find major compensating species for N acceptors, we calculate the formation energies and defect concentrations depending on stoichiometry and N gas source. For a normal N_2 gas as a doping source, N acceptors are mainly compensated by O-vacancies and N-acceptor–Zn-anti-site complexes. When an active N_2 plasma is used, the N solubility limit is increased. However, it is still difficult to achieve high hole carrier densities due to the compensation by N_2 molecules at O sites and $N_O-(N_2)_O$ complexes.

The total energies of native and N-related defects are calculated using the first-principles pseudopotential

method within LDA [9]. The details of our calculation method are given elsewhere [10].

Since atomic N has five valence electrons, it acts as an acceptor at a substitutional O site in ZnO. To find possible donor defects which compensate for N acceptors in ZnO, we first examine the electronic structure of native point defects such as vacancies (V_O and V_{Zn}), interstitials (Zn_i and O_i), and antisites (Zn_O and O_{Zn}). We find that Zn_i and Zn_O behave as a shallow double donor, because their single particle donor levels are mainly composed of the Zn-4s orbitals, which derive the conduction band minimum (CBM) state. Other calculations [11] also reported that Zn_i and Zn_O are shallow donors, and experimentally, Zn_i was shown to behave as a shallow donor [12]. The single particle donor level of V_O is located well below the CBM state, corresponding to the A_1 state of the Zn-4s orbitals in the neighborhood of V_O . In fact, since the V_O donor level is characterized by the hybridization of the Zn-4s and O-2p orbitals, V_O is likely to be a deep donor [10]. In the 2+ charge state of V_O , the surrounding Zn atoms are relaxed outward by 0.34–0.42 Å from the vacancy site. The $(2+/0)$ transition level of V_O is found to lie at 0.73 eV below the CBM state, indicating that V_O becomes a negative-U defect. We investigate various configurations of O_i , and find that a split-interstitial configuration gives rise to a donor level, while O_i at an octahedral site behaves as an acceptor, with the acceptor level lying close to the valence band maximum (VBM). Since V_{Zn} and O_{Zn} are acceptors, they are not responsible for the compensation of N acceptors. Compared with the measured value of 3.3 eV, the calculated LDA band gap of 0.90 eV is severely underestimated, similar to other calculations [13,11], which treat the Zn-3d electrons as valence states. Since the underestimation of the LDA gap may cause errors up to 2.5 eV in the formation energies of donors, we include a band gap correction for shallow donors such as Zn_i and Zn_O . For V_O , we test the transition levels lying between 1.1 eV above the VBM and the CBM, and find that main compensating species for N acceptors remain unchanged.

Besides the native donor defects, N-related donor defects play an important role in the compensation for N acceptors. Low-energy defect complexes between native defects and N acceptors are easily formed when the densities of individual defects are sufficiently high. We find that N_O - Zn_i , N_O - Zn_O , N_O - V_O , and N_O - O_i complexes are single donors. In these complexes, N_O - Zn_i and N_O - Zn_O have large binding energies of 1.06 and 1.52 eV, respectively, while the binding energies of N_O - V_O and N_O - O_i are 0.60 and 0.31 eV, respectively. Other important N-related donors are N_2 molecules at O sites [$(N_2)_O$] and N-acceptor- $(N_2)_O$ complexes [N_O -(N_2) $_O$]. For the $(N_2)_O$ complex, the N-N bond is very strong whereas interactions between the N and surrounding Zn atoms are extremely weak. Thus, two valence electrons

Fig. 1. Defect formation energies as a function of the stoichiometric parameter λ for the p-type condition ($\mu_e = 0$) when a normal N_2 gas source is used.

from the neighboring Zn atoms are almost in a nonbonding state, resulting in a double donor state. Similarly, an $(N_2)_{Se}$ molecule at an Se site in ZnSe is known to act as a shallow double donor [14].

We investigate the dominant compensating species for N acceptors under growth conditions using normal and plasma N_2 gas sources, assuming the p-type condition ($\mu_e = 0$). The stoichiometric condition of ZnO is represented by a single parameter λ , lying between 0 and 1 under extreme Zn- and O-rich conditions, respectively. Among the native donor defects, V_O or O_i has the lowest formation energy, depending on the stoichiometric condition. The formation energy of Zn_i is higher by 0.26 eV than for V_O . We find that the energy of the N_O - Zn_i complex is lower than those for N_O - V_O and N_O - O_i , independent of λ . However, going to the extreme Zn-rich condition, the energy of N_O - Zn_O becomes lower than for N_O - Zn_i . For defects purely composed of N atoms, N_O -(N_2) $_O$ becomes more stable than $(N_2)_O$, as the N chemical potential increases. Fig. 1 shows the formation energies of the N acceptor and several important compensating donors as a function of λ , when a normal N_2 gas source is used. In this case, μ_N is fixed to satisfy the extreme N-rich condition, i.e., $\mu_N = \mu_{N_2}/2$. The formation energies are drawn only for the lowest-energy states, i.e., the 1+ and 2+ charge states for single and double donors, respectively, which are expected to have no errors despite the underestimation of the LDA band gap. We find that V_O has the lowest formation energy for stoichiometric conditions of $\lambda < 0.8$, while O_i is stabilized for $\lambda > 0.8$. Since the maximum amount [N] of incorporated N impurities is below 10^{10} cm^{-3} for $\lambda > 0.62$ (see Fig. 2), O_i is not an important compensating donor when practical N doping levels are considered. For all the stoichiometric

Fig. 2. Maximum N solubilities are plotted as a function of λ for normal and plasma N_2 gas sources.

conditions, the formation energy of the N acceptor is always higher by 2.53–3.99 eV than that of the lowest-energy donor, which explains the difficulty in achieving low-resistance p-type ZnO. The $(N_2)_O$ is higher by 0.34 eV than for V_O . Under the extreme Zn-rich condition, the formation energies of N_O-Zn_O and N_O-Zn_i are higher by 0.02 eV and 0.62 eV, respectively, than for V_O . However, as μ_c increases, N_O-Zn_O and N_O-Zn_i become energetically more stable than V_O . For example, for $\mu_c = 1.0$ eV, the formation energies of N_O-Zn_O and N_O-Zn_i are lower by 0.98 and 0.38 eV, respectively, than for V_O . When we vary μ_c , which is in fact determined by the charge neutrality condition [10], we find that the major compensating donor is V_O at low N doping levels, while it is the N_O-Zn_O complex at high doping levels.

When an active N_2 source is used, the N solubility increases greatly under O-rich conditions, as shown in Fig. 2, where native point defects and N-acceptor-native-defect complexes are rarely formed. Then, the p-type doping efficiency is expected to increase. Under the O-rich condition of $\lambda = 0.6$, the maximum N concentration is found to increase from 10^{11} to $7 \times 10^{18} \text{ cm}^{-3}$. To simulate theoretically the active N_2 source, we choose μ_N , which is higher by about 1.5 eV than that for N_2 molecules ($\mu_{N_2}/2$). This N chemical potential is determined by assuming that equal amounts of N_2 molecules are in the ground and excited states; the energy of an excited N_2 molecule in the $^3\Sigma_u^+$ state is higher by 3.09 eV per N atom, as compared to the ground state ($^1\Sigma_g^+$). In this case, as shown in Fig. 3, $(N_2)_O$ or $N_O-(N_2)_O$ has the lowest formation energy, depending on λ . For all the stoichiometric conditions, the formation energies of the N acceptor is higher by 3.74–4.15 eV than for the major compensating donor. Thus, N acceptors are still compensated sig-

Fig. 3. Defect formation energies as a function of λ for the p-type condition ($\mu_c = 0$) when a plasma N_2 gas source is used.

nificantly, although the N solubility is increased using an active N_2 source. This result indicates that it is unlikely to enhance the p-type doping efficiency even if an active N_2 source is used. This feature also explains the failure of obtaining low-resistance p-type ZnO with a plasma N_2 source [15].

In conclusion, we find a mechanism for the compensation of N acceptors in ZnO, based on the first-principles pseudopotential calculations. When a normal N_2 gas source is used, N acceptors are mainly compensated by O vacancies at low N doping levels, while main compensating donors are defect complexes of N acceptors and native donors at high doping levels. An active plasma N_2 source increases the N solubility, however, the doping efficiency is found to be still low because of the compensation effect by N_2 molecules at O sites and $N_O-(N_2)_O$ complexes.

Abstract

We use In species as reactive codopants for N acceptors to realize p-type ZnS. We find a change in the impurity states of N acceptors between ZnS:N and ZnS:(2N, In), based on the calculated results using ab initio electronic band structure calculations: while we find highly localized states of N acceptors for ZnS:N, we verify delocalized states for ZnS:(2N, In). © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Blue-Ag emission; Codoping; ZnS

1. Introduction

In this paper, a materials design using a triple-codoping method for the fabrication of low-resistivity p-type zinc sulfide (ZnS) with blue-Ag emission is proposed in order to realize highly efficient blue-light-emitting diodes (LED) and blue injection-laser diodes (LD). ZnS has a large band gap of 3.68 eV at room temperature. Ag impurities, which are Zn-substituting species, are well known to be the blue-Ag center (usually called *activator*) [1,2]. In order to realize the blue emission of approximately 440 nm (2.81 eV), it is necessary to introduce donors as *coactivators* into ZnS films. Conductivity control is a necessary prerequisite for device applications: ZnS must be doped with acceptors in order to realize p-type ZnS films. To date, we have reported on p-type ZnS doped with N acceptors (ZnS:N) [3,4] and the triple-codoped p-type ZnS:(Ag, In, and N) [5]. Vapor-phase epitaxial (VPE) ZnS:(Ag, In, and N) layers were grown on semi-insulating (SI) GaAs(100) substrates with hydrogen carrier gas flow. The source material was a luminescent-grade unactivated ZnS powder [5]. Based on photoluminescence

spectra, an emission at 436 nm was found to be dominant for the ZnS:(Ag, In and N) layer and it shifted to a shorter wavelength with increasing excitation intensity; this is the characteristic feature of donor–acceptor pair-type recombinations [5]. Hall-effect measurements at room temperature revealed free hole concentration and mobility values of $(0.56\text{--}1.4) \times 10^{19} \text{ cm}^{-3}$ and $11\text{--}25 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, respectively, for ZnS:(Ag, In and N) [5]. Moreover, the hole concentrations of the triple-codoped layers did not show temperature dependence, indicating that the impurity bands are formatted [5].

Svob et al. have reported p-type ZnS:N with hole concentrations up to 10^{18} cm^{-3} [6]. They found that the energy levels of the N acceptors are slightly deep, about 0.19 eV above the valence band [6]. Sufficiently, high free hole concentrations at room temperature should be realized by the codoping method previously proposed by us [7–9].

The purpose of this study is to investigate the effects of In codopants on the N states of ZnS codoped with N and In species based on ab initio electronic band structure calculations.

2. Methodology

The results of our band structure calculations for ZnS crystals with zincblende structures were based on the

local density approximation (LDA) treatment of electronic exchange and correlation [10–12] and on the augmented spherical wave (ASW) formalism for the solution of effective single-particle equations [13]. For these calculations, the atomic sphere approximation (ASA) with a correction term was adopted. For undoped ZnS crystals, the Brillouin zone integration was carried out for 84-k points in an irreducible wedge and for 24-k points for doped and codoped ZnS crystals. For valence electrons, we employed the outermost s, p and d orbitals of Zn and S atoms and the outermost s and p orbitals of In and N atoms. The Madlung energy, which reflects the long-range electrostatic interaction within the system, was assumed to be restricted to the sum over monopoles.

We studied the crystal structures of doped and codoped ZnS under periodic boundary conditions by generating supercells having 64 atoms that contain the object of interest: (1) for ZnS:N, we replaced one of the 32 sites of S atoms with an N site; (2) for ZnS:In, we replaced one of the 32 sites of Zn atoms with an In site; (3) for ZnS codoped with N and In (ZnS:(N, In)), we replaced one of the 32 sites of S atoms with a N site and one of the 32 sites of Zn atoms with an In site. First, we calculated the total energy for all cases to be considered for ZnS:(N, In). Second, we determined the crystal structure of the material under the condition that the total energy is minimized. The total energy calculations show that the formation of a N–In pair which occupies nearest-neighbor sites in the crystal is energetically favorable. Finally, to determine the crystal structure of ZnS:(2N, In), we replaced one of the remaining 31 sites of S with another N site for ZnS:(N, In), as mentioned above. Under the same total energy condition as that of ZnS:(N, In), we determined the crystal structure for ZnS:(2N, In). We find that the formation of the cluster, N–In–N, which occupies nearest-neighbor sites, is energetically favorable based on the total energy calculations. The difference in the total energy between the crystal structure having the lowest total energy and the one having the second-lowest total energy, such as the In–N pair and another N which occupy the second-nearest-neighbor sites from the In sites, is 832 meV. In this treatment, we ignore the effects of relaxation due to the dopants.

3. Results and discussion

We show the total density of states (DOS) for undoped ZnS crystals as a standard reference, for ZnS:N, and for ZnS:(In, 2N), in Fig. 1. The S 3s states are included in the calculation as valence states, but those which are located between -12.04 and -13.31 eV are omitted in the Fig. 1. Energy is measured relative to the Fermi level (E_F). For undoped ZnS, zero energy

Fig. 1. Total DOS for (a) undoped, (b) N-doped and (c) (2N, In)-codoped ZnS. Energy is shown relative to the Fermi level (E_F).

indicates the top of the valence band. The calculated band gap of undoped ZnS is 2.08 eV. In general, the band-gap values calculated based on the LDA are less than the values obtained by optical experiments. Inaccuracy in determining the optical band gap has little influence on the present discussion.

Fig. 1(a) shows two groups in the valence band. The first group includes bands from -7.01 to -6.16 eV with strong d characteristics originating mostly from d states at Zn sites; the second group, located in the upper valence band above approximately -5.61 eV, mainly originates from the S 3p states. The letter A at -4.97 eV refers to a strong interaction between S p states and Zn s states. From approximately -3.5 eV to the top of the valence band, S p states mainly contribute to the DOS. The lowest conduction bands, antibonding states of the interaction stated above, have a strong Zn 4s contribution; there are charge transfers from Zn 4s to S 3s and 3p due to the mixing between the s and p states at S sites and the s states at Zn sites. As a result, the s and p states of the surrounding Zn shift the center of gravity of the local DOS at the S sites towards the lower energy region. In the following, we discuss the stability of the ionic

charge distributions in ZnS doped with acceptors or donors in terms of the change of electrostatic energy, the Madelung energy.

Fig. 1(b) shows that a hole is generated at the top of the valence band. The arrow in Fig. 1(b) at -0.1 eV refers to a sharp DOS peak induced by N doping. The peak originates in a very localized N-impurity state of which the center of gravity of the DOS at N sites shifts to a higher energy region due to the strong repulsive potential. This indicates that N doping generates a slightly deeper acceptor level above the valence band, which explains the experimental data well [6]. It is necessary that the N-impurity state change to a delocalized state for the realization of low-resistivity p-type ZnS.

For ZnS:(In, 2N), no sharp DOS peak is observed, as shown in Fig. 1(c). The arrow at -3.67 eV indicates a DOS peak resulting from the interaction between p states at S sites close to the In site and s states at the Zn site which occupies the nearest-neighbor site from the S sites and second-nearest-neighbor sites from the In atoms. We predict an increase in DOS around the corresponding energy regions for ZnS:(2N, In) compared with undoped and only N-doped ZnS, which can be verified by X-ray photoemission spectroscopy (XPS).

Next, we show the DOSs at N sites for ZnS:N in Fig. 2(a) and for ZnS:(2N, In) in Fig. 2(b) in order to illustrate what happens to the electronic structures, i.e., N-impurity states, near the top of the valence band upon In-codoping. They show that the impurity states at N sites change markedly from localized states, as presented in Fig. 2(a) for only N-doped ZnS, to delocalized states, as presented in Fig. 2(b) for p-type codoped ZnS. Based on the analysis of the DOS at the E_F for ZnS:N, we determined that the ratio of the partial DOS of p-states at the N sites to the total DOS at the E_F is 22%. The other DOS at the E_F is the sum of those at the S sites in the vicinity of the N sites. This indicates a small radius of the N-acceptor orbital. In other words, the Bohr radius of the N acceptors is very small, resulting in the high ionization energies due to the heavy effective mass of holes. In addition, the Madelung energy increased by 1.19 eV compared to undoped ZnS. We propose the following codoping method [7–9]: a deliberate codoping of the donors is essential for the delocalization of the impurity states at the acceptors and the stabilization of the ionic charge distributions in p-type highly doped semiconductors. The donor is not the p-type killer but a good by-player that activates acceptors, i.e., the reactive codopant.

From the calculations of the DOS at the E_F , we determined that the ratio of the sum of partial DOSs of p-states at the two N sites to the total DOS at the E_F is 9.2%; note that the partial DOSs not only at the S sites in the vicinity of the N sites but also at the more distant

Fig. 2. Decomposed DOS at the N sites for (a) ZnS doped with N only and (b) ZnS codoped with In and 2N species. p states at the N sites are presented.

S sites contribute to the total DOS at the E_F for ZnS:(2N, In). The simultaneous codoping of In as the reactive codopant and N as the acceptor into ZnS causes a large radius of the N-acceptor orbital, resulting in the low effective mass of the hole, which is a consequence of the broadened impurity band. Considering the acceptor ionization energy given by hydrogenic calculations based on the Bohr theory, it is reasonable to predict that the N-acceptor ionization energy will decrease very well. This explains experimental data for the Hall measurement of ZnS:(Ag, In, and N) [5].

There remains one further factor concerning the effects of the In-codoping on ZnS:N that we need to consider. The Madelung energy of ZnS:(2N, In) decreased significantly by 30 eV compared with that for ZnS:N, which is due to a large charge transfer from In to N atoms. This decrease causes stabilization of the ionic charge distributions of the codoped materials according to the ionic picture. We verified the same effects of the codoping on the N-acceptor states for ZnS:(2N, Ga) as those discussed above for ZnS:(2N, In). Taking into consideration that the ZnS under investigation does not have a wurtzite structure, which is favored by more ionic compounds, but a zincblende structure, the optimum amount of In or Ga to be codoped must be determined by further experiments.

4. Conclusion

Simultaneous codoping using N as the acceptor and In as the reactive donor is very effective for the fabrication of low-resistivity p-type ZnS. The main role of In is to delocalize the N-impurity state by improving the incorporation of N species into ZnS. We propose a model for ZnS:(Ag, In, and N) in which some of the In species act as *coactivators* with Ag *activators* and other In species act as *reactive codopants* with N acceptors.

Abstract

The assignment of muon spin rotation spectra to muonium counterparts of hydrogen shallow-donor states is reviewed in four II–VI widegap semiconductors, CdS, CdSe, CdTe and ZnO. The existence of extended electronic orbitals is argued from the muon–electron hyperfine parameters and supported by the new muon spin repolarization data for CdS and ZnO, characterizing the superhyperfine parameters on the sparse Cd and Zn dipolar nuclei. The possibility of a more tightly bound electron occupying a compact orbital is reasonably excluded in these materials, contrasting with the muonium state in HgO. © 2001 Elsevier Science B.V. Keywords: Hydrogen; Muonium; Shallow donors; ZnO; CdS

Muonium, the light pseudo-isotope of hydrogen, provides an experimentally accessible model for interstitial hydrogen in the II–VI compounds, as in other semiconductors. In these experiments, positive muons are implanted in the materials, where they are expected to adopt the same crystallographic sites as protons. In the Cd chalcogenides, and in ZnO, the implanted muons bind electrons weakly into a muonium state which has all the characteristics of a hydrogenic shallow donor [1–3]. The ZnO result is especially significant in that it confirms the theoretical prediction for protium [4]. Parameters characterizing the defect centres are given in Table 1. The muon–electron hyperfine parameters in these materials are exceedingly low, suggestive of an extended electron wave function. They were measured directly from the frequency splittings of the muon spin

rotation (μ SR) spectra in the Paschen–Back régime, i.e. in a magnetic field (applied transverse to the initial muon polarization) sufficient to decouple the muon and electron spins. The temperature dependences of the μ SR signals are also suggestive of ionization or dissociation of shallow-donor states: the activation energies deduced from the detailed temperature dependences of the signal amplitudes are fully consistent with estimates of these quantities in the effective-mass model.

Despite the overall consistency of this picture, the shallow-donor interpretation should be distinguished from a possible alternative model in which the electron wave function is more compact, but in which the spin density on the proton or muon is small due to some symmetry of the singly occupied orbital or special feature of the local bonding. Such a molecular–radical species would be tightly bound and unlikely to dissociate at cryogenic temperatures, but the disappearance of its

ZnO	500 ± 20	260 ± 20	38 ± 2	58 ± 6	52

^a The slightly anisotropic hyperfine interactions are expressed as isotropic (contact) and traceless (dipolar) components. The contact terms A_μ are four orders of magnitude smaller than the free-muonium hyperfine constant, which is isotropic and equal to 4.5 GHz. Donor depths are derived assuming equilibrium statistics; if the process involved is, in fact, direct ionization to the conduction band, the corresponding activation energies are about half these values. Shown for comparison are the shallow-donor depths calculated in the simple effective-mass model.

hyperfine signature might be attributed to spin-exchange depolarization, when extrinsic carriers are released by the ionization of other defects or impurities.

In this paper we present new information on the local electronic structure of the muonium states in ZnO and CdS, namely estimates of the transferred hyperfine interactions on surrounding nuclei. We refer to these as superhyperfine interactions, reserving the term hyperfine for the central muon, and probe them in these experiments by examining the muon response in low longitudinal fields, i.e. in magnetic fields applied parallel to the initial muon polarization. Host nuclei carrying a dipole moment are sparse in these materials but a measurement of how electron spin density is distributed over them would, in principle, allow a mapping of the wavefunction. In CdS, the relevant isotopes are ¹¹¹Cd and ¹¹³Cd, both with spin $\frac{1}{2}$ and a combined natural abundance of 25%. At below 1% abundance, ³³S can reasonably be neglected even though the muon may bond or antibond to S atoms. In ZnO, ⁶⁷Zn has spin $\frac{5}{2}$ and 4.1% abundance; no feature is likely to be observable in μ SR spectra from ¹⁷O in natural abundance although a study of samples enriched in this isotope would be worthwhile.

In Fig. 1, we show examples of the expectations of longitudinal-field measurements. The simulated quantity is muon polarization averaged over certain time windows and the field dependences are variously known as repolarization, decoupling or quenching curves. Fig. 1(a) is for ZnO and includes a simulation for muon–electron coupling alone (using the parameters of Table 1 from the transverse-field experiments). In this particular case, i.e. in the absence of nuclear superhyperfine couplings, it may be seen that the contact interaction is rapidly decoupled, in fields of order $A_\mu(2\pi/\gamma_e) = 0.02$ mT, and that the main feature is a level crossing resonance at a field close to $A_\mu(\pi/\gamma_\mu) = 1.8$ mT. The resonance occurs where the applied field “tunes out” the parallel hyperfine field, leaving the muon spin precessing around transverse components: an

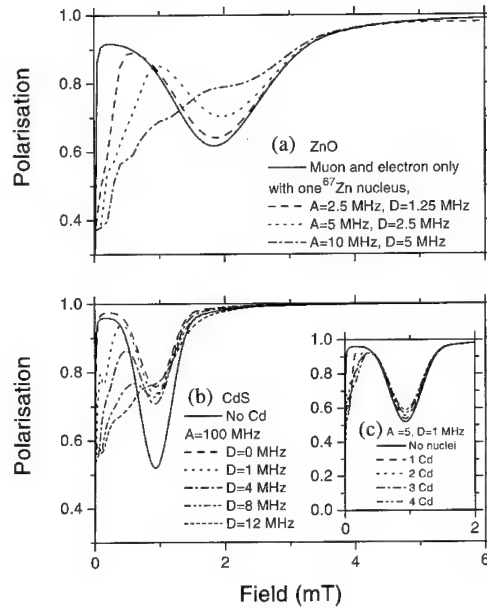

Fig. 1. Simulated muon spin repolarization curves for (a) ZnO and (b) CdS. The solid lines are in each case for the two-spin system of muon and electron only, using the hyperfine parameters as determined experimentally (Table 1). The broken lines are simulations including couplings to a third spin—⁶⁷Zn in (a) and ¹¹¹Cd in (b)—for various combinations of contact (A) and dipolar (D) superhyperfine couplings. The evolution of polarization is averaged over the time interval 0.8–8 μ s in (a) and 8–16 μ s in (b) for comparison with the experimental data of Fig. 2, where the level-crossing resonance is more prominent in the later time window. The inset to (b) shows an approximately \sqrt{N} dependence when more than one nuclear spin with identical coupling parameters are included.

oscillatory signal at the dipolar frequency is indeed visible in the time-domain signal at this field, confirming the parameters. Addition of superhyperfine interaction with, to begin with, a single ⁶⁷Zn nucleus, modifies both the strength of the resonance and the form the initial

repolarization. Simulations are shown for CdS in Fig. 1(b) and (c), where the corresponding level-crossing resonance falls around 0.9 mT. Varying the parameters independently, the strength of the resonance is found to be most sensitive to the nuclear contact interaction, up to a certain value beyond which there is no further suppression (roughly 100 MHz for CdS); the initial repolarization, on the other hand, is sensitive to both the dipolar component of nuclear coupling and to the number N of coupled nuclei, the decoupling field varying roughly as \sqrt{N} .

Experimental repolarization curves for comparison with these simulations are shown in Fig. 2. Here polarization is measured as usual via the muon decay asymmetry (a summary account is given in an accompanying paper [5]; these signals were recorded using the μ SR instrument at ISIS. Data for two different time windows are shown, indicating that the cross relaxation occurs on the timescale of several microseconds and that the hyperfine level-crossing resonance is more or less obscured by superhyperfine decoupling according to the time window and the relative strengths of the interactions in the two materials. Cross relaxation to the host nuclei is certainly mediated by the paramagnetic

electron, since measurements above the ionization temperature show close to maximum asymmetry throughout this field range. (That is, cross-relaxation due to purely nuclear–dipolar couplings in the diamagnetic or dissociated state is weak.) Below the ionization temperature it is apparent that the initial repolarization is more gradual than can be accounted for by the muon hyperfine parameters alone and that the form and strength of the level-crossing resonances, though visible, are greatly modified. The following conclusions can be drawn.

From the muon dipolar parameters D_μ in Table 1, we can state that major spin density (1 Bohr magneton) must either be localized at a distance greater than 1.5 nm from the muon in ZnO (and at even larger distances in the other materials) or else it must be distributed so that the dipolar term almost vanishes by symmetry. This already argues against a compact molecular radical comparable with bond-centred hydrogen or muonium in Si or GaAs, for which the (muonium) dipolar parameters are 51 and 86 MHz, respectively [6]. Such a compact state may well be formed in HgO, for which the hyperfine and ionization parameters are all quite large ($A_\mu = 15$ MHz, $D_\mu = 5$ MHz, $T_i = 150$ K, $E_d^{\text{exp}} = 300$ meV [7,8]) but we can reasonably exclude it for the materials of Table 1. For ZnO and CdS we can also state that all the muons which form paramagnetic centres are subject to the same superhyperfine interactions: there are not different components to the μ SR signals according to the isotopic abundance of near neighbours.

Pending simulations for a large number of coupled nuclei, with a distribution of coupling strengths, the following estimate of characteristic superhyperfine parameters may be made. We treat the electron spin density as distributed equally over N cations (spin density on the muon itself being so small). If the free-atom coupling for the cation in question is A_0 in frequency units and the isotopic abundance of the dipolar nuclei is c , there are cN interactions to be decoupled, each of A_0/N . The characteristic contact interaction to be decoupled may therefore be estimated as $\sqrt{cN}(A_0/N) = \sqrt{c/N}A_0$, and likewise for the dipolar parameter. We use the values of the atomic couplings given by Moreton and Preston [9]: $A_0 = 2087$ MHz for $4s(^{67}\text{Zn})$, 13650 MHz for $5s(^{111}\text{Cd})$. (The value for ^{113}Cd is not given by these authors, so we take it equal to that for ^{111}Cd ; dipolar parameters corresponding to occupation of the atomic p orbitals are not given for these elements.) Setting N equal to the number of cations contained within the effective Bohr radius of a hydrogenic shallow donor, we obtain parameters as in Table 2.

These values of $A_0\sqrt{c/N}$, the effective contact superhyperfine interactions to be decoupled, are not inconsistent with the repolarization curves of Fig. 2 if the accompanying dipolar parameters are about 5 MHz in ZnO and 10 MHz in CdS. The present model of

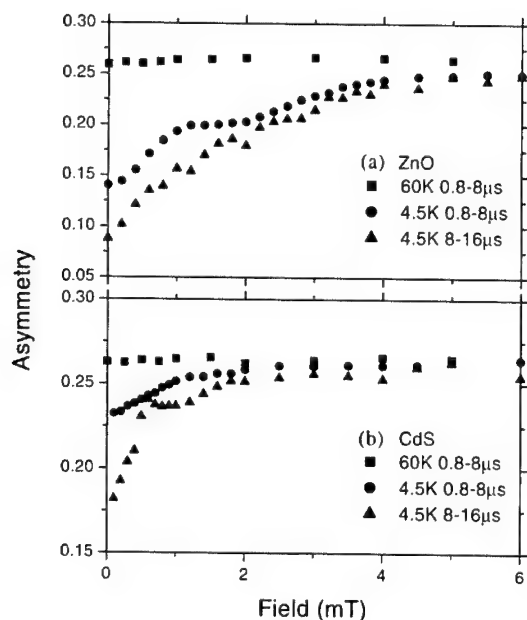

Fig. 2. Muon spin repolarization data for (a) ZnO and (b) CdS, for the temperatures and time windows indicated. The time evolution of muon polarization or relaxation function in response to Zeeman, hyperfine and superhyperfine interactions, is averaged over these time windows and expressed as muon decay asymmetry. According to the relative strengths of the various parameters, the level-crossing resonance due to the muon hyperfine interactions alone is more prominent in the early or late windows.

Table 2
Decoupling parameters as described in the text^a

	A_0 (MHz)	c	a^* (nm)	N	cN	A_0/N (MHz)	$A_0\sqrt{c/N}$ (MHz)
ZnO	2087	0.041	1.7	2000	80	1	10
CdS	13650	0.25	3.4	3000	750	5	100

^a a^* is the effective Bohr radius of hydrogenic shallow donors in these materials, calculated from electron effective mass and dielectric constant.

equivalent nuclear couplings is crude and these values may only indicate orders of magnitude. A more sophisticated treatment of the shallow-donor model would evidently involve simulating the muon response to a distribution of superhyperfine interactions. With individual couplings varying with radius according to a hydrogenic spin-density function $\rho(r) = \rho_0 \exp(-2r/a^*)$, the expected distribution has the form $P(\rho) \propto (\ln \rho)^2 / \rho$ (with limits $0 < \rho < \rho_0$). Our estimates of the typical couplings do suggest, however, that resonant cross-relaxation with the nearer nuclei (at fields given approximately by $(A_\mu - A_n)(\pi/(\gamma_{\text{mu}} - \gamma_n))$ [10]) may be accessible—the low isotopic abundance making these resolvable, if weak. Pending this more sophisticated treatment, and a search for these resonances, we can at least reasonably exclude a tightly bound and compact electronic orbital interacting with a small number of cation nuclei. The present data are more compatible with an extended electronic orbital.

Investigation of the defect structure in $\text{Cd}_{1-x}\text{Zn}_x\text{Te}$ by positron lifetime spectroscopy

M. Martyniuk, P. Mascher*

*Department of Engineering Physics, Centre for Electrophotonic Materials and Devices, McMaster University,
Hamilton, Ont., Canada L8S 4L7*

Abstract

Positron lifetime spectroscopy has been employed to explore grown-in defects in $\text{Cd}_{1-x}\text{Zn}_x\text{Te}$ (CZT) as a function of increasing Zn content. We find that with the increase of Zn content, both the average positron lifetime τ_{Avg} , and the lifetime in the bulk τ_{Bulk} , change smoothly from values typical for CdTe to those for ZnTe. In all samples, a defect-related lifetime component, τ_{D} , could be resolved with values decreasing from 347 ps in CdTe to 333 ps in ZnTe. This lifetime component is attributed to neutral $\text{Na}_{(\text{Cd,Zn})}\text{-V}_{\text{Te}}$ complexes in concentrations of around 10^{16} cm^{-3} , with a transition energy level below 0.19 eV above the valence band. It is established that these complexes are not connected to the p-type conductivity and their general characteristics are independent of the Zn content. This picture holds for stoichiometrically grown CZT and is independent of the growth method, whereas growth under Cd-rich conditions introduces a neutral impurity- V_{Te} complex with higher concentrations as compared to growth from stoichiometric conditions. © 2001 Elsevier Science B.V. 1. Introduction and experimental details

Certain characteristics of $\text{Cd}_{1-x}\text{Zn}_x\text{Te}$ (CZT) make this material an attractive choice for a variety of applications that stretch from X-, and γ -ray detectors to optoelectronic devices. Pre-existing native defects, however, appear to be the key reasons for its limited success to date. In this paper, we exploit positron lifetime spectroscopy (PLS) in an investigation aimed at exploring grown-in defects in CZT as a function of increasing Zn content, as well as the influence of growth conditions.

The series of samples used to study the influence of the Zn content were grown under stoichiometric conditions by the physical vapor transport technique (PVT) [1].

They exhibited p-type conductivity and consisted of CdTe, CZT ($x = 0.05, 0.10, 0.14, 0.15, 0.20$, and 0.25) and ZnTe. Two sets of samples were investigated: as-grown, exhibiting low resistivity, and annealed under cation overpressure, resulting in high resistivity. The values of various physical parameters are gathered in Table 1.

An additional three CZT ($x = 0.05$) samples, grown by the Bridgman method, were investigated to reveal the influence of the growth conditions. Two samples were grown under Cd-rich conditions; one was In doped ($[\text{In}] = 2 \times 10^{14} \text{ cm}^{-3}$), the other was undoped. The third sample was undoped and grown under stoichiometric conditions. PLS experiments were performed at temperatures between room temperature and 15 K. For details of the positron annihilation technique, the reader is referred to a recent comprehensive publication [2]. The details of the experimental set-ups as well as the data acquisition and analysis are given in Ref. [3].

Table 1

Physical parameters of samples used to study the influence of the Zn content in CZT. Annealing was performed for 2–3 weeks under Cd overpressure at 720°C for CZT and under Zn overpressure at 820°C for ZnTe [1]

Physical parameter	CZT	ZnTe
<i>As-grown crystals ('low resistivity')</i>		
Etch pit density (cm ⁻²)	5×10^3 – 10^4	5×10^3 – 10^4
Resistivity (p-type) (Ω cm)	10 – 10^2	10 – 10^2
Free hole concentration (cm ⁻³)	10^{16}	10^{16}
<i>After annealing ('high resistivity')</i>		
Resistivity (Ω cm)	10^6 – 10^7	10^6 – 10^7
Free hole concentration (cm ⁻³)	$< 10^{14}$	$< 10^{14}$
Net acceptor concentration (cm ⁻³)	$< 10^{16}$	$< 10^{15}$

2. Results and discussion

2.1. Influence of Zn content in CZT

All of the obtained spectra required at least two lifetime components to be satisfactorily fitted and the one-defect-type trapping model [4] was utilized in the calculation of the annihilation parameters. Fig. 1 shows the positron average, τ_{Avg} , and bulk, τ_{Bulk} , lifetimes for low and high resistivity samples as a function of Zn content. Both parameters change smoothly from values typical for CdTe to those for ZnTe as the Zn content increases. τ_{Bulk} values are in agreement with previously published results [5–8] and theoretical predictions [9,10]. No significant difference was detected between the low and high resistivity CdTe and CZT ($x \leq 0.25$) samples. In the case of ZnTe, the τ_{Avg} values for the two ZnTe samples are significantly different suggesting different characteristics of the open volume defects in low resistivity ZnTe, as compared to high resistivity ZnTe.

A defect-related lifetime, τ_{D} , was resolved in all samples, indicating the presence of open volume defects

in significant concentrations. Its dependence on the Zn content is shown in Fig. 2a for both low and high resistivity samples. No significant difference was found in the values of τ_{D} before and after annealing, but there is a linear decreasing tendency with increasing Zn content from around 347 ps for CdTe to 333 ps for ZnTe. This change is directly linked to the change in the unit cell volume. Specifically, positrons 'see' a slightly smaller open volume as the lattice constant decreases with the increase in Zn content.

The ratio of the defect-related lifetime to the bulk lifetime, $\tau_{\text{D}}/\tau_{\text{Bulk}}$, can be used to estimate the size of the detected open volume. A ratio of less than 1.20 is typical for an open volume of a monovacancy, whereas a ratio of 1.3–1.5 is typically assigned to an open volume of a divacancy defect. In our case, $\tau_{\text{D}}/\tau_{\text{Bulk}}$ is between 1.20 and 1.25 for CdTe and ZnTe, respectively, for both resistivity cases (Fig. 2b). Its assignment to a mono- or a divacancy thus is somewhat uncertain, but favors a monovacancy-size open volume.

Identification of the detected defects as isolated intrinsic monovacancies can be ruled out with the help of the band diagram shown in Fig. 3, where defect

Fig. 1. Positron average and bulk lifetimes as a function of the Zn content measured in CZT.

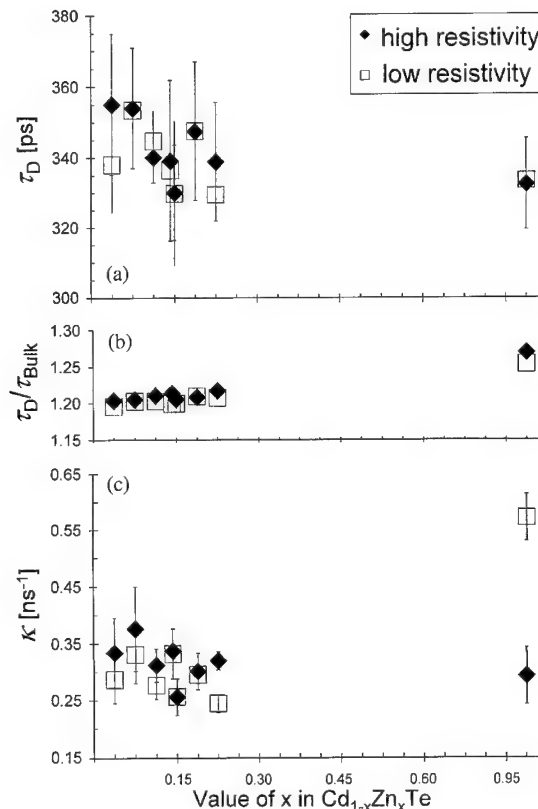

Fig. 2. Defect related lifetime (a), ratio of defect related lifetime to the bulk lifetime (b), and position trapping rate (c) as a function of the Zn content in CZT.

Fig. 3. Transition energy levels for isolated intrinsic anion, V_{Te} (—) and cation, $V_{(Cd,Zn)}$ (■) monovacancies in CdTe and ZnTe. Full symbols: experimental data; open symbols: experimentally not confirmed, based on chemical trends and theoretical predictions. Positions of the energy levels are shown to undergo a smooth transition in CZT with the increase in the Zn content [12]. Fermi levels for low and high resistivity samples are also indicated. The energy scale is relative to the top of the valence band in CdTe.

energy levels [12] are indicated. As a first step, we proceed with the elimination of positive vacancies (as they are not detectable with positron techniques), as well as the ones with energy levels in the valence band. This eliminates V_{Te}^+ , V_{Zn}^+ , V_{Cd}^+ , and V_{Cd}^0 . Negative vacancies can be ruled out as none of the annihilation parameters exhibited any marked temperature dependence down to 15 K, indicating that the defects are electrically neutral in all the samples. Thus V_{Cd}^- , V_{Zn}^- , and V_{Zn}^0 are ruled out. Consideration of the positions of the Fermi level, reported to be located at 0.19 eV and above 0.5 eV for low and high resistivity samples, respectively [1], eliminates V_{Te}^0 . If V_{Te} were present in our samples, it would be in its positive state in low resistivity samples and in the neutral state in high resistivity samples. This would result in very different behaviors of the annihilation parameters before (V_{Te}^+ not detected) and after (V_{Te}^0 'visible') annealing. Clearly, this hypothesis contradicts our results.

The amounts of the major contaminants (Na and K) in the source material (0.1–0.5 ppm) are high enough to be detectable by positron techniques, if associated with trapping centers. Na is a more likely candidate to play the role of the small atom discussed above, as its signature has been observed in these samples by photoluminescence [11]. Moreover, it is found as a contaminant by many crystal growers [12]. It is highly mobile and in our case it is reasonable to suppose that it will fill cation vacancies and pair up with V_{Te} . It is logical that V_{Te} instead of V_{Cd} should act as the unfilled vacancy. First of all, group I elements are more likely to fill group II rather than group VI vacancies, due to bond completion considerations. Furthermore, theoretical

analysis predicts similar τ_D/τ_{Bulk} ratios for cation vacancies in CdTe and ZnTe, whereas for V_{Te} it is to be significantly larger in ZnTe compared to CdTe [10]. The slightly larger τ_D/τ_{Bulk} ratio obtained for ZnTe than for CdTe (Fig. 2b) could be a manifestation of this prediction. The proposed defect complex would act as a single donor. To be in agreement with our results it must be in its neutral state. This puts the transition level below at most 0.19 eV (Fig. 3, the Fermi level position for low resistivity samples) above the valence band (or even in the valence band). Such a position of the defect level is quite likely if one considers the trends of vacancy related defects levels in the material system under discussion (Fig. 3).

Following the trapping model, the defect concentration can be determined from the trapping rate, κ (Fig. 2c). For CZT ($0 \leq x \leq 0.25$) we obtain a value of 0.3 ns^{-1} for both sample series. Using a trapping coefficient of $\sim 5 \times 10^{14} \text{ s}^{-1}$ we estimate the complex concentration to be around $2 \times 10^{16} \text{ cm}^{-3}$ for both the low and high resistivity cases. A distinct difference in κ , however, is observed between the low and high resistivity ZnTe samples. As a result of annealing, the concentration of the detected defects in ZnTe is reduced by 50% from $\sim 4 \times 10^{16} \text{ cm}^{-3}$ to $\sim 2 \times 10^{16} \text{ cm}^{-3}$.

Our results have shown no difference in the size (Fig. 2a and b) and concentration (Fig. 2c) of the monovacancies between low and high resistivity CdTe and CZT samples. The detected complex was unaffected by the performed temperature treatment. In ZnTe, however, annealing did reduce the concentration of the detected defect, but it is still present with a concentration of $\sim 10^{16} \text{ cm}^{-3}$. The reduction factor is at least two orders of magnitude too small to explain the reduction of the hole concentration upon annealing (Table 1). This is direct evidence that during annealing the detected defect complex does not take part in the process of increasing the resistivity, and is not connected to p-type conductivity.

2.2. Influence of growth conditions

Table 2 summarizes the results of our study on CZT ($x = 0.05$) grown under different conditions. As was the case in previous samples, low temperature measurements showed no temperature dependence from 15 K up to room temperature, indicating that we are still dealing with a neutral defect. It can be noticed that all of the positron annihilation parameters are in excellent agreement for samples grown from stoichiometric conditions. On this basis, we extend the above discussion and conclusions to undoped stoichiometrically grown CZT material.

The parameters obtained for Cd-rich grown CZT show that growth conditions significantly influence the

Table 2
Comparison of positron lifetime results for CZT ($x = 0.05$) grown under various conditions and/or methods

Growth conditions			Growth method	τ_{Avg} (ps)	τ_{Bulk} (ps)	τ_{D} (ps)	$\tau_{\text{D}}/\tau_{\text{Bulk}}$	κ (ns ⁻¹)	C (cm ⁻³)
Stoichiometric	Undoped		PVT	290 ± 2	285 ± 2	353 ± 16	1.24	0.31 ± 0.14	~2 × 10 ¹⁶
Stoichiometric	Undoped		PVT	290 ± 1	285 ± 1	354 ± 17	1.24	0.33 ± 0.11	~2 × 10 ¹⁶
Stoichiometric	Undoped		Bridgman	291 ± 1	286 ± 1	354 ± 12	1.24	0.26 ± 0.08	~2 × 10 ¹⁶
Cd-rich	Undoped		Bridgman	289 ± 1	284 ± 1	326 ± 8	1.15	0.56 ± 0.13	~4 × 10 ¹⁶
Cd-rich	[In] = 2 × 10 ¹⁴ cm ⁻³		Bridgman	288 ± 1	283 ± 1	330 ± 15	1.17	0.54 ± 0.19	~4 × 10 ¹⁶

end product. The $\tau_{\text{D}}/\tau_{\text{Bulk}}$ ratio clearly indicates that τ_{D} is related to a monovacancy. The value of τ_{D} is distinctively shorter than in the stoichiometric growth case, indicating that a defect of smaller open volume is dominant. It is generally accepted that Cd-rich growth does not produce V_{Cd} in significant concentrations. Rather, it will induce the presence of grown-in V_{Te} . It is reasonable that the open volume of V_{Te} is detected as a part of a neutral impurity complex. This picture is further supported by the observation that the obtained $\tau_{\text{D}}/\tau_{\text{Bulk}}$ ratio agrees more so with the theoretical predictions for V_{Te} rather than V_{cation} . The increase in κ , which reflects an increase in the defect concentration compared to stoichiometric growth, is also consistent with this picture, as more V_{Te} result from Cd-rich growth than from stoichiometric growth.

3. Conclusions

Electrically neutral defects were found in undoped, p-type CdTe, CZT, and ZnTe. Their general characteristics are independent of the Zn content. Isolated native monovacancies can be ruled out and a $(\text{Na}_{(\text{Cd}, \text{Zn})}-V_{\text{Te}})^0$ complex is proposed in concentrations of around 10¹⁶ cm⁻³, with a transition energy level below 0.19 eV above the valence band. The complex has been shown not to be connected to the p-type conductivity and is not affected by annealing under cation overpressure in CdTe and CZT ($x \leq 0.25$), but in ZnTe its concentration is reduced by a factor of two upon annealing.

Both stoichiometric and Cd-rich growth conditions result in grown-in neutral impurity- V_{Te} defect complexes. Cd-rich growth results in smaller open volumes with increased defect concentration as compared to stoichiometric growth.

Influence of the molecular spin–orbit interaction on the orbital triplet levels 4T_1 and 4T_2 of Mn^{2+} in ZnS

R. Parrot^{a,*}, D. Boulanger^b

Abstract

An extended cluster model is used to calculate the first-order spin–orbit (SO) interaction for levels 4T_1 (G, P and F) and 4T_2 (G, D and F) of Mn^{2+} in ZnS. The first-order SO interaction is analyzed by using the molecular SO interaction which involves the SO coupling constants of the electrons of the cation and of the ligands. The most striking effect of the molecular SO interaction is obtained for the fluorescent level $^4T_1(G)$. For this level, it is shown that, with respect to the results of the crystal-field (CF) model, the first-order SO interaction is roughly reduced by an order of magnitude. For the level $^4T_1(P)$, it is shown that the first-order SO interaction increases with respect to the results of the CF model, but strongly depends on the mixing parameters of the states 4T_1 . For levels $^4T_1(F)$ and $^4T_2(G, D \text{ and } F)$, it is shown that the first-order SO interaction is reduced by a factor of 0.5–0.7 with respect to the results of the CF model. © 2001 Elsevier Science B.V. 1. Introduction

The fine structure of the optical energy levels of d^5 ions, as Mn^{2+} and Fe^{3+} , has been studied in numerous II–VI and III–V compounds [1–13]. For example, the energy levels of Fe^{3+} have been studied in ZnS [1], ZnO [2], GaAs [3,4], GaN [5], and InP [6]. The fluorescent level and the levels at higher energy of Mn^{2+} have been studied in cubic and axial ZnS [7,8], in ZnSe [9–11], ZnTe [12], and also in GaP [13].

The fine structure of the fluorescent level $^4T_1(G)$ of Mn^{2+} in cubic symmetry as in cubic ZnS, ZnSe and GaP has long been interpreted by considering a strong Jahn–Teller (JT) reduction (corresponding to a Huang–Rhys factor S of approximately 2) of the spin–orbit (SO) interaction as given by the CF-model [14–16]. First, this model failed to account for the fine structure of the levels $^4T_2(G)$ of Mn^{2+} in ZnS and in ZnSe [17,18].

Second, the previous interpretation of the fine structure of the fluorescent level $^4T_1(G)$ of Mn^{2+} in cubic ZnS has recently been questioned [19,20]. Very surprisingly, a careful analysis of the fine structure lines led us to consider that the first-order SO interaction should be very strongly reduced with respect to that given by the CF-model.

The aim of this paper is to compare the molecular SO interaction for the orbital triplet levels $^4T_1(P)$, $^4T_1(F)$, and $^4T_2(G)$, $^4T_2(D)$, $^4T_2(F)$ of Mn^{2+} in ZnS to the SO interaction restricted to electrons d of the configuration d^5 following the CF-model of Sugano et al. [21].

2. Molecular orbitals and molecular spin–orbit interaction in orbital triplet states

In the proposed molecular model for the tetrahedral MnS_4 cluster, the mono-electronic molecular orbitals $4t_2$ and $2e$ of the half-filled shell are written in terms of the mono-electronic orbitals of the electrons $3d$ and $4p$ of the cation, and in terms of the orbitals σ_s , σ_p , and πp

E-mail address: robert.parrot@libertysurf.fr (R. Parrot).

of the ligands as:

$$|t_2\gamma\rangle = a^d|dt_2\gamma\rangle + a^p|pt_2\gamma\rangle + a^s|\sigma st_2\gamma\rangle \\ + a^{\sigma p}|\sigma pt_2\gamma\rangle + a^{\pi p}|\pi pt_2\gamma\rangle,$$

where $\gamma = \xi, \eta$ or ζ refers to the components of the molecular monoelectronic level $4t_2$, and

$$|e\gamma'\rangle = b^d|de\gamma'\rangle + b^{\pi p}|\pi pe\gamma'\rangle,$$

where $\gamma' = \theta$ or ε refers to the components of the molecular monoelectronic level $2e$.

The first-order SO interaction is calculated by using the molecular SO interaction H_{SOM} defined by Misetich and Buch [22]:

$$H_{\text{SOM}} = \sum_q \sum_i \tau_u^i s_q^i,$$

where τ_u^i is the molecular angular momentum of electron i and where s_q^i are the complex components of the spin operators. $u = x$ or y if $q = \pm 1$ and $u = z$ if $q = 0$.

The relevant matrix elements $\zeta_{et_2} = (i/2)\langle e|\tau_z|t_2\xi\rangle$ and $\zeta_{t_2t_2} = -i\langle t_2\xi|\tau_z|t_2\eta\rangle$ are given in terms of the mixing coefficients of the monoelectronic wave functions and of the SO constants of the metal and of the ligands by

$$\zeta_{et_2} = a^d b^d \zeta_M + [1/(2\sqrt{3})]b^{\pi p}(a^{\pi p} + a^{\sigma p}\sqrt{2})\zeta_L$$

and

$$\zeta_{t_2t_2} = (a^d a^d - a^p a^p)\zeta_M + a^{\pi p}(a^{\sigma p}\sqrt{2} - a^{\pi p}/2)\zeta_L.$$

3. First-order molecular so interaction for levels ${}^4T_1(\text{G, P, F})$ and ${}^4T_2(\text{G, D, F})$ of Mn^{2+} in ZnS

For the calculation of the molecular orbitals, the interatomic distance Mn–S of 4.56 a.u. is chosen to be slightly greater than the interatomic distance Zn–S of 4.41 a.u. to account for a slightly greater covalent radius of Mn than of Zn. The effective charge of manganese is $Q_{\text{Mn}} = 0.973$, the effective charge of the lattice is $Q_{\text{lat}} = +0.80$ and $Dq = -420 \text{ cm}^{-1}$.

The calculated monoelectronic wave functions are:

$$|4t_2\gamma\rangle = 0.898|dt_2\gamma\rangle - 0.132|pt_2\gamma\rangle - 0.120|\sigma st_2\gamma\rangle \\ + 0.464|\sigma pt_2\gamma\rangle - 0.364|\pi pt_2\gamma\rangle$$

and

$$|2e\gamma'\rangle = 0.863|de\gamma'\rangle - 0.611|\pi pe\gamma'\rangle.$$

It can be noted that the monoelectronic wave functions $|4t_2\gamma\rangle$ are strongly coupled to the wave functions $|dt_2\gamma\rangle$, $|\sigma pt_2\gamma\rangle$, and $|\pi pt_2\gamma\rangle$, and that the coupling to the wave functions $|pt_2\gamma\rangle$ and $|\sigma st_2\gamma\rangle$ is relatively small. The wave functions $|2e\gamma'\rangle$ are strongly coupled to the wave functions $|de\gamma'\rangle$ and $|\pi pe\gamma'\rangle$. These values for the coupling coefficients of the

monoelectronic wave functions are in agreement with those obtained in covalent models for Mn in tetrahedral molecules [23,24].

The SO coupling constants of the electrons 3d of the cation and 3p of the ligands, are obtained by interpolating the SO coupling constants given by Blume and Watson [25] for various ionization states of the atoms. Explicitly (all values are in cm^{-1}) we get: $\zeta_{\text{Mn}} = 286 + 47(Q_{\text{Mn}} - 1)$ and $\zeta_{\text{L}}(\text{S}) = 298 + 65(Q_{\text{L}} + 1)$. From the effective charges given above, we get: $\zeta_{\text{Mn}} = 285 \text{ cm}^{-1}$ and $\zeta_{\text{L}} = 308 \text{ cm}^{-1}$ for the electrons p of sulfur.

It is now possible to compare the matrix elements ζ_{et_2} and $\zeta_{t_2t_2}$ as given by the covalent and the CF-model. For ζ_{et_2} , the contribution of the term in ζ_{M} is of 220 cm^{-1} in the covalent model while it is of 300 cm^{-1} for the CF-model. (In the CF-model, we have $\zeta_{t_2t_2} = \zeta_{et_2} = \zeta_{\text{M}}$, with $\zeta_{\text{M}} = \zeta_{3d} = 300 \text{ cm}^{-1}$). In the covalent model, the contribution of the term in ζ_{L} , due to two terms of opposite signs, is of 15 cm^{-1} only, so that the contribution of the ligands is almost negligible. Finally, with respect to the CF-model, the strong reduction of ζ_{et_2} is primarily due to the mixing of the orbitals d of the cation with the orbitals of the ligands.

For $\zeta_{t_2t_2}$, the contribution of the terms in ζ_{M} and ζ_{L} are of 224.8 and -94 cm^{-1} respectively. For the term in ζ_{M} , the contribution involving the orbitals p is very small, so that the contributions of the cation to $\zeta_{t_2t_2}$ and ζ_{et_2} are almost identical. For the term in ζ_{L} , the contributions of the ligands πp and σp are both negative so that their overall contribution is relatively large.

Then, the orbital triplet states $|{}^4T_1\rangle$ and $|{}^4T_2\rangle$ are built from the configurations $4t_3^2e$, $4t_3^2e^2$, and $4t_3^2e^3$, by diagonalizing the matrix of Sugano et al. [21]. The mixing parameters for the states $|{}^4T_1\rangle$ and $|{}^4T_2\rangle$ are given for two sets of values for the Racah parameters B, C, and from the cubic field coefficient Dq . For the first set, we have: $B = 730 \text{ cm}^{-1}$, $C = 2880 \text{ cm}^{-1}$, and $Dq = -420 \text{ cm}^{-1}$ [26]. For the second set, we have: $B = 630 \text{ cm}^{-1}$, $C = 3040 \text{ cm}^{-1}$, and $Dq = -540 \text{ cm}^{-1}$ [27]. The results are summarized in Table 1. This table shows that for the states $|{}^4T_1\rangle$, some mixing parameters differ at most by roughly 10–15% depending on the chosen set of parameters. For the states $|{}^4T_2\rangle$, it can be noted that the mixing parameters for the state $|{}^4T_2(\text{G})\rangle$ are of opposite sign and that some mixing coefficients differ by roughly 10–20%.

The first-order SO interaction for the orbital triplet levels can be described by the equivalent operator $\chi_1 \mathbf{L} \cdot \mathbf{S}$ with $l = 1$ and $S = 3/2$. By using the mixing parameters for the triplet states $|{}^4T_1\rangle$ and $|{}^4T_2\rangle$, we obtain χ_1 in terms of a linear combination $\alpha\zeta_{t_2t_2} + \beta\zeta_{et_2}$ of the matrix elements $\zeta_{t_2t_2}$ and ζ_{et_2} . The values for α and β are given for the six levels considered and for the two sets of parameters in Table 1. The values for χ_1 as given by the proposed molecular model and by the CF-model are given in Table 2 for the six studied levels.

Table 1

Values for the coefficients α , β defined in Section 3 and wave functions for the states 4T_1 and 4T_2 of Mn in ZnS. The wave functions are linear combinations of the form: $a_1 4t_{3/2}^2 e^2 + a_2 4t_{3/2}^2 e^2 + a_3 4t_{3/2}^2 e^3$. The values are given for two sets of parameters B , C , and Dq . Set 1: $B = 730 \text{ cm}^{-1}$, $C = 2880 \text{ cm}^{-1}$, and $Dq = -420$. Set 2: $B = 630 \text{ cm}^{-1}$, $C = 3040 \text{ cm}^{-1}$, and $Dq = -540 \text{ cm}^{-1}$. The energies are in cm^{-1} .

Table 2

First-order spin-orbit interaction for the levels ${}^4T_1(\text{G})$, ${}^4T_1(\text{P})$, ${}^4T_1(\text{F})$, and ${}^4T_2(\text{G})$, ${}^4T_2(\text{D})$, ${}^4T_2(\text{F})$. The values for χ_1 are obtained from the CF-model and from the molecular model (M-model). The two sets of values, as given in Table 1, for B , C , and Dq have been used. For the CF-model, the calculations have been performed by taking: $\zeta(t_2, t_2) = \zeta(e, t_2) = 300 \text{ cm}^{-1}$. For the M-model, we have used: $\zeta(t_2, t_2) = 131 \text{ cm}^{-1}$ and $\zeta(e, t_2) = 205 \text{ cm}^{-1}$. The matrix elements $\zeta(t_2, t_2)$ and $\zeta(e, t_2)$ are defined in Section 2

4T_1	B, C, Dq	$\chi_1({}^4\text{G})$	$\chi_1({}^4\text{P})$	$\chi_1({}^4\text{F})$
CF-model	Set 1	17.70	12.70	-30.40
	Set 2	22.24	21.30	-43.54
M-model	Set 1	1.42	17.71	-19.13
	Set 2	4.22	22.94	-27.17
4T_2	B, C, Dq	$\chi_1({}^4\text{G})$	$\chi_1({}^4\text{D})$	$\chi_1({}^4\text{F})$
CF-model	Set 1	-31.58	80.73	-49.14
	Set 2	-34.00	88.30	-54.30
M-model	Set 1	-25.17	51.33	-26.16
	Set 2	-28.63	57.02	-28.39

Table 2 shows that for the levels 4T_1 , $\chi_1({}^4T_1\text{G})$ is very strongly reduced with respect to the value $\chi_{1\text{CF}}$ of 17.7 cm^{-1} as deduced from the CF-model (by taking $\zeta_{3d} = 300 \text{ cm}^{-1}$), this is due to the fact that χ_1 depends on two terms having approximately the same magnitude and opposite signs. For $\chi_1({}^4T_1\text{P})$, the values given by the molecular model for the set 1 are much greater than those given by the CF-model, while for the set 2, the values are almost identical. It can be noted that for $\chi_1({}^4T_1\text{P})$, the values given by the CF-model strongly depend on the set of parameters B , C , and Dq . For $\chi_1({}^4T_1\text{F})$, the values given by the covalent model are two-thirds of the values of the CF-model.

For the levels 4T_2 , all values of χ_1 as given by the molecular model are reduced with respect to the values of the CF-model. For example, for the set 1, the

reduction factors are of 16–20% for $\chi_1({}^4T_2\text{G})$, 35–36% for $\chi_1({}^4T_2\text{D})$, and 47–48% for $\chi_1({}^4T_2\text{F})$.

4. Conclusion

By analyzing in detail the molecular model for the SO interaction, it has been shown that the first-order molecular SO interaction described by the term $\chi_1 \mathbf{L} \cdot \mathbf{S}$ can be decomposed into three contributions. The first one is due to the mixing of the mono-electronic wave functions, the second depends on the SO coupling constants of the relevant electrons of the cation and of the ligands, and the last is due to the mixing coefficients of the orbital triplet states. It has been

shown that for the studied orbital triplet levels of Mn^{2+} in ZnS, all contributions are of importance.

Abstract

High temperature defect equilibrium (HTDE) in ZnS was analysed to study the conditions of making p-type material. High temperature electrical conductivity (HTEC) under defined component vapour pressure was investigated in undoped ZnS in the temperature range from 600 °C to 1140 °C. HTEC measurements were carried out using a two-zone resistance furnace and a vacuum sealed quartz ampoule with four sealed tungsten or graphite electrodes. All ZnS HTEC isotherms can be divided into three regions. The high zinc vapour pressure (p_{Zn}) and the high sulphur vapour pressure (p_{S_2}) regions are characterized by dominant native donors. In the ZnS HTDE model, antistructure disorder is dominating at high p_{S_2} values, similar to CdS and CdTe HTDE models. Changes occur at low p_{Zn} or at low p_{S_2} values. The increase of HTEC at low p_{Zn} or at low p_{S_2} values is explained by the existence of the p-type area in this region. This p-type area appears in the total range of temperature investigated. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Zinc sulphide; Electrical conductivity; Defects

1. Introduction

The physical properties of ZnS depend on the properties of point defects. The concentration of native and impurity defects in turn depends on the conditions of preparation and the presence of dopants. Although the room-temperature properties are of interest, the initial defect structure is formed usually at much higher temperatures during crystal growth or annealing, when the high temperature defect equilibrium (HTDE) is established. Our study within high temperature electrical conductivity (HTEC) in undoped and in doped ZnS has been in progress for several years [1–3]. Our earlier work [1] on HTEC in the additive coloration region of ZnS did not concern the phase transition (PT) region. HTEC measurements in ZnS are complicated because of the multiphase origin of ZnS. We found that adequate measurements for determination of HTEC isotherms and isobars without PT confusion can be performed at

temperatures over 1070 °C. At lower temperatures, the effects of PT on HTEC must be taken into account [2]. On the basis of HTEC measurements under zinc vapour pressure (p_{Zn}) we could not explain the HTEC isotherm behaviour at low p_{Zn} values [3]. In the present work, the results of HTEC isotherm and isobar measurements are performed both under p_{Zn} as under sulphur vapour pressure (p_{S_2}) and at large ZnS crystal temperature range.

2. Experimental procedure

HTEC isotherms and isobars were measured in undoped ZnS single crystals, grown by the Bridgman vertical method. The concentration of residual impurities was no more than 10^{16} cm^{-3} . HTEC measurements were carried out using a two-zone resistance furnace and a vacuum sealed two-zone quartz ampoule with four sealed tungsten or graphite electrodes. The HTEC σ was measured as a function of sample temperature T and the partial pressures p_{Zn} or p_{S_2} . The component vapour

E-mail address: klott@edu.ttu.ee (K. Lott).

pressure (p_{comp}) (p_{Zn} or p_{S_2}) was maintained by controlling the temperature of the reservoir of zinc or sulphur. In all cases, the ampoule was placed in a quartz furnace tube, which was evacuated to 10^{-2} Pa or fulfilled by inert gases. The HTEC experiments within ZnS led us to a power dependence of electron concentration n , on p_{comp} and temperature T as $n \sim p_{\text{comp}}^{\alpha} \exp(-\Delta E/kT)$. Our attempts to measure Hall effect in ZnS at high temperatures were not very successful because of low free carrier mobility values. The sign of Hall coefficient indicates that the conductivity is n-type. The $T^{-3/2}$ dependence of mobility [4] is taken into account by the factor $T^{+3/2}$, so that the conductivity $\sigma T^{+3/2}$ is proportional to the free carrier concentration.

3. Results and discussion

3.1. HTEC isotherms of undoped ZnS

HTEC isotherms of undoped ZnS, measured under p_{Zn} and under p_{S_2} are shown in Figs. 1 and 2. The plots in Fig. 1 can be divided into two regions. If the dependence of the HTEC σ on p_{comp} in Fig. 1 is expressed as $\sigma \sim p_{\text{comp}}^{\alpha}$, then at high p_{Zn} , $\alpha > 0$ and at low p_{Zn} side $\alpha < 0$. The $\alpha = 0$ values shift systematically towards higher p_{Zn} values with increasing the temperature of the crystal. At congruent sublimation, component vapour pressures upon ZnS in equilibrium are calculated from $K_{\text{ZnS}} = p_{\text{Zn}} p_{\text{S}_2}^{1/2}$ values [5]. Unexpected results were obtained in HTEC measurements under sulphur pressures. The absolute value of HTEC in the p_{S_2} region is more than one order of magnitude higher than in the p_{Zn} region. The slopes α in Fig. 2 are not constant in a large range of p_{comp} and varied between 0.1

and 0.4 under high p_{S_2} (p_{S_2} values in Fig. 2 are translated into p_{Zn} values through K_{ZnS} values). It is characteristic that at low p_{S_2} the sign of α is reversed. Between the two conductivity minimums in Figs. 1 and 2, there exists an area of increased conductivity. This region may be characterized as the p-type or bipolar conductivity area. No Hall voltage was measured in this region because of low mobility of holes. Similarly, increasing role of holes at low p_{S_2} and at low p_{Cd} has been observed in CdS [6].

3.2. HTEC isobars of undoped ZnS

HTDE isobars measured under p_{Zn} and under p_{S_2} are shown in Figs. 3 and 4. The step-like changes, caused by PT below 1070°C [2], are eliminated by using only

Fig. 2. HTEC isotherms of undoped ZnS, measured at the p_{S_2} side. p_{S_2} is expressed by p_{Zn} using K_{ZnS} [5]. The dashed line connects minimum values of the conductivity.

Fig. 1. HTEC isotherms of undoped ZnS, measured at the p_{Zn} side and at temperatures over the PT temperature. Under Zn saturated conditions, the α values are: $\alpha \approx 0.5$ at 1100°C and $\alpha \approx 0.4$ at 1070°C .

Fig. 3. HTEC isobars of undoped ZnS, measured at the p_{S_2} side. The HTEC isobar activation energies at different p_{comp} : (A) $p_{\text{S}_2} = 1.1$ atm, $\Delta E = 1.1$ eV; (B) $p_{\text{S}_2} = 0.00026$ atm, $\Delta E = 1.8$ eV.

Fig. 4. HTEC isobars of undoped ZnS, measured at the p_{Zn} side: (A) $p_{Zn} = 0.015$ atm, $\Delta E = 1.9$ eV; (B) $p_{Zn} = 0.48$ atm, $\Delta E = 1.6$ eV.

cooling down or heating up isobar curves. The existence of different activation energies for HTEC isobars in Figs. 3 and 4 at different p_{Zn} and p_{S_2} values is characteristic. This indicates that the compensating defects in these regions are different.

3.3. The preliminary HTDE model

We cannot propose any simple HTDE model to calculate Brouwer's approximation [7]. HTEC isotherm slopes α at different temperatures and HTEC isobar activation energies ΔE at different p_{comp} are different which still leaves many possibilities open for the exact defect model. For analysis, we used the method for solving the system of quasi-chemical reactions without approximation [8]. Here we represent some highlights of our preliminary model. For temperature values above the PT temperature and under zinc saturated conditions, sulphur vacancies are the dominant native donor defects and in frozen-in crystals F -centre phenomenon appears [9]. It means that Schottky disorder dominates in hexagonal phase and Frenkel disorder dominates in cubic phase. Our earlier experiments [10] have shown that the total excess of zinc in additively coloured ZnS, determined by atomic absorption photometry, appears to be significantly larger than the concentration of EPR-detected F -centres or the concentration of HTEC measured free carrier concentration. If so, then in the region of high p_{Zn} , the large deviation from stoichiometry must arise at first from the presence of high concentration of neutral vacancies and interstitials compared with the free carrier concentration. The second reason may be related to the adsorption of the excess component on crystal surfaces and interblock boundaries [10]. The appearance of zero slope ($\alpha = 0$) on HTEC isotherms can be explained by a two carrier conduction mechanism involving electrons and holes.

The inversion of sign of α at low p_{Zn} values means the increasing role of free carriers in the electrical compensation of defects. Between these two $\alpha = 0$ values, the p-type region may be formed. In this region no F -centre phenomenon can be found in frozen-in crystals. As in the case of CdS [6], the double inversion of sign of α requires introduction of a specific model. Antistructural disorder involves the occurrence of sulphur at the zinc lattice (S_{Zn}). It must be expected to be a donor. Electrically it must be compensated by zinc vacancies. Tellurium antisite as compensating donor has also been introduced in CdTe defect model [11]. The species S_{Zn} is expected to disappear with increasing p_{Zn} because the energies of formation for antisite defects and defect pairs in ZnS are higher than for vacancies and interstitials [12,13].

4. Conclusions

HTEC was studied in undoped ZnS. It has been found, that at high p_{Zn} and at high p_{S_2} native donors cause the increase of HTEC with increasing of component vapour pressure. The increase of free carrier concentration at low p_{Zn} or at low p_{S_2} is caused by an increasing role of the concentration of holes. In this region p-type HTEC can be found.

Mechanism of laser damage of transparent semiconductors

V.A. Gnatyuk*

Center for Sustainable Development and Ecological Research at the Inter-Regional Academy of Personnel Management,
Frometivs'ka St. 2, 03039 Kyiv, Ukraine

Abstract

Damage of transparent semiconductors and dielectrics under the action of high-intensity laser radiation fluxes is mainly attributed to absorptive inclusions, which being heated up to the melting threshold, result in thermal stresses due to the occurrence of microcracks and pores in materials. In this connection a local spherical area molten by laser radiation and then solidifying in a transparent solid in conditions of external cooling is considered and the temperature fields in the solidified region are calculated. The temperature fields and temporary stress dependences on thickness of a solidified region at different speeds of a solidified front are graphically analyzed. The conditions of occurrence of caverns in irradiated crystals are discussed. The present results can be used in the analysis of the damage processes of optical components of power laser devices, in particular made from ZnSe semiconductors. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Stress simulation; Temperature field; Laser irradiation; ZnSe crystals

1. Introduction

Interacting with transparent semiconductors high-intensity laser radiation fluxes usually result in local heating of inhomogeneities in the bulk up to the melting point of the material [1]. This has been attributed to the presence of light-absorptive macroinclusions and microinclusions with dimension of the order of wavelength in the crystals. In the last case these inhomogeneities are heated in a recombination mechanism [2]. It was shown [3] that there is also an own mechanism of nucleation of an elementary defect related to accumulating light energy in a thermal fluctuation of density (tensile strain) resulting in the formation of a stable germinal crack. Nevertheless, in all cases laser irradiation of transparent materials with an intensity close to a melting threshold results in heating, melting and subsequent solidifying of local areas in the bulk of a solid. In particular, it is related to short laser pulses of nano- and femtosecond duration [4]. Fast crystallization of a laser-melted area in a crystal forms elastically deformed regions that can

cause the occurrence of microcracks and caverns in materials. It was shown that the irradiation of highly pure, specially undoped, ZnSe single crystals with nanosecond ruby laser pulses can result in both tensile and compressive strain [5,6] as well as in increase of optical absorption in the transparency range of the semiconductor [7]. In the present paper the model of a local spherical area molten by laser radiation and then solidifying in a transparent solid in conditions of external cooling is considered according to the approach reported in Ref. [8]. The stresses and temperature fields in the local solidified region of the bulk of a transparent solid are determined.

2. Definition of the state of solidifying sphere

2.1. The strained state of elastic solid sphere with radial temperature distribution

We consider a hollow sphere with spherically symmetrical distribution of temperature $T(r)$. R is the external radius of a sphere, r_0 is the internal radius. The state of an elastically deformed solid is featured by the strain

*Tel.: +38-44-264-5796; fax: +38-44-264-9511.

E-mail address: gnatyuk@mailcity.com (V.A. Gnatyuk).

vector U , strain tensor U_{ik} and stress tensor σ_{ik} [9]. The equilibrium equation for a deformed solid is

$$\frac{\partial \sigma_{ik}}{\partial x_k} = 0, \quad i, k = 1, 2, 3. \quad (1)$$

The relation between strain tensor and stress tensor, which characterizes an elastic medium, is expressed by the Hook law

$$\sigma_{ik} = 2\mu U_{ik} + \left(K - \frac{2}{3}\mu\right) U_{jj} \delta_{ik} - 3K\alpha(T - T_0)\delta_{ik}, \quad (2)$$

where T_0 is the equilibrium temperature. The last item of this expression represents the stresses which are due to a temperature variation of a body. Here α is the linear expansion coefficient, μ is the shear modulus and K is the compression modulus for an elastic body. These values are regarded as constants. Solving Eqs. (1) and (2) in the spatial polar coordinates (r, φ, θ) and using boundary conditions that both the external and internal sphere surfaces are stressless $\sigma_{rr}|_{r=r_0} = 0$, $\sigma_{rr}|_{r=R} = 0$, the radial and circular components of the stress tensor can be obtained in a view:

$$\sigma_{rr}(r) = \frac{2\mu 9K}{3K + 4\mu} \times \left[\frac{r^3 - r_0^3}{R^3 - r_0^3} \frac{2}{r^3} \int_{r_0}^R \alpha T(r) r^2 dr - \frac{2}{r^3} \int_{r_0}^r \alpha T(r) r^2 dr \right], \quad (3)$$

$$\sigma_{\varphi\varphi}(r) = \sigma_{\theta\theta}(r) = \frac{2\mu 9K}{3K + 4\mu} \left[\frac{2r^3 + r_0^3}{R^3 - r_0^3} \frac{1}{r^3} \times \int_{r_0}^R \alpha T(r) r^2 dr - \frac{1}{r^3} \int_{r_0}^r \alpha T(r) r^2 dr - \alpha T(r) \right]. \quad (4)$$

2.2. The temperature distribution in solidifying sphere

In a solidifying sphere the temperature field $T(r)$ is related with motion of a solidified front. In order to define the temperature dependence $T(r)$ for Eqs. (3) and (4) it is necessary to consider the problem of temperature distribution in a body with varying boundary, the so-called Stephan problem [10]. The condition on the phase boundary is

$$\frac{Q}{c} \frac{\partial \eta(t)}{\partial t} \Big|_{r=\eta(t)} = \frac{\partial T}{\partial t} \Big|_{r=\eta(t)},$$

where Q is the crystallization heat, c is the heat capacity, $\eta(t)$ is the radius of the phase boundary which moves under the law

$$\eta(t) = \sqrt{4wa(t_* - t)}, \quad (5)$$

where w is the dimensionless parameter characterizing the intensity of a heat rejection and thus determining the speed of motion of the phase boundary, $a = \chi/C_v$ is the thermal diffusivity, χ is the thermal conductivity, C_v is the heat capacity at constant volume, t is the time and t_*

is the time during which the crystallization is finished. The initial condition for the solidification boundary is $\eta(0) = 1$ and the second boundary condition requires stationary temperature at a solidified front

$$T(r, t)|_{r=\eta(t)} = T_*,$$

where T_* is the crystallization temperature. Solving the thermal conduction equation [10] for a centrally symmetric temperature field in spatial polar frame while taking into account the initial and boundary conditions above, one can compute the temperature field in a solidifying sphere under external cooling:

$$T(r, t) = \frac{Q}{c} e^{-w} w^{3/2} \int_{(w(r^2 - \eta^2(t)))}^w e^x x^{-3/2} dx + T_*, \quad (6)$$

2.3. Definition of temporary stresses in solidifying sphere

We consider a melted sphere with radius $R = 1$. The internal surface of a sphere is a solidified front. The crystallization process is started at $t = 0$ and for $t \geq 0$ a position of the crystallization boundary $r = \eta(t)$ is defined by Eq. (5) and the temperature distribution in the solidified region $T(r, t)$ is expressed by Eq. (6). It is guessed that the speed of material elements is small compared to that of a solidified front. In the solidified region the equilibrium equations, Eq. (1), and the Hook law, Eq. (2) are valid. The thickness of the solid region varies during solidification. Thus it is necessary to determine stresses in a body with a variable boundary. It was shown [8] that the description of such problems was convenient to make using variables characterizing an instantaneous state of a solid. Such variables are a vector field of speeds and tensor field of speeds of deformations. Therefore, in order to characterize an instantaneous state of a solid, Eqs. (1) and (2) differentiated with respect to time are used. These expressions are valid for an ideal liquid using the shear modulus $\mu = 0$. \tilde{K} is the compression modulus for a liquid and the pressure p of a melt instead of stresses σ_{ik} is supposed. In this case the change rate of pressure is used as an instantaneous variable.

The joint change of state of both a strained liquid and solid is esteemed. Therefore the conjugation conditions at the boundary between a melt and solid are used. The density at the crystallization boundary undergoes a jump. The conjugation, which is a consequence of the mass conservation law, reflects this fact:

$$\rho \left(v - \frac{d\eta(t)}{dt} \right) \Big|_{r=\eta(t)} = \tilde{\rho} \left(\tilde{v} - \frac{d\eta(t)}{dt} \right) \Big|_{r=\eta(t)}, \quad (7)$$

where ρ , $\tilde{\rho}$ are the densities and v , \tilde{v} are the strain speeds of a solid and melt, respectively. Usually at solidification of a melt there is a shrinkage which is due to the fact that the density of a solid is more than the density of a melt ($\tilde{\rho}/\rho < 1$); therefore, the liquid appears comprehensively

tensile ($p(t)|_{t \neq 0} < 0$). In the process of moving a solidified front the tension of a liquid increased. At some value of tension (at the moment of $t = t_c$) the collapse in a liquid occurs with forming a gap and therefore a cavern in a solid. Thus, the pressure inside a sphere drops to the zero point.

On the basis of the discussed model and using the initial, boundary and conjugation conditions, the expressions for the temperature dependences and temporary stresses dependences on thickness of a solidified region at different speeds of a solidified front w (or intensity of a heat rejection) were obtained. Inasmuch as the obtained analytical expressions were very cumbersome, it was possible to expediently analyze them graphically in dimensionless variables, using computer calculation (Figs. 1–4). The dimensionless variables were defined using the radius of a melted sphere $R = 1$ and by dividing the obtained expression on the combination of dimension constants characterizing the material [8]. The ZnSe semiconductor constants were used [11].

3. Analysis of theoretical results

The motion of a solidified front (i.e. an increase in thickness of a solidified region) is represented as a decrease in r in the figures. The two cases of the heat rejection intensity ($w_1 = 0.01$ and $w_2 = 0.02$) are considered. Fig. 1 demonstrates that the temperature field is dependent on the thickness of solidified layer. On moving a solidified front, the temperature on the external surface of a sphere is lowered in the course of time because of the heat to be retracted through a more

Fig. 1. Temperature distributions $T(r)$ in a solidifying sphere at different thicknesses r of solidified region and at different heat rejection intensities w (solidified front speed).

Fig. 2. Radial stresses $\sigma_{rr}(r)$ in a solidifying sphere before forming a cavern at different thicknesses r of solidified region and at different heat rejection intensities w (solidified front speed). Envelopes (thin curves) represent a module of the pressure p of a melt.

Fig. 3. Radial stresses $\sigma_{rr}(r)$ in a solidifying sphere after forming a cavern at different thicknesses r of solidified region and at different heat rejection intensities w (solidified front speed).

and more thick layer of a rising solid. When the gap in a liquid was not derived yet, the radial stresses have the greatest values on a solidification boundary and numerically are equal to the pressure of a melt (envelopes, i.e. thin curves p_1 and p_2 in Fig. 2) which

Fig. 4. Circular stresses $\sigma_{\phi\phi, \theta\theta}(r)$ in a solidifying sphere after forming a cavern at different thicknesses of solidified region r and at different heat rejection intensities w (solidified front speed).

sharply increases with moving a solidified front. After formation of a cavern the maximum of radial stresses is shifted to a solidification boundary on moving a solidified front (i.e. toward smaller r in Fig. 3). The circular stresses have negative values at large radius (Fig. 4) that is an evidence of the formation of tensile strained areas in a solid. The difference in the quantitative nature of the stresses is due to the dependence of the temperature on w in a solidifying body. A rise of w results in an increase in the heat rejection intensity (Fig. 1). The intensive cooling of a body (i.e. an increase in w) results in an increase of the stresses. The stresses also increase on raising the thickness of a crystallized region (Figs. 2-4).

The formation of elastically deformed regions could be the reason for the modification of the photoconductivity spectra of ZnSe crystals [5,6] under irradiation with nanosecond ruby laser pulses. In particular, a shift of the maximum and the red edge of the spectrum toward lower energies can be attributed to the formation of deformed regions with residual stresses (tensile strains) in irradiated crystals. The formation of these regions with a smaller bandgap in irradiated samples conformed with the positive pressure coefficient of the change of the bandgap $dE_g/dp = 6 \times 10^{-9} \text{ eV Pa}^{-1}$ for ZnSe [11]. The formation of caverns in local solidified areas of crystals after power laser irradiation (in particular at absorptive inclusions) could cause a rise of the optical absorption in the transparency range of the semiconductor [7].

Stability of chlorine-based complex defects in group II–VI semiconductors

V. Valdna*

Tallinn Technical University, Ehitajate tee 5, 19086 Tallinn, Estonia

Abstract

The influence of variable thermal treatments and cooling rate upon the defect structure and luminescence properties of ZnSe phosphors doped with different dopants has been investigated. It has been found that chlorine-doped and vacuum-annealed ZnSe phosphor samples exhibit an increase of the photoluminescence intensity during the storage at room temperature whereas acceptor codopant copper decreases the instability of samples. The observed unstability of samples has been supposed to be caused by the dissociation of isoelectronic complexes $V_{Zn}2Cl_{Se}$ that gives rise to the concentration of active luminescence centres Cl_{Se} and $V_{Zn}Cl_{Se}$. © 2001 Elsevier Science B.V. Keywords: II–VI compounds; ZnSe; Complex defects; Stability

1. Introduction

Group II–VI semiconductor compounds are extensively used as luminescence materials, starting materials for radiation detectors from the far infrared to gamma radiation, solar energy converters, acoustoelectric and optical devices. Chlorine is the most commonly used dopant in II–VI materials as halide fluxes $CdCl_2$ and $ZnCl_2$ are often used for the recrystallization of II–VI powders and films. Substitutional chlorine at the chalcogen site is a single donor. Chlorine forms different complexes with the host intrinsic defects. A-centre, chlorine complex with metal vacancy is an acceptor. A complex that consists of two chlorine atoms and metal vacancy is a neutral defect.

CdTe is the most investigated narrow-gap II–VI compound. Single Cl_{Te} is a shallow donor in CdTe with a binding energy of $E_d = 14$ meV [1]. The A-centre, an acceptor complex $V_{Cd}Cl_{Te}$ with a binding energy of $E_a = 120$ meV, has been identified in CdTe by Meyer

et al. [1]. A-centre is a stable complex [2] that enables to receive as low as 1Ω cm p-type resistivity in CdTe thin films [4]. $V_{Cd}2Cl_{Te}$ is an isoelectronic complex [4] that causes a high resistivity up to $10^9 \Omega$ cm of chlorine-saturated CdTe [5]. Acceptor levels at 45 meV [6] and 80 meV [7], and a donor level at 60 meV [8] have also been ascribed to this complex. Vacuum annealing of Cl-doped CdTe generates $V_{Te}-V_{Cd}$ pairs that cause a 1.22 eV PL peak and unstable photoconductivity [9].

Wide-gap ZnS and ZnS-based solid solutions are the most efficient and widely used host materials for electroluminescent displays [10]. Compared with group III–V semiconductors, II–VI compounds have been much less studied [11]. ZnSe has long been used as an efficient red electroluminescent phosphor [12], in the last few years it has also been used as a material for the blue and blue–green laser diodes [13], and for the X-ray conversion screens, due to a high radiation stability of ZnSe [14]. A-centre locates in ZnSe band gap at $E_V + 0.35$ eV [15]. Information about other complexes and host intrinsic defects in ZnSe is scarce. A double-charge deep acceptor locates at $E_C - 2.2$ eV [16]. A deep donor V_{Se} has been positioned at $E_V + 1.4$ eV [17], zinc interstitial at donor level $E_C - 0.9$ eV [18].

E-mail address: vellov@hot.ee (V. Valdna).

2. Experimental

For the phosphor samples, starting materials of 6N purity, and ZnCl_2 flux and chemicals for doping of 4–5N purity were used. Mixed with 4wt% ZnCl_2 flux, ZnSe powders were recrystallized isothermally in the evacuated quartz ampoules for 1 h at 1100°C , then cooled down to room temperature together within the tube furnace at a rate of about 1.2 K min^{-1} . For part of the samples 0.02–0.04 at% Ag or 0.05 at% Cu codopants were used. ZnCl_2 flux residue was removed from the recrystallized samples by the vacuum annealing at 470°C . Thereafter samples were vacuum annealed for 30 min at 850°C , then quenched or slowly cooled to room temperature.

3. Results

The integral intensities of phosphor samples measured under X-ray excitation after the thermal treatment and after 9 days storage at room temperature are summarized in Table 1. Samples doped only with chlorine exhibit the lowest conversion efficiency whereas acceptor codopant, especially copper, increases the efficiency, in part, due to a better spectral matching of copper-doped samples to a silicon detector. After 9 days storage at room temperature, all samples showed an increased conversion efficiency. Samples doped only with chlorine have the highest instability, especially at Cl-saturated sample. Copper codopant significantly decreases the rate of instability. PL measurements of the independent samples fabricated from the same phosphors confirm these results.

Fig. 1 shows PL spectrum of chlorine-saturated ZnSe after a thermal treatment with slow cooling to room temperature (curve 1), and after 2 weeks storage at 300 K (curve 2). The PL band peak at 2.02 eV belongs to a known self-activated (SA) emission band [16], caused

Fig. 1. (1) PL spectrum of ZnSe:Cl , slowly cooled to 300 K. (2) Sample 1, after 2 weeks storage at 300 K.

by charge transitions between the A-centre and donor levels as Cl_{Se} , Zn_i and others. A less intense peak at about 2.37 eV has been ascribed to the host intrinsic defects and bound excitons [19]. Vacuum annealing of chlorine-doped II–VI compounds generates chalcogen and metal vacancies [3,9].

A high cooling rate suppresses the 2.37 eV PL band, as it is seen in Fig. 2. Storage at 300 K causes less changes in the shape of this spectrum, yet a shift to a lower energy side is detected.

Fig. 3 depicts the PL spectra of chlorine- and silver-doped ZnSe . The slowly cooled sample has an intense donor–acceptor pair peak at 2.25 eV, formed by Cl_{Se} and Ag_{Zn} . SA and 2.37 eV bands can be also detected (curve 1). As at a ZnSe:Cl sample, fast cooling rate suppresses the 2.37 eV band, but promotes the SA band (curve 2). Storage at 300 K increases the intensity of this

spectrum also, further increasing the SA part of the broad band (curve 3).

Summarizing the results of this study one can suppose that some chlorine-based complex can cause an increase in the brightness of ZnSe samples stored at room temperature. A neutral complex $V_{Zn}2Cl_{Se}$ is a suitable candidate. We suppose that, supported by the lattice relaxation, part of these complexes can dissociate to the charged defects single Cl_{Se} and $V_{Zn}Cl_{Se}$. Supposedly, this mechanism causes divergent results of different authors [6,7,8]. It is possible that the shallow acceptor levels in II–VI tellurides unidentified so far can be

caused by chlorine complexes with interstitial tellurium [9].

4. Conclusions

It has been found that chlorine-doped and vacuum-annealed ZnSe phosphor samples exhibit an increase of the PL intensity during the storage at room temperature whereas acceptor codopant copper decreases the instability of samples. The observed instability of the PL intensity of samples at room temperature can be explained by post-annealing changes in the defect population. We suppose that part of the isoelectronic complexes $V_{Zn}2Cl_{Se}$ of chlorine-saturated ZnSe can dissociate at room temperature to give rise to the concentration of active luminescence centres Cl_{Se} and $V_{Zn}Cl_{Se}$.

Excitation mechanism of blue anti-Stokes and 2.4 μm infrared emission in ZnSe:Cr

V.Yu. Ivanov^{a,*}, A.A. Shagov^b, A. Szczerbakow^a, M. Godlewski^a^a *Institute of Physics, Polish Academy of Sciences, Al. Lotników 32/46, 02-668 Warsaw, Poland*^b *Solar Laser Systems, Minsk, Byelorussia*

Abstract

We report the observation and analyze the mechanism of efficient blue anti-Stokes emission in ZnSe:Cr. This emission and the intra-shell transition of chromium Cr^{2+} at 2.4 μm are induced by $2+ \rightarrow 1+$ ionization transition of chromium ions in ZnSe:Cr. The efficiency of the anti-Stokes photoluminescence anticorrelates with the efficiency of the infrared emission. The latter emission dominates at increased temperatures. We conclude that the photoionization excitation mechanism can be applied for optical pumping of 2.4 μm laser action in ZnSe:Cr. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: ZnSe; Chromium ion; Anti-Stokes emission; Infrared emission

1. Introduction

We reported recently observation of efficient energy up-conversion in chromium doped ZnSe [1]. Based on the results of electron spin resonance (ESR) investigations, we concluded that the anti-Stokes luminescence (ASL) in ZnSe:Cr is accompanying photoionization excitation of chromium ions. In this work, we discuss an inter-link between the ionization transition of Cr ions and the 2.4 μm infrared emission, due to $^5\text{E} \rightarrow ^5\text{T}_2$ emission of Cr^{2+} . The laser action was achieved for the latter photoluminescence (PL) in chromium doped wide bandgap II–VI materials [2–7]. The Cr^{2+} PL at about 2.4 μm , due to $^5\text{E} \rightarrow ^5\text{T}_2$ intra-shell transition, has a relative large PL line width of about 0.5 μm giving possibility of tuning in relatively large spectral range.

2. Experimental

ZnSe samples studied were bulk crystals grown from the melt by the Bridgman–Stockbarger (BS) technique

or from the vapor phase by Markov–Davydov (MD) technique. The first type crystals were purified by zone melting with following treatment in the zinc melt. We also studied some reference ZnSe epilayers obtained by simple deposition from the vapor phase or by atomic layer epitaxy in the gas flow version. Bulk BS crystals were grown from a chromium doped melt, with resulting chromium concentration, determined from the mass spectral analysis of the crystals, varying between 10^{16} and $5 \times 10^{19} \text{ cm}^{-3}$, i.e., both lightly and heavily doped samples were studied. Vapor phase MD crystals and ZnSe epilayers were doped with chromium by diffusion at 800°C temperature during 70–240 h treatment, with Cr metal deposited on the surface by magnetron sputtering. Cr concentration in these samples varied from $5 \times 10^{18} \text{ cm}^{-3}$ to $8 \times 10^{19} \text{ cm}^{-3}$.

A conventional PL set-up was used with samples mounted in a variable temperature cryostat. PL spectra were dispersed with Ebert–Fasti monochromator and detected with CCD camera (for visible and NIR region detection) or InAs photovoltaic detector (1–3.5 μm). The latter detector, assembled with digital oscilloscope was used for the PL kinetics measurements in the infrared. Visible light PL kinetics was measured with PMT in time-correlated photon counting mode. For cw excitation UV and visible lines of argon ion laser

E-mail address: ivanov@ifpan.edu.pl (V.Yu. Ivanov).

(Innova-400) together with dye-laser (with tuning range of 1.65–2.25 eV) and He–Cd laser (2.807 eV) were used. Excitation intensity was varied with a motorized attenuator in the range of 10^{17} – 10^{24} photon/cm²s. The ESR experiments were performed with Bruker 300 X-band spectrometer equipped with a continuous He gas-flow Oxford Instruments cryostat. Photo-excitation of the samples mounted in a microwave cavity was done either with laser sources used in the PL study or with a high-pressure mercury lamp and set of interference filters.

3. Results and discussion

In Fig. 1 we present the PL spectra observed under 2.41 and 2.807 eV excitation for the relatively heavily chromium doped sample (4.2×10^{18} cm⁻³) and at high excitation density of 10^{19} photons/cm²s. A very bright blue color donor acceptor pair (DAP) emission is observed under 2.41 eV excitation with a weak red DAP PL (not shown). The blue PL is excited by photons of lower energy, thus, it is identified as the ASL [1]. It should be mentioned, that neither excitonic transitions (donor (DBE) and acceptor (ABE) bound exciton) nor free-to-bound (FB) transition, which dominate at the above band gap excitation conditions, are observed under 2.41 eV excitation. This indicates efficient trapping of free carriers by ionized Cr centers. In addition to the visible light PL, two infrared intra-shell emissions of Cr²⁺, the 2.4 μ m PL due to $^5E \rightarrow ^5T_2$ transition and the 0.95 μ m PL (see Fig. 2), are observed upon 2.41 eV excitation. The latter PL was tentatively attributed to $^3T_1 \rightarrow ^5T_2$ emission of Cr²⁺ [8].

We measured temperature and excitation density dependences of anti-Stokes and infrared emissions and their excitation spectra. The PL excitation and photo-ESR data (Fig. 3) prove that the $2+ \rightarrow 1+$ ionization transition of chromium impurity excites the ASL and

Fig. 1. Low temperature photoluminescence spectrum of ZnSe:Cr under above band gap excitation and the ASL excitation.

Fig. 2. Chromium-related infrared PL emissions and the ASL emission observed in ZnSe:Cr under the photoionization excitation.

Fig. 3. Comparison of the PL excitation spectra of the ASL and infrared PLs with the Cr¹⁺ photo-excitation band determined in the ESR study.

the Cr²⁺ intra-shell PL. The important question is, if the ASL and the 2.4 μ m PL emissions do not compete as possible channels of energy relaxation. As explained previously, the ASL is excited due to two complementary ionization transitions of chromium ions [1]. Free carriers, photo-created in conduction and valence bands of ZnSe, participate in DAP PL responsible for the blue ASL emission.

For a two-quanta excitation mechanism, one could expect a quadratic dependence on the light intensity. In fact we observed the quadratic dependence of the ASL on excitation density for a two-photon excitation process, studied by us for undoped ZnSe samples. In the latter case a quantum efficiency of the ASL is fairly low, and is below 10^{-5} . The highly efficient ASL process observed by us in ZnSe:Cr (2×10^{-3} upon green color optical pumping and at helium temperature) shows, in a large range of excitation densities, a linear dependence of the ASL on excitation intensity. This, as results from

our photo-ESR studies, is a consequence of a metastable population of photo-excited Cr^{1+} centers, which is observed at low temperatures. Free holes, created in the valence band under chromium $2+ \rightarrow 1+$ ionization, are efficiently trapped by shallow acceptor centers being active in the ASL process. The second photon that is absorbed by photo-generated Cr^{1+} state induces a complementary ionization transition to the conduction band. Thus, both the types of free carriers are photo-generated and can participate in the ASL.

The efficiency of the ASL emission is reduced at increased temperatures, since required retrapping of photo-generated free carriers by shallow donor and acceptor centers active in the ASL becomes temperature deactivated. This is, why the deactivation of the ASL is characterized by deactivation energies of about 110–120 meV (Fig. 4) related to the thermal ionization of shallow acceptors.

The detrimental sensitivity of the ASL to the increase in the temperature turned out to be profitable for the second process studied by us. With decreasing efficiency of the ASL process, the intra-shell emission of Cr^{2+} is more efficient (Fig. 4). The photo-generated holes are at higher temperatures more efficiently retrapped by ionized chromium centers. As a consequence, Cr^{1+} state, an intermediate state in a two-quanta excitation transition, is no longer metastably occupied and a linear dependence on a light density is not observed for both the ASL and the intra-shell excitation processes.

High efficiency of the intra-shell PL means, that hole retrapping by ionized Cr^{1+} centers proceeds via the excited ^5E (and also $^3\text{T}_1$) state of Cr^{2+} impurity and that the process is very efficient at increased temperatures. Moreover, our photo-ESR studies indicate, that such a process occurs also under injection of free carriers. Our ESR studies demonstrate, that the generation of free carriers leads to efficient carrier trapping by Cr ions, by the so-called bypassing mechanism [9]. For example, we observed very efficient Cr^{1+} photo-quenching under

neutralization transition of deep acceptors, and very efficient photo-generation (see Fig. 3) for excitation, when deep acceptors are ionized, i.e., at the conditions when free electrons are created. This means, that the Cr^{2+} centers can compete in electron trapping with shallow donor centers active in visible emission of ZnSe, whereas Cr^{1+} centers in trapping of free holes from the valence band. Thus, we can avoid limitation of optical pumping and obtain efficient 2.4–2.5 μm infrared emission under injection of free electrons and holes.

4. Conclusions

2.4 μm PL of Cr^{2+} is efficient at room temperature and can be either optically pumped upon Cr ionization transitions or it can be excited by injection of free carriers. The former process can be important both for the optical pumping of this PL by easily available and very efficient light sources in green color. The latter process may be important in light emitting devices working under carrier injection conditions.

Donor–acceptor pair transitions in ZnO substrate material

K. Thonke*, Th. Gruber, N. Teofilov, R. Schönfelder, A. Waag, R. Sauer

Universität Ulm, Abteilung Halbleiterphysik, Albert-Einstein-Allee 45, D-89069 Ulm, Germany

Abstract

We investigate the state-of-the-art ZnO substrate material grown by seeded chemical vapour transport. The low-temperature photoluminescence (PL) spectra are dominated by very sharp bound exciton lines, which are followed by two-electron satellite transitions. This identifies the major bound exciton lines as donor related and allows us to derive a binding energy of ≈ 40 meV for the very similar donors observed here. From a donor–acceptor pair transition at ≈ 3.22 eV and its associated band-acceptor line emerging at sample temperatures above 40 K, we calculate the acceptor binding energy as ≈ 195 meV. Hall data confirm these findings. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: ZnO; Two-electron satellite; Donor–acceptor pair transition; PL

1. Introduction

The semiconductor ZnO with its direct band gap of ≈ 3.5 eV is a possible candidate for optoelectronics in the UV and blue spectral ranges. It was initially investigated nearly 40 years ago [1,2] and the wurtzite type band structure was also analysed. ZnO is typically n-type, and light-emitting diodes could only be prepared with metal–semiconductor contacts [3]. The nature of the dominant native donor is still under debate: experimental and theoretical works provide arguments for either interstitial zinc or oxygen vacancies [4].

Attempts to implement p-type doping failed for a long time. Recently, reports on successful p-type doping of ZnO were published [5], and theoretical work also predicted that co-doping should allow to produce shallow acceptors [6,7].

The low-temperature photoluminescence (PL) spectrum of ZnO has been investigated in many aspects in the previous work. Around 30 sharp donor- and acceptor-bound exciton lines were reported in the narrow energy range from 3.348 to 3.372 eV close to the free X_A and X_B exciton–polariton (for a tabulation,

see [8]), and quite a few have been analysed in Zeeman measurements. Nevertheless, the chemical origin of the underlying dopant atoms remained unclear. Also, the ionisation energy of the dominant donor as determined from temperature dependent Hall or conductivity measurements shows a spread from 20 to 130 meV [8].

2. Experimental and results

The ZnO substrates have been obtained from Eagle Picher (USA). They were grown by a seeded chemical vapour transport (SCVT) technique. Hall measurements between 45 and 360 K have been performed using a van der Pauw geometry and a standard DC measurement set-up. Ti/Au contacts have been fabricated by a simple evaporation technique. Typical carrier concentrations at room temperature of $(1\text{--}2) \times 10^{17} \text{ cm}^{-3}$ have been obtained. At 45 K, the carrier concentration is in the $8 \times 10^{14} \text{ cm}^{-3}$ range. We simulated the experimental $n(T)$ curve using Fermi statistics and solving the charge neutrality equation numerically under the assumption of partial compensation. We obtain a donor concentration of $1.7 \times 10^{17} \text{ cm}^{-3}$, a donor activation energy of 35 ± 5 meV, and a concentration of compensating acceptors of $2 \times 10^{15} \text{ cm}^{-3}$. The carrier mobility changes from a value of $(100\text{--}200) \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at room temperature to $\approx 800 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at 45 K.

E-mail address: klaus.thonke@physik.uni-ulm.de (K. Thonke).

In high resolution X-ray diffraction (HRXRD) ω - and $\theta/2\theta$ -scans on several substrates, we observe in several cases asymmetric contributions to the main peak within Bragg angles of $\approx 0.1^\circ$, which are $\approx 1\frac{1}{2}$ orders of magnitude less intense. This hints at the existence of polycrystals in the substrate, which are slightly tilted relative to the main c -axis.

For the optical characterisation, we recorded reflection spectra at 4.2 K in order to get information on the fundamental excitonic band gaps. From a fit to the very pronounced resonances due to the A and B exciton-polariton ($n = 1, 2$) states observable in a $(\mathbf{E} \perp \mathbf{k} \parallel \mathbf{c})$ configuration, we determine for the excitonic band gaps $E_{X,A} = (3374 \pm 1) \text{ meV}$, $E_{X,B} = (3380 \pm 1) \text{ meV}$, and for the exciton binding energies $E_{BX,A} = 64 \text{ meV}$ and $E_{BX,B} = 53 \text{ meV}$. This results in an energy for the fundamental A band gap of $E_{g,A} = 3.438 \text{ eV}$ (literature value: 3.441 eV [8]).

The low-temperature PL spectra are dominated by several close lying bound excitons in the range from 3.3595 to 3.364 eV (see Fig. 1, inset). According to the literature [8], the most intense line at 3.3628 meV is commonly assigned to a donor-bound exciton (“ I_4 ”), whereas the slightly weaker line at 3.3597 eV is closer to the location of the acceptor-bound exciton “ I_8 ”. All these lines are replicated at 29.9 meV lower energy in the region labelled “TES” (=two-electron satellite). A “TES” related to a donor-bound exciton (D^0, X) occurs in the spectrum, if in the bound exciton recombination

process the neutral donor (i.e. the final state of the recombination process) is excited from the $1s$ ground state to an excited state like $2s$, $2p$, etc. In Fig. 2, the (logarithmic) PL spectrum of the BEs is shifted by 29.9 meV and compared to the TES part. Apart from a line broadening, the TES spectrum mirrors the principal bound exciton spectrum. This strongly suggests that not only the upper BE line is a donor bound exciton, but even the lower energy lines around 3.360 eV are donor- (and not acceptor-) related. (This does not apply for the next weaker line at 3.3566 eV.) Zeeman measurements confirm this conclusion [9]. Obviously, we are concerned with several, but very similar donors in the ZnO substrate material. From the spacing of the TES lines from the (D^0, X) lines, we directly obtain the energy splitting $1s \leftrightarrow (2s/p)$ of the lowest donor states: For the dominant donor in the present sample this splitting is $(29.9 \pm 0.2) \text{ meV}$. Assuming that the effective-mass theory gives a good description of these donors and neglecting central cell corrections, the ionisation energy for these donors should be $4/3 \times 29.9 \text{ meV} = 39.9 \text{ meV}$. The origin of the similarly structured, but weaker hump at $\approx 3.320 \text{ eV}$, shifted by 11.4 meV relative to the TES, is presently not clear. Transitions $1s \rightarrow 3(s/p)$ to the next higher excited states would require an energy of $\approx (1 - \frac{1}{9}) \times E_D = 35.5 \text{ meV}$, i.e. they would be shifted by further 5.6 meV relative to the $1s \rightarrow 2(s/p)$ transition described above. Possibly, the band at $\approx 3.320 \text{ eV}$ is also a TES due to a second donor with a higher binding of

Fig. 1. PL overview spectrum of ZnO substrate material recorded at 4.2 K. The bound exciton lines at $\approx 3.36 \text{ eV}$ are followed by a two-electron replica (“TES”) 30 meV low in energy. At 3.220 eV, the donor-acceptor pair transition (D^0, A^0) is observed. All lines are repeated as LO phonon replicas. Inset: high resolution PL spectrum of the bound exciton region (resolution = $50 \mu\text{eV}$).

Fig. 2. Details of the BE (upper trace, top energy scale) and the TES regions (lower trace, bottom energy scale) in PL in comparison. The major features of the BE pattern can be rediscovered in the TES spectrum, and similarly repeated in the next peak, which is 11.4 meV low in energy. Note that the top energy axis is shifted by 29.9 meV relative to the bottom energy axis. Inset: The excitation of the D^0 final state taking place in the recombination process, which results in the “TES” line.

$4/3 \times (29.9 + 11.4) \text{ meV} = 55 \text{ meV}$. Independent evidence that the major BE lines are *donor*-related comes from the relative weak coupling to LO phonons for all these transitions: The LO replicas are roughly two orders of magnitude less intense than the BE lines. This is similar to the case of GaN and II–VI semiconductors, where (D^0, X) lines commonly couple only weakly with the optical phonons, while the (A^0, X) lines show much more intense replicas.

After having found a reliable value for the binding energy of the dominant native donors present in the ZnO substrate, we can take a closer look at the donor–acceptor pair transition (D^0, A^0) . This is observed at 3.220 eV in the PL spectrum (Fig. 3). For low sample temperatures, this line is much broader than the BE lines. It is followed by a series of LO replicas, which are relatively intense (hinting at the participation of an acceptor in this transition). With the increasing sample temperature, its intensity drops, and an adjacent line at 3.236 eV on the high energy side increases and gains intensity. This temperature dependence is typical of donor–acceptor pair transitions (D^0, A^0) turning into free electron–acceptor transitions (e, A^0) , when the

donors are thermally ionised. If the average density of the dominant impurity is known from Hall measurements, then the donor binding energy E_D can be calculated from the energy difference of the peak position of the (D^0, A^0) and (e, A^0) lines (see, e.g. [10]):

$$E_D = [E(e, A^0) - k_B T/2] - [E(D^0, A^0) - \alpha N_D^{1/3}]. \quad (1)$$

Here, $N_D^{1/3}$ represents the average distance of the donors, and α is a material dependent constant [8]

$$\alpha = \sqrt[3]{\frac{4\pi}{3}} \frac{e^2}{4\pi\epsilon_0\epsilon} = 2.7 \times 10^{-8} \text{ eV cm}$$

$$\text{for } \epsilon(\text{ZnO}) = 8.6. \quad (2)$$

This constant is needed to calculate the average Coulomb energy between D^0 and A^0 after the recombination process. Using the data determined for our substrates, we calculate a value of $E_D \approx 28 \text{ meV}$. This value is less reliable than the one determined from the $\text{TES} \leftrightarrow (D^0, X)$ energy spacing, but is—within the expected accuracy—compatible with the latter one and the Hall data. With the knowledge of E_D and N_D , we proceed in calculating the acceptor energy from the absolute spacing of the (D^0, A^0) line from the band gap:

$$E_A = [E_{\text{gap}} - E_D] - [E(D^0, A^0) - \alpha N_D^{1/3}]. \quad (3)$$

If we use the value of $E_{\text{gap}} = 3.438 \text{ eV}$ determined from our reflection data, then we get an ionisation energy $E_A = (195 \pm 10) \text{ meV}$ for the unintentional acceptor present in the ZnO substrate. The chemical nature of this relatively shallow acceptor remains presently unclear. Recent first-principle calculations predict for the Zn vacancy a much higher ionisation energy of $\approx 0.8 \text{ eV}$, which seems to rule out V_{Zn} as the acceptor in our ZnO substrates. A good candidate for the acceptor might be substitutional nitrogen on O sites, for which a binding energy of $\approx 200 \text{ meV}$ was calculated [11]. The chemical analysis of the substrate material indeed indicates as the most abundant impurity nitrogen with a content of $\approx 2 \text{ ppm}$ [12]. The donors with 30 meV binding energy might be possibly due to the interstitial hydrogen [4].

3. Conclusions

We investigate the principal PL features in ZnO substrate material and identify the major bound exciton recombination lines as donor-related. From the two-electron-transitions observed for these (D^0, X) lines, we obtain an exact value for the energy difference between the donor $1s$ and $2(s,p)$ ground states, and thus a very reliable estimate for the donor ionisation energy $E_D = 40 \text{ meV}$. The donor–acceptor pair transition at 3.220 eV allows to determine the binding energy of the acceptor involved as $E_A \approx 195 \text{ meV}$. The chemical

Fig. 3. Series of PL spectra of ZnO substrate material recorded at different temperatures. The plots are vertically shifted, each for a better visibility. Between 30 and 100 K the donor–acceptor pair transition at 3.220 eV decreases, and the adjacent band–acceptor transition at 3.236 eV increases. (The strong BE lines are saturated due to the long exposure time of the CCD camera.)

species responsible for the acceptor might be nitrogen, whereas the donor could be hydrogen.

Optical properties and surface morphology of Li-doped ZnO thin films deposited on different substrates by DC magnetron sputtering method

Galal A. Mohamed, El-Maghraby Mohamed*, A. Abu El-Fadl

Physics Department, Faculty of Science, Assiut University, Assiut 71516, Egypt

Abstract

Thin films of zinc oxide doped with $\text{Zn}_{1-x}\text{Li}_x\text{O}$ with $x = 0.2$ ($\text{ZnO}:\text{Li}$), have been prepared on sapphire, MgO and quartz substrates by DC magnetron sputtering method at 5 mTorr. The substrate temperatures were fixed to about 573 K. We have measured the transmission and reflection spectra and determined the absorption coefficient, optical band-gap ($E_{\text{gd}}^{\text{opt}}$), the high frequency dielectric constant ϵ'_{∞} and the carrier concentration N for the as-prepared films at room temperature. The films show direct allowed optical transitions with $E_{\text{gd}}^{\text{opt}}$ values of 3.38, 3.43 and 3.29 eV for films deposited on sapphire, MgO and quartz substrates, respectively. The dependence of the obtained results on the substrate type are discussed. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: ZnO:Li films; DC sputtering; Band gap; Optical properties

1. Introduction

Among different oxides, ZnO thin films (undoped and doped) have in recent years been rediscovered as a subject of considerable research interest due to their very unique physical properties (piezoelectricity, conductivity, magnetic and optical) and a wide range of possible device applications. Special care is directed to optical and magnetic memory devices, laser systems, blue light diodes, solar cells (transparent conducting electrodes), displays, ultrasonic transducers and sensors [1–3]. Since ZnO has the hexagonal structure (Wurtzite type) with four-fold tetrahedral coordination [4] and lies in the border between ionic and covalent semiconductors (II–VI), it is both suitable and important for fabrication of a high-quality oriented or epitaxial thin film which shows typical n-type piezoelectric semiconductor character. This is besides the fact that ZnO-based semiconductors can cover the same wavelength as GaN with an excitonic band energy much larger than that of GaN with large

direct band-gap (3.1–3.32 eV). Hence, ZnO-based thin films are increasingly being used as potential materials for highly coherent light generation and in optical devices in the blue to UV wavelength region.

In order to develop ZnO films with high quality for devices with good performance, it is necessary to clarify the role and effect of so many additives, different conditions of growth and substrate types. This will result in different microstructures being suitable for different applications. Now, it is well established that doping ZnO with Al ions decreases its resistivity while doping with Li ions increases its resistivity [5–8] and induces a ferroelectric phase suitable for optical memory devices [5,9–10].

The study of optical constants with their variation with frequency enables to make correlation with the band structures derived by other methods.

In this research, ZnO:Li thin films have been prepared on sapphire, quartz and MgO substrates at ~573 K by DC magnetron sputtering method. Our goal is to investigate growth and microstructure of ZnO:Li thin films. Another goal is to measure the absorption, reflectance and determine the optical band-gap ($E_{\text{gd}}^{\text{opt}}$), the high frequency dielectric constant ϵ'_{∞} and the carrier

E-mail address: maghrabym@yahoo.com (El-Maghraby Mohamed).

concentration N for the as-prepared films at room temperature and discuss its dependence on the type of substrate.

2. Experimental

Using DC magnetron sputtering method, we prepared ZnO:Li thin films deposited on sapphire MgO and quartz substrates. The sputtering target was a mixture of Li powder and Zn powder, with atomic ratio of Zn/Li (80/20), pressed on a copper saucer with diameter of 100 mm. Li powder was mixed in 20% excess in order to compensate the loss of Li during deposition. It is necessary to continue sputtering for over 40 h to make the target surface Li-rich and the film composition was saturated to the value nearly equal to the target composition. The deposition time for this experiment is fixed to be about 3 h long. When the film samples were deposited, presputtering was carried out for 5 min before opening the shutter which covered the substrate. The discharge was a mixture of Ar and O₂ with the ratio 70:30 and its pressure was about 5 mTorr. The voltage was fixed to 310 V and the current was about 110 mA. The substrate temperature was fixed at 573 K. After deposition, the samples were immediately cooled to room temperature. The identification of the crystalline structure and surface morphology were performed by X-ray diffraction analysis (XRD) (Philips Type: 1710) using Cu K_α radiation ($\lambda = 1.5418 \text{ \AA}$) and scanning electron microscope (SEM Jeol type: JSM-5400 LV).

The optical transmittance and reflectance of ZnO:Li films were recorded using Shimadzu UV-VIS 2101 PC dual beam spectrometer in the wavelength range from 190 to 900 nm. The measurements were carried out at room temperature with surrounding medium of dried air.

3. Results and discussion

Typical XRD measurements of the as-deposited films are shown in Fig. 1(a). It is clear that the type of substrate plays an important role in the crystallinity of the ZnO:Li films. The films deposited onto quartz substrates showed a large peak at $2\theta \cong 34^\circ$, which was attributed to (002) ZnO. This indicates that the deposited film has a good orientation along the c -axis. For films deposited on MgO and Sapphire substrates, c -axis ordering is degraded as shown in Fig. 1(a) but they still give the Wurtzite hexagonal structure. SEM images revealed smooth surface morphology without cracks and hillocks, see Fig. 1(b). The grain distribution is uniform but dense microstructure is relevant in films deposited onto quartz substrate.

The optical transmission and reflection spectra are given in Figs. 2 and 3 in the wavelength from 300 to

800 nm. The observed high transmittivity of these films suggests that ZnO:Li films have good transparency, especially above 700 nm wavelength.

The total absorption coefficient was calculated using the relation [11]

$$\alpha = \frac{1}{d} \ln \left[\frac{(1-R)^2}{2T} + \left\{ \frac{(1-R)^4}{4T^2} - R^2 \right\}^{0.5} \right], \quad (1)$$

where d is the thickness, R is the reflectance and T is the transmittance.

Generally, the equation (written here in a simplified form) used to determine the band-gap nature and the value of E_g (the gap energy) is [12]

$$(\alpha h\nu) = A(h\nu - E')^n. \quad (2)$$

Here, A is a constant that depends on the transition, $h\nu$ is the photon energy and E' the transition energy ($E_{\text{gd}}^{\text{opt}}$ for direct transitions, $E_{\text{gd}}^{\text{opt}} \pm E_p$ for indirect transitions [13], i.e. E_p being the energy of the associated phonon) and the value of the exponent n depends on the nature of the optical transition type ($n = \frac{1}{2}, \frac{1}{3}, 2, \frac{2}{3}$ for allowed and forbidden indirect transitions, and for allowed and forbidden direct ones, respectively). An analysis of the absorption spectrum of Fig. 2 shows that the absorption coefficient can be reasonably well fitted by Eq. (2) with $n = \frac{1}{2}$. This means that (ZnO:Li) films deposited on sapphire, MgO and quartz substrates have an allowed direct interband transition which corresponds to the fundamental absorption edge of these films.

Fig. 4 shows the plot of $(\alpha h\nu)^2$ versus photon energy near the absorption edge of ZnO:Li. Values of the optical energy gap for films deposited on sapphire, MgO or quartz substrates are obtained by extrapolating the linear regions to $(\alpha h\nu)^2 = 0$. Values of the room temperature optical energy gap $E_{\text{gd}}^{\text{opt}}$ and the constant A are listed in Table 1. It is clear that the obtained values of $E_{\text{gd}}^{\text{opt}}$ depend on the substrate type. Also, the admixture of ZnO with Li ions generally increases the value of $E_{\text{gd}}^{\text{opt}}$ over that of pure ZnO films. We can say that Li doping converts the shallow donor Zn sublevels to deep sublevels below the conduction band. This coincides with the results of Sbrveglieri et al. [14]. They conclude that Li ions lead to the formation of two deep-level donors in ZnO thin films which are, respectively, 0.38 and 0.81 eV below the conduction band, while the undoped films show two levels at 0.16 and 0.48 eV. In the case of the quartz substrate, the value of $E_{\text{gd}}^{\text{opt}}$ is near to that of pure ZnO films which may be attributed to the very good c -axis orientation in this case (see Fig. 1 (a)).

For a better understanding of the physical properties of ZnO:Li films, it is interesting to study some optical constants used to describe the optical properties, e.g. the high-frequency dielectric constant ϵ'_∞ and the relative carrier concentration N/m^* .

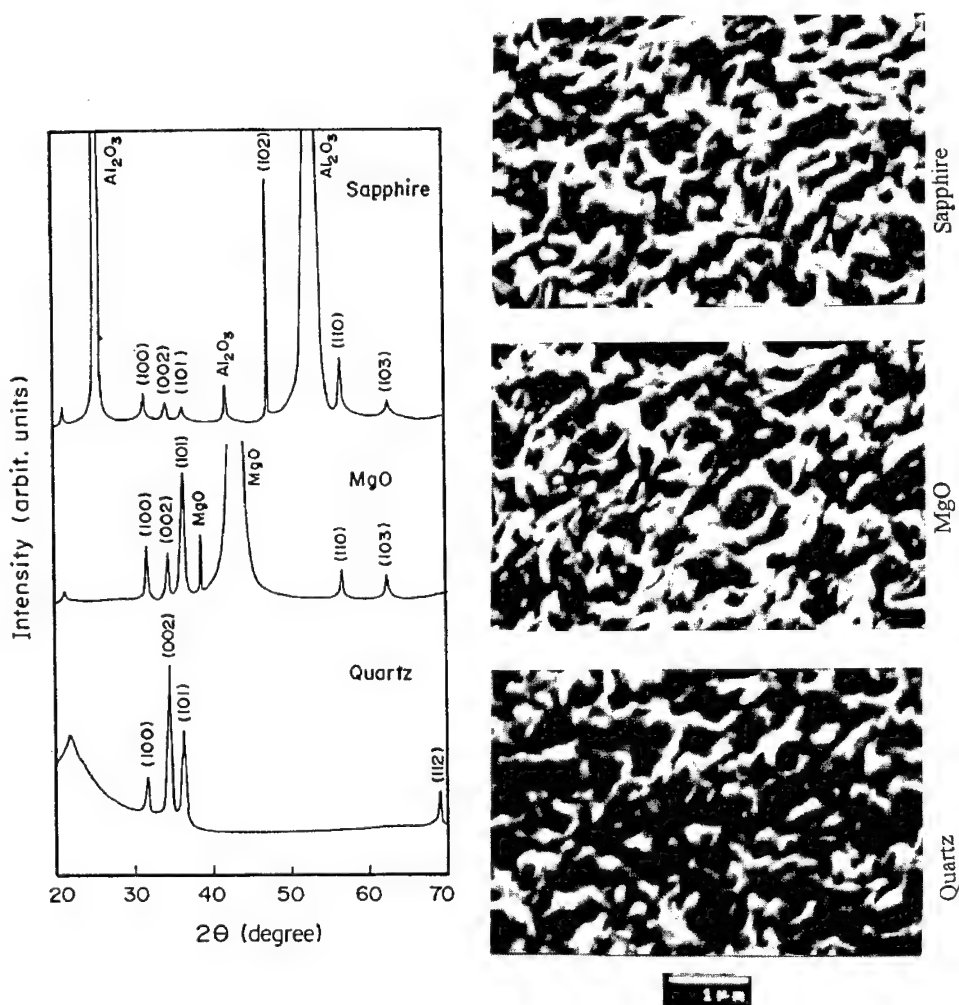

Fig. 1. (a) X-ray diffraction patterns and (b) SEM images of the as-prepared ZnO:Li films deposited on sapphire, MgO and quartz substrates at 573 K.

Table 1
Optical constants for as-prepared ZnO:Li films deposited on sapphire, MgO and quartz substrates

Physical quantity	Films deposited on sapphire substrates	Films deposited on MgO substrates	Films deposited on quartz substrates
Direct allowed energy gap $E_{\text{gd}}^{\text{opt}}$ (eV)	3.384 ± 0.05	3.425 ± 0.05	3.285 ± 0.05
The constant ($A \times 10^{12}$)	2.45	3.61	3.93
High-frequency dielectric constant (ϵ'_{∞})	8.33 ± 0.05	9.06 ± 0.05	4.13 ± 0.05
N/m^* (10^{21} cm^{-3})	8.07 ± 0.05	8.65 ± 0.05	3.39 ± 0.05

Accordingly [15], the real component of relative permittivity (ϵ') and the square of the wavelength (λ^2) are related by

$$\epsilon' = n^2 = (1 + \sqrt{R}/l(1 - \sqrt{R}))^2,$$

$$= \epsilon' - e^2/\pi c^2 N/m^* \lambda^2, \quad (3)$$

where n is the refractive index, e is the electronic charge and c the velocity of light.

From this equation, the high-frequency component of the relative permittivity (ϵ'_{∞}) and the ratio of the carrier

Fig. 2. Spectral distribution of the optical transmittance for the as-prepared ZnO:Li films deposited on sapphire, MgO and quartz substrates at 573 K.

Fig. 3. Spectral distribution of the optical reflectance for the as-prepared ZnO:Li films deposited on sapphire, MgO and quartz substrates at 573 K. The inset is the real dielectric permittivity (ϵ') versus λ^2 .

concentration to the effective mass N/m^* could be determined.

The inset of Fig. 3 shows the relation between relative permittivity (ϵ') and λ^2 for (ZnO:Li) films deposited on sapphire, MgO and quartz substrates. It can be noticed that relative permittivity decreases exponentially with increasing λ^2 . To obtain the high-frequency dielectric constant, Eq. (4) was applied on the linear parts of these curves. The values of ϵ' , and N/m^* are given in Table 1.

In general, it can be concluded that both the the high-frequency dielectric constant and the ratio N/m^* are related to the internal microstructure, as can be emphasized by considering the results in Table 1 together

Fig. 4. Relation between $(\alpha h\nu)^2$ and photon energy ($h\nu$) for the as-prepared ZnO:Li films deposited on sapphire, MgO and quartz substrates at 573 K.

with those in Fig. 3, most of the changes in the N/m^* ratio are regarded as corresponding to the change in N .

4. Summary

Zn_{1-x}Li_xO films with $x = 0.2$ onto sapphire, MgO and quartz substrates are prepared by DC sputtering method at about 573 K. The films are highly c -axis-oriented, normal to the surface with high transmittance in the case of quartz substrate, while non-uniform orientation with reduced transmittance is obtained for both sapphire and MgO substrates. The films show direct allowed optical transitions with $E_{\text{gd}}^{\text{opt}}$ values of 3.38, 3.43 and 3.29 eV for films deposited on sapphire, MgO and quartz substrates, respectively. Values of ϵ' , and N/m^* are dependent on the substrate kind. It is important to study the effect of temperature on the optical properties of ZnO:Li thin films. These films are good to examine the ferroelectric phase transition at 613 K by optical measurements at high temperatures above ambient, this is now under study. In this case, the present samples will be very suitable for applications in optical memory devices.

Metastable defect characterization in $\text{Cd}_{0.9}\text{Mn}_{0.1}\text{Te}:\text{In}$

E. Placzek-Popko^{a,*}, P. Becla^b^a*Institute of Physics, Wrocław University of Technology, Wybrzeże Wyspiańskiego 27, 50 370 Wrocław, Poland*^b*Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, USA*

Abstract

In indium doped $\text{Cd}_{0.9}\text{Mn}_{0.1}\text{Te}$, the presence of metastable defects has been detected by observation of persistent photoeffects. By DLTS measurements several deep levels have been found and one of them exhibited thermally activated capture cross section, indicating on its metastable character. Photocapacitance measurements performed at liquid nitrogen temperature yield optical threshold energy for the deep-shallow transition equal to around 0.75 eV. This value is 0.63 eV higher than the thermal activation energy. The large difference between these two energies has confirmed strong interaction of related defect with surrounding lattice. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Deep levels; Metastability; CdTe

1. Introduction

It has been well established that persistent photoeffects observed in many III–V and II–VI semiconducting compounds are due to the presence of metastable defects in the materials, the so-called DX centers. For $\text{Cd}_{1-x}\text{Mn}_x\text{Te}:\text{In}$ persistent photoconductivity has been reported for manganese content $x > 7\%$ [1]. These photoeffects were also observed by us in indium doped $\text{Cd}_{0.9}\text{Mn}_{0.1}\text{Te}$ [2] and $\text{Cd}_{0.8}\text{Mn}_{0.2}\text{Te}$ [3]. In the former case the persistent photoeffects were observed after exposure of the samples to illumination at temperatures as high as 150 K, approximately. Illumination from a halogen lamp at 77 K increased the conductivity of the material by about two orders of magnitude and such high conductivity persisted for a very long time after turning off the light [2]. The existence of metastable defects in this material has been further confirmed by the results of thermally stimulated capacitance studies. Identification of the levels responsible for the persistent photoeffects has been reported in Ref. [2]: DLTS studies,

carried out within the 77–360 K temperature range, revealed five distinct traps. One of the traps, labeled as E1, of binding energy equal to 0.12 eV, had a high concentration and its capture cross section was found to be thermally activated. It has been assumed therefore that trap E1 is related to DX center in the studied $\text{Cd}_{0.9}\text{Mn}_{0.1}\text{Te}:\text{In}$ and this trap is responsible for the persistent photoeffects observed in the material.

Direct evidence for DX center presence in the material would be large Stokes shift, i.e. the difference between optical threshold and thermal activation energy of the deep level associated to the center. The aim of present paper was to determine the photoionization threshold energy corresponding to the metastable defect in order to evaluate the Stokes shift. For this purpose, photocapacitance measurements have been performed and the results have been given in this paper.

2. Experiment

Experiments were performed on the as-grown samples of indium doped $\text{Cd}_{0.9}\text{Mn}_{0.1}\text{Te}$ processed by the Bridgman method. Prior to the measurements, the samples were annealed in cadmium atmosphere to reduce the

level of compensation in the material due to cadmium vacancies. Slices of the material were prepared by mechanical polishing followed by chemical etching in 2% Br_2 in methanol solution to remove the remaining surface layer. In order to perform capacitance and DLTS measurements, Schottky barriers were prepared by evaporation of gold 1 mm^2 layer on the front side of the samples in the vacuum of 10^{-6} Torr. Ohmic contacts were produced by soldering indium onto the fresh backside surface. Capacitance–voltage measurements yielded the room temperature donor concentration equal to $2 \times 10^{16}\text{ cm}^{-3}$.

The photocapacitance measurements were carried out after exposing the samples, at 77 K, to monochromatic light. Photons of energy within 0.6–1.5 eV range were used. As a light source a tungsten lamp was applied. The monochromatic light beam coming out of the monochromator was focused with the help of a fiber optic onto the sample, mounted in the sample holder immersed into liquid nitrogen. It should be pointed out that photocapacitance measurements are used as a technique complementary to DLTS. The DLTS system (DLS-82E) used by us allows determination of deep levels of energies within 0.1–0.9 eV interval. The photocapacitance measurements provide us with missing higher energy levels.

3. Results and discussion

The photocapacitance transient measurements comprise of the measurements of change in a capacitance of a diode due to photoemission of carriers from metastably occupied deep levels. Initially the diode is cooled down to 77 K at zero voltage bias, so that the deep levels are neutral (here in the case of an n-type sample, occupied by electrons). At this temperature reverse bias is superimposed and after a few minutes, when capacitance reaches its quasi-equilibrium value, the light is switched on and the diode is illuminated with monochromatic light. For a metal–n-type semiconductor, electrons photoemitted from the metastably occupied levels to conduction band are immediately swept out of the depletion region of a diode, revealing increase in the net positive charge of the region and increase in capacitance of a diode. The capacitance transients are then recorded for several minutes by a computer. Since in the case of studied material photoionization was persistent at 77 K, the sample had to be warmed up to the temperature at which persistent photoeffects were no more observed prior to measurement for each wavelength.

It was found that the optical threshold for the light induced capacitance change was equal to 0.67 eV. Exemplary capacitance transients taken at 77 K for three different wavelengths, 1.65 (0.75 eV), 1.35 (0.92 eV)

and $1\text{ }\mu\text{m}$ (1.24 eV) are given in Fig. 1. It was found that only the capacitance transients related to photons of energy lower than 0.83 eV could be well fitted with a single exponential. Photons of higher energies resulted in photocapacitance transients composed of two exponentials: “fast” component of time constant of the order of seconds and “slow” components of the order of tenths or hundreds of seconds, already existing for lower photon energies. The first component dominated capacitance transients for short time period after onset of illumination, whereas the slow was predominant for the longer time periods. Above statements are better documented in Fig. 2, in which parts of the transients presented in Fig. 1, corresponding to the capacitance under illumination, are given in a semi-logarithmic plot. In Fig. 2, capacitance change due to illumination, $\Delta C = C(t) - C(0)$, has been normalized to its steady state value $\Delta C_{ss} = C(\infty) - C(0)$ at each wavelength. The value ΔC_{ss} was determined from the least square fit of capacitance

Fig. 1. Exemplary capacitance transients for indium doped $\text{Cd}_{0.9}\text{Mn}_{0.1}\text{Te}$ taken at 77 K for three different wavelengths, 1.65 (0.75 eV), 1.35 (0.92 eV) and $1\text{ }\mu\text{m}$ (1.24 eV).

transients by a single exponential, or sum of exponentials, if necessary.

The results of photocapacitance measurements run within 0.6–1.5 eV photon spectral range are given in Fig. 3. In the figure, the dependence of steady state capacitance ΔC_{ss} on photon energy is shown. The spectrum increases monotonically for photons of energy higher than 0.67 eV. Several steps can be distinguished in the spectrum. In Fig. 3 the steps have been marked by arrows and corresponding threshold energies have been given. The steps are followed by a plateau (or increase), excluding the 1.3 eV threshold, followed by a decrease in capacitance. In order to explain the results, let us remind that $\Delta C_{ss}(h\nu)$ is proportional to the sum of contributions from different levels, located within energy interval extending up to $h\nu$. Each level introduces a step in the spectrum, near its threshold energy. The height of a step is related to the trap concentration N_T [4]:

$$\Delta C_{ss} \propto N_T \frac{e_{no}}{e_{no} + e_{po}}, \quad (1)$$

where e_{no} and e_{po} are electron and hole optical emission rates, and it has been assumed that thermal emission processes can be neglected at 77 K. If the process of photoemission of electrons dominates over the photoemission of holes, then ΔC_{ss} is directly related to N_T . Comparing results presented in Fig. 3 with Eq. (1) we may assume that for all measured capacitance transients excluding those connected with the 1.3 eV threshold, photoemission of electrons prevails over hole photoemission in spite of the fact that the higher energy levels are close to the valence band. According to Eq. (1) it means that for all measured capacitance transients besides the 1.3 eV threshold, photoemission of electrons prevailed over hole photoemission in spite of the fact that the higher energy levels are close to the valence band. This fact has been confirmed by MCTS measure-

ments. It was found, that only one hole trap is present, located 0.16 eV from the valence band top, which makes 1.34 eV distance from the bottom of conduction band, approximately equal to 1.3 eV threshold.

Assuming therefore, that in the case of 0.67, 0.75 and 1.05 eV thresholds, $\Delta C_{ss} \propto N_T$, we may conclude that the concentration of the trap related to the second threshold is predominant, and the contributions from the third and fourth levels can be neglected. We also noted that the decay of all the transients for energy higher than the second threshold was much faster than for the transients related to the first or second thresholds (cf. Fig. 1). Moreover, we also found that turning off the light for energies higher than 0.9 eV revealed immediate capacitance fall off to the level it reached for this energy. The same was observed for the transients induced by photons higher than the first threshold and lower than the second, after turning off the light capacitance relaxed to the value it had for 0.65 eV. Thus, we may assume that the first two thresholds are related to the photoemission from some metastable defects. Bearing this in mind, it becomes clear that the two exponentials, “fast” and “slow”, fitting well experimentally determined capacitance transients, are connected with photoionization of 0.67 and 0.75 eV deep levels related to the metastable defects.

Comparing this result with the previously mentioned suggestion based on DLTS studies, that level *E1* is related to a metastable defect, we come to the conclusion that one of the two thresholds 0.67 and 0.75 eV has to be related to optical transition from the level *E1*. As it was mentioned in introduction, level *E1* is related to some metastable defect of very high concentration. Of the two, 0.67 and 0.75 eV transitions, the latter is referred to as transition from a deep level of very high concentration. Therefore, it seems that we may attribute the 0.75 eV threshold to the optical transition and 0.12 eV energy to thermal transition from the same deep level, *E1*, yielding 0.63 eV Stokes shift. Such a high value of Stokes shift means large lattice relaxation for the defect, which is in accordance with the model of LLR proposed for DX centers in II–VI compounds [5]. Thus, obtained results confirm suggestion that the level *E1* is related to DX center in $\text{Cd}_{0.9}\text{Mn}_{0.1}\text{Te}:\text{In}$.

4. Conclusions

DLTS studies revealed the presence of a deep level, labeled as *E1*, attributed to metastable defect in $\text{Cd}_{0.9}\text{Mn}_{0.1}\text{Te}:\text{In}$, of binding energy equal to 0.12 eV. The photocapacitance measurements yield photoionization thresholds at energies equal to 0.67, 0.75, 1.05 and 1.3 eV. All of them, besides the last one are related to electron photoemission. The 0.75 eV threshold is related to metastable defects of a very high concentration. It has

Fig. 3. Photocapacitance spectrum, i.e. the dependence of steady state capacitance ΔC_{ss} on photon energy. The value ΔC_{ss} was determined from the least square fit of capacitance transients by a single exponential, or sum of exponentials, if necessary.

been therefore attributed to the optical transition from the level *E*1. The difference between the optical and thermal transitions for the level *E*1 yields large Stokes shift, equal to 0.63 eV. Thus, it may be assumed that this level is related to DX center.

Vacancies in CdTe: experiment and theory

S. Lany*, V. Ostheimer, H. Wolf, Th. Wichert

Technische Physik, Universität des Saarlandes, 66041 Saarbrücken, Germany

Abstract

Ab initio calculations in the framework of density functional theory are employed to complement experimental PAC and EPR data on vacancies in CdTe. The Te vacancy is found to be a negative-U centre with a large lattice relaxation in the neutral and the doubly charged state. The electronic state introduced by V_{Te} lies below the valence band maximum for V_{Te}^0 and shifts to above the conduction band minimum for V_{Te}^{+1} . An experimentally observed electric field gradient is interpreted in terms of acceptor compensation by V_{Te}^{+1} . Experimental data available for the Cd vacancy are discussed in the context of the calculated electric field gradients. A Jahn–Teller effect for V_{Cd} is not confirmed. © 2001 Elsevier Science B.V. 1. Introduction

Besides intentionally introduced dopants and residual impurity atoms, intrinsic defects, e.g. vacancies and interstitials, can strongly influence the optical and electrical properties of semiconductors and consequently have been a subject of intense research [1,2]. Except for the positron annihilation spectroscopy (PAS), most locally sensitive methods investigate vacancies indirectly via the hyperfine interaction (HFI) at neighbouring nuclei. In order to determine vacancy-related HFI parameters, methods such as Mössbauer spectroscopy, electron paramagnetic resonance (EPR), electron nuclear double resonance (ENDOR) and perturbed angular correlation spectroscopy (PAC) have been used. The correct experimental identification and characterisation of vacancies, however, is more difficult compared to the investigation of impurity atoms, which can be introduced into the semiconductor crystal by a controlled doping process, e.g. by ion implantation.

As a theoretical instrument being generally helpful to characterise dopants in semiconductors as well as

intrinsic defects (e.g. Ref. [3]), the density functional theory (DFT) formalism is used in order to compensate for the particular difficulty to investigate vacancies. The DFT calculations yield defect-related information that is difficult to access by experiment such as about the electronic structure and structural relaxations. Additionally, the identification of a particular defect is supported by the calculation of defect-related parameters, such as the electric field gradient (EFG), which is used experimentally as a “fingerprint” of the studied defect.

In the present work, the EFG tensor—characterised by the largest component V_{zz} and the asymmetry parameter η —is measured by PAC (for details, see e.g. Ref. [4]), using the radioactive probe nuclides ^{111}In and ^{111}Ag . In II–VI semiconductors, the $^{111}\text{In}_{\text{Cd}}$ donor and the $^{111}\text{Ag}_{\text{Cd}}$ acceptor form donor–acceptor (D–A) pairs with dopants, residual impurities or intrinsic defects, and in either case the EFG is determined at the $I = 5/2$ excited state of the daughter isotope ^{111}Cd [4]. It is emphasised that in CdTe, the daughter isotope ^{111}Cd is a host atom and consequently the measured EFG characterises the isolated defect. The absolute number of radioactive probe atoms needed for PAC measurements is 10^{11} – 10^{12} , and the resulting concentrations are generally low enough (10^{15} cm^{-3} and less) that the

electrical properties of the semiconductor crystals are not changed significantly.

The DFT calculations are performed using the linearised augmented plane wave (LAPW) method implemented in the WIEN97 [5] program package. The general treatment of an impurity in a semiconductor for EFG calculation within this method is described in Ref. [6]. In addition to the 32-atom supercell in BCC structure with T_d symmetry used in that work, a 32-atom cell with C_{3v} symmetry is used in the present case of the cadmium vacancy. In the LAPW method, the basis set consists of plane waves augmented by a spherical harmonics expansion within the so-called “muffin-tin” spheres around the atomic positions. In general, the wave functions are described by the plane wave basis at a vacancy site, but the use of an “empty sphere” allows an angular momentum decomposition of the vacancy-related states for analysis purposes. Magnetic hyperfine fields are not calculated in the present work.

2. The tellurium vacancy

From simple valence arguments, the tellurium vacancy V_{Te} accounts for a double donor, having an occupied a_1 level (s-like) and an unoccupied t_2 level (p-like) in the neutral state. Thus, no Jahn–Teller effect and no symmetry lowering from T_d symmetry is expected. A paramagnetic centre observed by EPR [7] and ENDOR [8] has been interpreted as V_{Te}^+ , but this assignment was questioned in Ref. [9], where calculations with the linear muffin-tin orbital method in the atomic sphere approximation (LMTO-ASA) yielded HFI constants incompatible with the experimental results. Furthermore, the ENDOR data require that the electron spin is localised at the vacancy site to about 96%, which is rather implausible for a vacancy and strongly differs from the theoretical localisation of 20% of the electron spin within the ASA sphere.

Using a 32-atom cell with all neighbouring atoms of the tellurium vacancy fixed at ideal lattice positions, i.e. suppressing the relaxation, we find the a_1 level (Kohn–Sham eigenvalue) within the gap for all three charge states V_{Te}^0 , V_{Te}^+ and V_{Te}^{++} , occupied by two, one and zero electrons, respectively. The localisation of 10% of the electron (a_1 level) within the LAPW muffin-tin sphere for V_{Te}^+ compares well with the 20% for the LMTO-ASA sphere, taking into account the different volumes of the respective spheres. From the positions of the a_1 level for the three charge states with respect to the valence band maximum (VBM), the transition energies $E(+ + / +) = E_{VBM} + 0.76$ eV and $E(+ / 0) = E_{VBM} + 1.22$ eV are inferred, which are in good agreement with the electron removal energies of 0.67 and 1.27 eV, reported in Ref. [9].

Taking into account the relaxation of nearest neighbour (NN) Cd atoms, which was not possible in the LMTO calculations from Ref. [9], has drastic implications. With exception of V_{Te}^+ , strong relaxation occurs resulting in a shift of the energetic position of the a_1 level and a significant lowering of the total energy (see Table 1). In Fig. 1a, the total electronic density of states (DOS) is shown for the relaxed configurations of the three charge states (note that for the unrelaxed configuration of all three charge states, the DOS resembles the DOS shown for V_{Te}^+ , except from the occupation number). In Fig. 1b, the a_1 level and the t_2 level are identified by the respective s and p character within the muffin-tin sphere at the vacancy site. Only for V_{Te}^+ , the a_1 level is still positioned within the band gap after relaxation. While for V_{Te}^0 , the strong inward relaxation of the NN-Cd atoms leads to a shift of the a_1 level to below the VBM, this level is shifted to above the conduction band minimum (CBM) during the outward relaxation in the $2+$ state. The $2+$ state of V_{Te} is comparable with the $3+$ state of the arsenic vacancy in GaAs, which also has an empty a_1 level and was calculated in Ref. [10]. There, the observed outward relaxation of the NN-Ga atoms was interpreted by the authors in terms of a rehybridisation towards sp^2 bonding. A similar argument holds in the present case for V_{Te}^{++} , where the NN-Cd atoms move about 60% of their way towards a planar sp^2 bonding configuration with the NNN-Te atoms. In the neutral state of V_{Te} , the a_1 orbital is *fully occupied* and there is a pronounced p_z -like contribution within the NN-Cd spheres (the local z -axis directs towards the vacancy). Consequently, the sp^3 configuration is retained from the point of view of an NN-Cd atom, causing the strong inward relaxation of the NN-Cd shell. After relaxation, the a_1 level is located 0.5 eV below the VBM (cf. Fig. 1b, left-hand side). In the singly charged state V_{Te}^+ , where the a_1 level is *half occupied*, the counteracting mechanisms described for V_{Te}^0 and V_{Te}^{++} approximately cancel each other, leading to only little relaxation and energy gain (cf. Table 1).

The transition energy between two charge states measures the Fermi level E_F for which the formation

Table 1

Relaxation Δd_{NN} of the NN-Cd atoms about V_{Te} (in per cent of the bond length 2.81 Å of CdTe, a negative sign is indicating an inward relaxation), along with the relaxation energy ΔE_r , which is the energy lowering due to relaxation, and the calculated electric field gradient V_{zz} at a NN-Cd site ($\eta = 0$ due to symmetry)

	Δd_{NN} (%)	ΔE_r (eV)	V_{zz} (10^{21} V/m ²)
V_{Te}^0	−22	0.98	+2.0
V_{Te}^+	−2	0.05	+16.2
V_{Te}^{++}	+20	0.69	+24.6

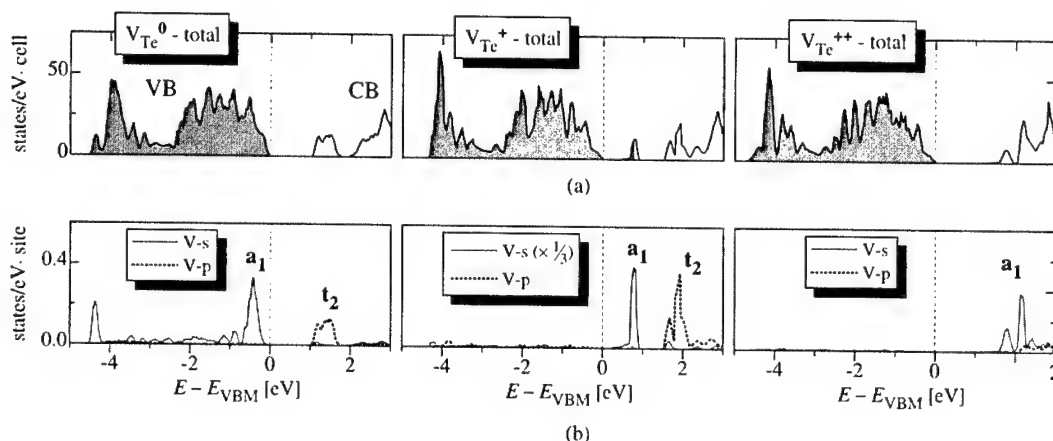

Fig. 1. (a) Total DOS for V_{Te}^0 , V_{Te}^+ , V_{Te}^{2+} . Occupied states are shaded. (b) Local DOS at the vacancy site decomposed into s and p contributions. For V_{Te}^+ , the half filled a_1 level in the band gap is very narrow, therefore the s contribution needs a different scaling ($\times 1/3$) to be displayed.

Fig. 2. Relative formation energies for the different charge states of V_{Te} as a function of E_F . (a) Relaxation suppressed. (b) Including relaxation. The left and the right margin of each plot corresponds to the VBM and the CBM, respectively; $\Delta E_{\text{form}} = 0$ corresponds to the unrelaxed configuration of V_{Te}^0 .

energy E_{form} of both states is equal (the formation energy of charged defects depends on E_F). Accordingly, the relative formation energy ΔE_{form} with respect to V_{Te}^0 is plotted in Fig. 2a in the case of suppressed relaxation. Due to the relaxation, however, the formation energies are lowered by the respective relaxation energies ΔE_r (Fig. 2b). In fact, the large relaxation energies for V_{Te}^0 and V_{Te}^+ (cf. Table 1) result in a negative-U behaviour with a transition energy of $E(+ + / 0) = E_{\text{VBM}} + 0.85 \text{ eV}$ between V_{Te}^+ and V_{Te}^0 , and the paramagnetic state V_{Te}^+ is never the most stable state, independent of the Fermi energy. Consequently, it should not be observed in an EPR experiment. Therefore, the rejection of the EPR identification of V_{Te} in Ref. [9] is confirmed. The fact that for the calculations of the HFI constants in Ref. [9] relaxation was neglected, does not harm, because in the paramagnetic $1+$ state the relaxation is quite small (cf. Table 1).

It is pointed out that the tellurium vacancy exhibits a rather extreme Franck–Condon effect, and thermal and optical excitation energies are no longer comparable. An optical excitation does not seem possible at all, because in the stable states V_{Te}^0 and V_{Te}^{2+} , the a_1 level is “hidden” in the valence band and in the conduction band, respectively. According to our LAPW calculations, the negative-U effect for the Te vacancy is very strongly pronounced, so that this property should not be affected by errors that may arise from the local density approximation and the estimation of the transition energies via the level positions. The negative-U behaviour accompanied by large lattice relaxation seems to be a rather general feature of anion vacancies in II–VI semiconductors; it has been found also for V_{Se} in ZnSe [11], while the extreme shift of the a_1 level into the valence band (neutral state) and into the conduction band ($2+$ state) was not reported there.

In order to investigate the interaction between Ag and Cu dopants, 2 nm copper were evaporated onto a CdTe crystal implanted with ^{111}Ag ions. After subsequent annealing at 500 K, PAC measurements yield an EFG of $V_{zz} = \pm 22.8(9) \times 10^{21} \text{ V/m}^2$ with $\eta = 0.0(3)$ ($T_M = 295 \text{ K}$). This value, which is unusually high for an EFG measured at the ^{111}Cd nucleus in CdTe, is close to the calculated EFG at an NN-Cd site for V_{Te}^+ , $V_{zz} = +24.6 \cdot 10^{21} \text{ V/m}^2$ with $\eta = 0$ (see Table 1). Based on the EFG calculations for interstitial Ag in CdTe, it is not expected that the interaction of ^{111}Ag with Cu atoms, e.g. the formation of $^{111}\text{Ag}_{\text{Cd}}\text{—Cu}_i$ pairs, would result in the observation of such a strong EFG. Therefore, the observed EFG is interpreted with the formation of close $^{111}\text{Ag}_{\text{Cd}}\text{—}V_{\text{Te}}^+$ pairs and shows the capability of the Te vacancy to compensate group I acceptors.

3. The cadmium vacancy

After the D–A pair formation of ^{111}In donors with the double acceptor V_{Cd} , the PAC probe is a NNN-atom with respect to the defect causing the EFG. Three distinct EFG have been reported in literature for the $^{111}\text{Cd}-V_{\text{Cd}}$ pair: One, labelled EFG1 in the following (values are given in Table 2), is observed after annealing ^{111}In -doped CdTe under tellurium vapour pressure [12,13]. A set of two EFG, EFG2 and EFG3, is observed simultaneously in crystals doped additionally with stable In to a level higher than 10^{18}cm^{-3} [14]. Similar EFG have been reported for ternary $\text{Hg}_{0.05}\text{Cd}_{0.95}\text{Te}$ compounds [15]. The stronger EFG, EFG2 and EFG3, which are observed when a background donor doping level is present, have been discussed in Refs. [14] and [15] in terms of a different charge state of V_{Cd} and the possibility that two In donors (one stable In atom and one ^{111}In isotope) bind to the double acceptor V_{Cd} . The LAPW calculations, using a 32-atom supercell in T_d symmetry containing a Cd vacancy, yield an atomic relaxation ($\Delta d_{\text{NN}} \approx -13\%$) which is less pronounced than in the case of V_{Te} and essentially independent of the charge state. In Table 2, the experimentally observed EFG are compared with the EFG calculated for the NNN-Cd site: Assigning EFG1, EFG2, and EFG3 to the neutral, singly, and doubly charged Cd vacancy, respectively, yields a relatively good agreement between experimental and theoretical data. It is noted, however, that in the 32-atom supercell, only three of the four Te neighbours to the Cd probe are contained within the supercell and a larger cell should be used. First calculations with a 64-atom supercell are currently running, indicating changes in the calculated EFG that are not very large, but significant. Therefore, the assignment of EFG1, EFG2, and EFG3 to the three charge states of V_{Cd} is only tentative at present, and the possibility that two In atoms bind to V_{Cd} cannot be excluded.

In the simple orbital model, the neutral cadmium vacancy has a fully occupied a_1 level and a t_2 level, which is partly occupied by four electrons. In principle, V_{Cd}^0 and the paramagnetic state V_{Cd}^- can be subject to a Jahn–Teller effect due to the partial occupation of the t_2

level. In this case, the t_2 orbital (p-like) would split into an occupied e level (p_{xy} -like) and an unoccupied (V_{Cd}^0) or half occupied (V_{Cd}^-) upper a_1 level (p_z -like), accompanied by a symmetry lowering from T_d to C_{3v} ; i.e. one NN-Te atom would relax stronger towards the vacancy site than the others (cf. Ref. [16], where V_{Zn} in ZnSe is discussed). An EPR signal, presenting trigonal symmetry, has been interpreted as resulting from V_{Cd}^- in a Jahn–Teller distorted configuration with the hole localised at one Te neighbour [17]. In order to investigate the Jahn–Teller effect theoretically, calculations with a 32-atom supercell in C_{3v} symmetry were performed. The interesting result is that the calculated forces on the NN-Te atoms tend to restore deviations from T_d symmetry for both the neutral and the singly charged state. Even for a strong trigonal distortion, no single, unoccupied band (the upper a_1 level, containing the holes localised at one Te neighbour) would separate from the valence band in the case of V_{Cd}^0 , as expected in the presence of a Jahn–Teller effect. Rather the holes occupy valence band like states and are moderately localised at the NN-Te shell (6% within each muffin-tin sphere of the NN-Te atoms). Thus, the DFT calculations clearly disagree with the assumption of a Jahn–Teller effect. It is further noted that in case of a Jahn–Teller distortion, the NNN-Cd atoms are no longer equivalent, and a set of three EFG instead of a single one should be observed for both the neutral and the singly charged state of V_{Cd} . This behaviour is not reflected by the PAC experiments. The discrepancies regarding the Jahn–Teller effect and the different possible interpretations of the experimentally observed EFG show that the cadmium vacancy still deserves further investigation.

4. Summary and outlook

DFT calculations of the tellurium vacancy in CdTe give access to the complex behaviour of this defect regarding the lattice relaxation and the electron structure which both change drastically with the charge state. Thus, a negative-U behaviour of V_{Te} is predicted and the paramagnetic V_{Te}^+ state should not be stable. Additionally, the acceptor compensation by doubly charged Te vacancies is discussed on the basis of the calculated EFG and experimental PAC data. As for the cadmium vacancy, the presence of a Jahn–Teller distortion is not confirmed. First calculations using a 32-atom supercell with symmetrical relaxation around the Cd vacancy yield a reasonable agreement with experimentally determined EFG, but due to the fact that the site of the probe atom is the next nearest neighbour to the vacancy, the use of a larger supercell is indicated. Calculations with a 64-atom supercell are expected to

Abstract

The diffusion of Ag atoms in CdTe was investigated using the radiotracer ¹¹¹Ag, which was introduced by implantation with an energy of 60 or 80 keV. The measured diffusion profiles are explained by assuming the existence of a repulsive interaction between Ag and residual Cu atoms causing a drift of the Ag atoms towards the centre of the crystal, which supposes the diffusion in a concentration gradient. This effect vanishes if the Ag concentration is increased and becomes more pronounced if the crystals are simultaneously co-doped with Cu. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Ag; Cu; Diffusion; CdTe

1. Introduction

The electrical and optical properties of semiconductors are essentially determined by the presence of impurities and defects. In addition, for the construction and thermal stability of devices, dynamic properties of dopant atoms are important. In CdTe, the group I elements represent potential acceptor atoms if they are incorporated substitutionally on Cd sites. The hole concentration achieved upon doping of CdTe with Ag atoms, however, is limited to about 10¹⁶ cm⁻³, although much higher concentrations of Ag are realised [1]. The formation of compensating defect complexes strongly depends on the concentration and the mobility of the participating defects. For Ag atoms in CdTe, the mobility is known to be very high, the experimental data describing the diffusion of Ag in CdTe in the literature are difficult to compare [2–5].

2. Experimental details

¹¹¹Ag atoms were implanted into CdTe single crystals using either the mass separator at the university Bonn or the isotope separator ISOLDE at CERN. The energy and dose used for implantation of the different samples are listed in Table 1. In order to investigate the influence of a higher Ag concentration, a 30 nm thick layer of stable Ag was deposited onto a CdTe crystal and the ¹¹¹Ag atoms were implanted into this layer. In addition, the influence of Cu on the diffusion of Ag was investigated. For this purpose, a 20 nm thick Cu layer was deposited onto the side implanted with ¹¹¹Ag (sample #5) before annealing of the crystal. In each case, the diffusion of the CdTe crystals (6 mm diameter and 500 μm thick) was performed in an evacuated quartz ampoule for 30 min.

The CdTe crystals were mechanically polished and the mass loss was determined by weighing the crystal after each step of polishing. The thicknesses of the abraded layers ranged between 2 and 20 μm. The number of ¹¹¹Ag atoms within each layer was determined by measuring the intensity of the 342 keV γ-line of the radioactive decay of ¹¹¹Ag with a Germanium well-detector.

Table 1

Preparation conditions of the CdTe crystals used for the diffusion experiments. The diffusion times were always 30 min

Sample	Ag layer	Energy (keV)	Dose (cm ⁻²)	Ag diffusion (K)	Cu diffusion
#1	—	80	10 ¹⁰	550	—
#2	—	60	10 ¹²	550	—
#3	—	60	10 ¹²	800	—
#4	30 nm	60	10 ¹²	800	—
#5	—	80	10 ¹⁰	550	550 K

Fig. 1. ¹¹¹Ag profiles measured after annealing at 550 K (top) and 800 K (bottom). The dashed lines correspond to the right axes and show the drift velocity (Eq. (2)) used for fitting the diffusion profiles. The vertical solid line marks the back of the CdTe crystal and the vertical dashed lines indicate the range of different drift velocities described by the parameter w in Eq. (2).

3. Results

Fig. 1 (top panel) shows the diffusion profile of sample #1 after implantation of 10^{10} Ag cm⁻² with an energy of 80 keV and diffusion at 550 K. The measured concentration profile exhibits a depletion layer with a thickness of about 80 μm starting directly at the crystal surface. This region is followed by an asymmetric peak of the Ag concentration at a depth of about 110 μm. Under slightly changed conditions this experiment, which exhibited a peak concentration of only 2×10^{12} Ag cm⁻³, was repeated with a higher Ag concentration: A second crystal (sample #2) was implanted with a dose 100 times higher and with a slightly lower energy of 60 keV. The data in Fig. 2, presented at an enlarged

Fig. 2. ¹¹¹Ag profile measured after annealing at 550 K, but in contrast to Fig. 1 (top), a 100 times higher dose of ¹¹¹Ag was implanted. Note, the enlarged depth scale.

Fig. 3. ¹¹¹Ag profile measured after diffusing of Cu at 550 K. The dashed line shows the Cu profile, expected on the basis of data published by Jones et al. The vertical solid line marks the back of the crystal.

depth scale, still show the depletion zone below the surface, which in this case extends over 10 μm. If the diffusion temperature is increased from 550 to 800 K (sample #3), the data in Fig. 1 (bottom panel) show that the profile becomes symmetric over the entire crystal. The ¹¹¹Ag concentration in the central region of this crystal is almost constant at a value of 10^{14} cm⁻³ and decreases by one order of magnitude within a layer of about 100 μm towards both surfaces. It should be noted that a sample treated at the same temperature of 800 K but containing a significantly higher Ag concentration (sample #4 in Table 1), shows a profile that is nearly homogeneous at a concentration level of 5×10^{18} cm⁻³ over the entire crystal.

A drastic effect is visible if, in addition, Cu is evaporated onto the ¹¹¹Ag implanted surface before diffusion annealing at 550 K (sample #5). The data in Fig. 3 show that in this crystal the ¹¹¹Ag atoms are nearly completely moved to the back (i.e. to the non implanted side) of the crystal. This observation can be explained by assuming a repulsive interaction between the Cu and Ag atoms which causes a diffusion of the Ag

atoms to the other surface of the crystal. By comparing these data with the corresponding results at 550 K shown in Figs. 1 and 2, it could be stated that in Fig. 3 the depletion layer is extended over almost the whole crystal.

4. Discussion

The depletion layers of the ^{111}Ag profiles, visible in Figs. 1 and 2, cannot be explained by out-diffusion of ^{111}Ag during the cooling down process: There was neither a significant loss of the ^{111}Ag activity of the crystals nor a strong enrichment of ^{111}Ag atoms on the surface detectable after annealing of the crystals. In order to explain the depletion layer below the surface the existence of a repulsive effect for the Ag atoms is proposed, as is most drastically reflected by the data in Fig. 3. Motivated by the observed strong influence of the presence of Cu on the Ag diffusion profile, the reason for the repulsive effects in Figs. 1 and 2 can be assigned to the presence of extrinsic or intrinsic defects in the depleted layers of these crystals, probably to Cu. Considering the data in Fig. 1, a quantitative description of the measured ^{111}Ag profiles can be found semi-empirically by assuming a depth dependent drift velocity $v(x)$ of the Ag atoms. The corresponding drift-diffusion equations describing the Ag concentration c can be expressed by

$$j = -D\partial_x c + v(x)c \quad \text{and} \quad \partial_x j = -\partial_t c, \quad (1)$$

where j denotes the flux of Ag atoms through a plane parallel to the surface per time unit and D is the diffusion coefficient for Ag in CdTe. The symmetric Ag profile of sample #3 visible in Fig. 1 (bottom panel) seems to indicate the state of thermal equilibrium at the diffusion temperature of 800 K. The shape within the layer of 100 μm below each surface is determined by the balance between the inward directed drift velocity and the diffusion in a concentration gradient. In order to fit the boundary condition of a symmetric profile in thermal equilibrium, the velocity profile has to be an asymmetric function with respect to the centre of the crystal with thickness L . For fitting the data of samples #1 and #3 the drift velocity $v(x)$ was parameterised by the function

$$v(x) = -v_0\alpha[\tanh(s(x-w)) + \tanh(s(x-L+w))] \quad (2a)$$

with

$$1/\alpha = \tanh(sw) + \tanh(s(L-w)), \quad (2b)$$

which is plotted as a dashed curve in both panels of Fig. 1. This function has the values $+v_0$ and $-v_0$ in the regions of width w neighbouring the two surfaces, is nearly zero in between, and the parameter s controls the

transient between the different regions. Using this function, Eq. (1) was solved numerically. The ^{111}Ag concentration at $t = 0$ is determined by the approximately Gaussian implantation profile of about 20 nm width close to $x = 0$, and the boundary conditions are defined by a vanishing flux ($j = 0$) of ^{111}Ag atoms at both surfaces of the crystal. The diffusion data of samples #1 and #3 were fitted by variation of the parameters D , v_0 , s , and w . The resulting fits (solid lines in Fig. 1) account in a satisfactory way for both diffusion profiles measured at 550 and 800 K. In case of sample #1, the diffusion coefficient D and the drift velocity v_0 are determined to be $D = 3 \times 10^{-8} \text{ cm}^2/\text{s}$ and $v_0 = 0.2 \mu\text{m}/\text{s}$, whereas in case of sample #3 only the ratio $D/v_0 = 45 \mu\text{m}$ can be extracted, which is larger by a factor of 3 than in sample #1. Extrapolating to 550 K the diffusion coefficients for Ag in CdTe, which were determined by Wartlick et al. [3] in the range between 320 and 350 K ($D = D_0 \exp(-0.22 \text{ eV}/kT)$ with $D_0 = 6.5 \times 10^{-6} \text{ cm}^2/\text{s}$) a value of $6.3 \times 10^{-8} \text{ cm}^2/\text{s}$ is obtained, which is in good agreement with the value determined for D in sample #1. The different values of the quotient D/v_0 for samples #1 and #3 are plausible because of the different diffusion temperatures.

This quantitative description of the experimental data in Fig. 1, however, gives no information about the origin of the repulsive interaction acting on the Ag atoms since the used function $v(x)$ is not derived from a physical model. The cause of this interaction may be qualitatively explained by a repulsive interaction between Cu and Ag atoms, best seen in Fig. 3. Cu atoms seem to be present in almost all CdTe crystals as a residual contamination, indicated e.g. by the Cu^0X bond exciton frequently observed in PL investigations [6,7]. Thus, a connection between the repulsive interaction exerted on the Ag atoms and the Cu contamination in samples #1, #2, and #3, which were not intentionally doped with Cu, seems to be possible. The reduction of the depletion layer in Fig. 2 (sample #2) and the invisibility of this interaction in sample #4 is explained by the increasing Ag/Cu ratio in these samples, yielding Ag concentrations that significantly exceed the concentration of the residual Cu contamination. In contrast to the data in Fig. 1, the ^{111}Ag profile of sample #2 shown in Fig. 2 could not satisfactorily be fitted using the simple function of Eq. (2) for describing the drift velocity $v(x)$. This may reflect the physical nature of the repulsive interaction, which is expected to depend on the gradient of the Cu concentration and the concentration of Ag.

Finally, the ^{111}Ag diffusion data of sample #5 shown in Fig. 3 will be considered. The diffusion of Cu in CdTe was investigated e.g. by Woodbury and Aven, Panchuk et al., and Jones et al. [8–10]. Jones et al. used an evaporated Cu layer as diffusion source, similar to the conditions for Cu diffusion chosen in the present experiments, and they detected a slow and a fast

diffusing component of Cu. The diffusion coefficient D and the solubility c_s of the fast component are reported to be nearly independent on temperature in the range 450–600 K and are determined to be $D = 3.3 \times 10^{-8} \text{ cm}^2/\text{s}$ and $c_s = 10^{17} \text{ cm}^{-3}$, respectively. On the basis of the data presented by Jones et al., the Cu profile was calculated assuming an infinite Cu source and plotted in Fig. 3 (dashed line). A comparison with the Ag data shows that the Cu concentration obviously exceeds the Ag concentration over the entire crystal, except for a thin layer at the back of the crystal where most of the Ag atoms are accumulated. The nearly complete diffusion of the ^{111}Ag atoms to the back of the crystal, therefore, seems obviously to be caused by the repulsive interaction between Cu and Ag. It should be remarked that the diffusion of Cu and Ag in CdTe observed here might show up some similarities with the interaction of p-type dopants, i.e. of Zn and Cd, in InP reported by Tuck et al. [11]. In that experiment, the presence of Cd was found to increase the diffusion depth of Zn but, contrary to the present data, the presence of the diffusing Zn greatly increased the rate of out-diffusion of Cd from the semiconductor.

5. Conclusion

The presented data on the diffusion of Ag in CdTe are interpreted in the framework of a repulsive interaction between the diffusing Ag and Cu atoms. In crystals that were not intentionally doped with Cu, the residual concentration of Cu causes a drift of the Ag atoms towards the centre of the crystal which superposes the diffusion in the presence of a concentration gradient. The visibility of this interaction vanishes with increasing Ag concentration. Upon intentional co-diffusion of CdTe with Cu, however, the observed effect becomes more pronounced indicating that the presence of Cu atoms seems to be responsible for the observed repulsion of the Ag atoms. Within a semi-empirical model, quantitatively describing the diffusion data at 550 and 800 K (Fig. 1), the diffusion coefficient of Ag in CdTe

corresponding to a temperature of 550 K was determined. This value is in good agreement with extrapolated data of the temperature dependent diffusion coefficient published by Wartlick et al. [3]. Although the measured ^{111}Ag profiles can be understood qualitatively, on the basis of the present data a microscopic interpretation about the nature of the long range repulsive interaction between Cu and Ag cannot be given yet.

Abstract

Copper and silver related local centres in CdS crystals were investigated by means of technique based on drift of defects in external electric field. The impurities were first introduced in crystals and then extracted from them under electric field 100–300 V/cm at 600–750 K. Acceptors Cu_{Cd} and Ag_{Cd} responsible for emission bands 1000 and 610 nm correspondingly were found to be the only local centres created after impurity incorporation. Local centres related to interstitials Cu_i and Ag_i were not revealed. Different photo-enhanced defect reactions were observed in the crystals before and after impurity incorporation. A transformation of the type of reaction as a result of impurity incorporation took place. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Defects; Electrodiffusion

1. Introduction

One of the important problems in semiconductor studies is the identification of defects related to certain local centres. In such investigations a method based on defect drift in electric field can be quite useful. When defects under consideration are charged and mobile enough, application of external electric field at a fit temperature gives possibility to make a desirable redistribution of these defects along the sample. So, drifting defects can be extracted from any region of the sample and then incorporated in it again. Comparison of electrical and optical characteristics of this region before and after such procedures allows identification of local centres related to the defects. Earlier we used this technique for investigation of mobile shallow donors in undoped and Li-doped CdS crystals [1]. Electron traps related to Cd and Li interstitials were found and participation of these defects in a number of photo-

enhanced defect reactions was established [1,2]. In the present work, Cu- and Ag- related centres in CdS crystals have been investigated.

2. Experimental procedure

Nominally undoped high-resistivity ($\rho > 10^8 \Omega \text{cm}$) bulk CdS crystals were used. The crystals have bright yellow colour. Samples were rectangular parallelepipeds of typical dimensions $5 \times 3 \times 1 \text{ mm}^3$ cut from large boules. The impurity was introduced from electrode containing Cu or Ag, the other electrode being pure In. The sample was heated to $T_d = 600\text{--}750 \text{ K}$ and then electric field $E_d = 100\text{--}300 \text{ V/cm}$ was applied to it during time interval Δt_d so that electrode with the impurity was the anode [3]. Doped region had reddish-brown (in the case of Cu) or bright brown (in the case of Ag) colour. A sharp boundary was observed between doped and undoped regions (Fig. 1(a) and (b)). When the sample was heated to T_d again and electric field of opposite direction was applied to it, extraction of the impurity from the sample took place and the crystal

(L.V. Borkovska).

Fig. 1. (a) CdS crystals under visible light at 300 K after incorporation of: (a) Ag ($T_d = 700$ K, $E_d = 250$ V/cm², $\Delta t_d = 80$ min); (b) Cu ($T_d = 650$ K, $E_d = 100$ V/cm², $\Delta t_d = 30$ min).

acquired the initial bright yellow colour. If both electrodes were pure indium, no change of crystal colour was observed after electric field application.

Transmission, photoluminescence (PL), photocurrent (PC) and thermally stimulated current (TSC) spectra of the same sample region were measured in 77–300 K temperature range before and after impurity incorporation and then after its extraction.

3. Results

Transmission spectra measurements showed that after Ag and Cu incorporation a transparency of crystals decreased and absorption edge shifted to the long wavelength side (Fig. 2(a) and (b)).

In PL spectra of initial crystals edge green emission at $\lambda = 515$ nm dominated (Fig. 3(a) and (b)). Doping with Ag or Cu resulted in this emission quenching, while strong orange band at $\lambda = 610$ nm appeared due to Ag introduction (Fig. 3(a)), or infrared (IR) band at $\lambda = 1000$ nm became much more intensive due to Cu introduction (Fig. 3(b)). At the same time, intensity of red band at $\lambda = 715$ nm that, as a rule, was also present in initial crystal PL spectra, remained factually unchanged after doping. In some initial crystals strong self-

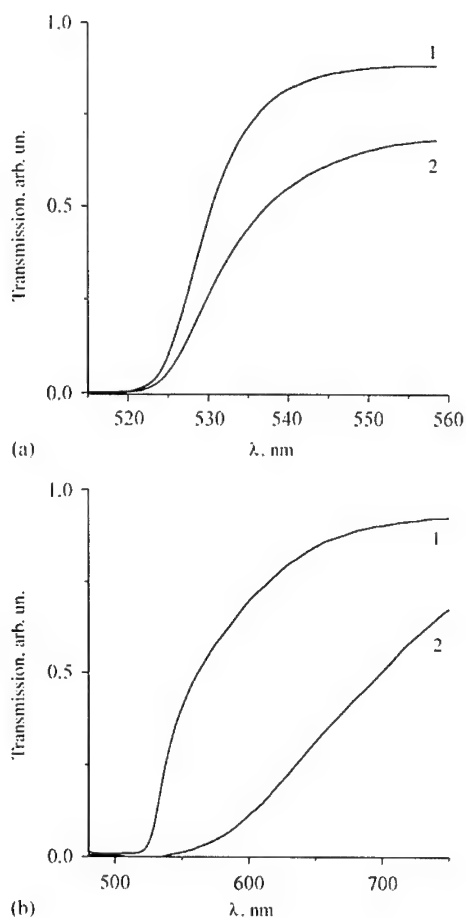

Fig. 2. Transmission spectra of CdS crystals at $T = 300$ K before (1) and after (2) incorporation of Ag (a) and Cu (b).

activated orange PL band at $\lambda = 590$ nm in addition to green and red ones was observed. When both electrodes supplied to the crystal were indium, no essential changes in PL spectra took place after sample treatment by electric field (Fig. 3(c)).

The incorporation of Ag and Cu was accompanied with the increase of crystal photosensitivity in the whole wavelength range, the most effect being observed in the extrinsic region at $\lambda \sim 600$ nm and $\lambda \sim 700$ nm correspondingly (Fig. 4(a) and (b)). Different photo-enhanced defect reactions (PEDR) were found to occur in crystals before and after impurity incorporation. In undoped crystals "sensitizing" PEDR [4] took place: when the crystal was cooled from 450 to 300 K in dark its photosensitivity was smaller then after cooling under visible light illumination (Fig. 4(a) and (b), curves 1, 2). After doping with Cu or Ag "degradation" PEDR [2] was observed: photosensitivity decreased due to visible light illumination (Fig. 4(a) and (b), curves 3, 4). In Cu-

Fig. 3. Photoluminescence spectra of CdS crystals at 77 K before (solid lines) and after (dashed lines) treatment under electric field, the anode containing: (a) Ag, (b) Cu and (c) no impurity.

doped sample regions photosensitivity degradation under illumination was already conspicuous at 300 K, while in Ag-doped ones this effect became noticeable only at $T > 350$ K.

Fig. 4. Photocurrent spectra of CdS crystals at 300 K before (1,2) and after (3,4) incorporation of (a) Ag, (b) Cu. Cooling from 420 to 300 K in dark (1,3) and under intrinsic light illumination (2,4).

After impurity extraction, initial transmission, PL and PC spectra were restored and sensitizing PEDR was again observed.

In TSC spectra of investigated crystals some peaks, in general different in different samples, were present (Fig. 5). After doping the increase of TSC current was observed in the whole temperature range due to the increase of photosensitivity. However, any peak did not appear after impurity incorporation or disappear after its extraction.

4. Discussion

In CdS, copper and silver can create defects of two types: site atoms Cu_{Cd} , Ag_{Cd} and interstitials Cu_i , Ag_i that act as single charged acceptors and donors, correspondingly [5]. The IR band at $\lambda = 1000$ nm and

Fig. 5. TSC spectra of CdS crystals before (1) and after (2) incorporation of (a) Ag. (b) Cu.

orange band at $\lambda = 610$ nm, that rose in PL spectra of investigated crystals after doping and quenched after impurity extraction, are probably due to Cu_{Cd} and Ag_{Cd} centres, correspondingly. In fact, these bands were proved to result from recombination of free electrons on acceptor centres [6]. At the same time, in CdS doped with Cu and Ag by usual techniques a strong red emission at $\lambda = 710\text{--}720$ nm is generally also observed and ascribed to Cu- or Ag- related centres [5–8]. This band, however, is often present in nominally undoped crystals [5,6] and, as our investigations showed, Cu and Ag transfer under electric field does not influence on its intensity. Therefore we suppose, that this band is due to native defects. Perhaps, the presence of Cu and Ag enables the creation of such defects. The fact that intensities of self-activated green $\lambda = 515$ nm, orange $\lambda = 590$ nm and red $\lambda = 715$ nm emission bands do not change after action of electric field is the evidence that defects responsible for these emission bands do not drift in electric field at $T \leq 650$ K.

The direction of Cu and Ag drift from the anode to the cathode indicates that these impurities diffuse interstitially as donors Cu_i^+ , Ag_i^+ [3]. Hence, the latter are present in the crystal during doping process. In high-resistivity crystals these donors must manifest themselves as electron traps [6]. The analysis of obtained TSC data showed, however, that any electron trap did not appear after Cu or Ag incorporation. This fact means that equilibrium in reactions $\text{Cu}_i + \text{V}_{\text{Cd}} = \text{Cu}_{\text{Cd}}$, $\text{Ag}_i + \text{V}_{\text{Cd}} = \text{Ag}_{\text{Cd}}$ is essentially shift to the right side. The similar situation takes place in Ge and Si, where copper ions also diffuse as donors Cu_i^+ , but in doped material only acceptors Cu_{Ge} have been revealed [9].

“Sensitizing” and “degradation” defect reactions observed in investigated crystals are known to be characteristic for nominally undoped bulk CdS crystals [4,6] and Cu-doped CdS ones [2,6] correspondingly. In both reactions mobile native donors Cd_i had been shown to participate [4,6]. PEDR in CdS:Ag crystals was observed for the first time. One can suppose, however, that mechanisms of PEDR’s in CdS:Cu and CdS:Ag crystals are similar. Transformation of “sensitizing” PEDR into “degradation” one after impurity incorporation leads to the conclusion that like Cu also Ag atoms participate in the “degradation” process. The fact that in CdS:Ag crystals degradation PEDR occurs at higher temperatures than in CdS:Cu ones can be due to lower mobility of Ag in CdS lattice [5].

Laser shock wave stimulated defects in p-CdTe crystals

A. Baidullaeva*, A.I. Vlasenko, A.V. Lomovtsev, P.E. Mozol'

Institute of Semiconductor Physics, National Academy of Sciences of Ukraine, 45, Prospect Nauki, 03028 Kiev-28, Ukraine

Abstract

The changes in the physical properties of high-resistance p-CdTe crystals both during and after the passage of a laser shock wave (SW) were investigated. It was shown that the electrical conductivity of the p-CdTe increases when the SW passes through the crystals and decreases after its passage. The changes in the aforementioned characteristics during the SW passage are defined by the generation of nonequilibrium carriers from deep centers. It is observed that the number of dislocations increases as the power density of the laser radiation increases. This increase is correlated with the decrease in the residual conductivity of the samples. The changes in the residual conductivity are due to the formation of stable defects and their subsequent interaction with defects, existing in the initial crystal. © 2001 Elsevier Science B.V. 1. Introduction

The irradiation of the p-CdTe crystals by ruby laser nanosecond pulses with power density below the damage threshold leads to a change in their electrical, photoelectric and optical properties. These changes occur both in the near-surface region of the material and at a depth of $\sim 5 \mu\text{m}$ which is much more than the light absorption depth (10^{-5} cm^{-1}) [1–3]. These changes are caused by the formation of intrinsic lattice defects due to the lattice “heat-up”, the generation of thermal elastic stresses, and the action of acoustic and shock waves in the course of irradiation of the crystal. Hypothetically, the energy of the laser pulse is transferred to the lattice via the generation, thermalization, and subsequent recombination of the electron-hole pairs. Even a small increase of temperature (up to 200°C) in the irradiation zone in a short time (10^{-8} s) results in a thermal shock. In this case, thermoelastic stresses $\sim 20\text{--}30 \text{ kbar}$, sufficient for breaking weaker

chemical bonds, arise in the lattice. A strong vibration excitation of the centers, located at the surface, could result in the detachment and evaporation of the atoms or different impurities in the semiconductors. The diffusion of impurities and defects into the volume of the crystal was also observed [4,5]. It is expected that a similar mechanism is observed in the case of the CdTe. However, it should be noted that the shock wave (SW) acts jointly with the photoeffect, thermoelastic deformation, and thermal heating.

It is of interest to identify the role of the SW in defect formation in CdTe separately from the above-indicated effects which accompany the laser radiation.

In this paper, we report the specific results of the SW action on the electrical properties and dislocation structures of the p-CdTe crystals.

2. Experimental procedure and results

The above-mentioned properties of the p-CdTe were investigated both during and after the SW passage through the crystal. Nondestructive SW was generated by Q-switched ruby laser pulses of $2 \times 10^{-8} \text{ s}$ duration. The intensity of the laser pulses was varied in the range

10^7 – 10^9 W cm $^{-2}$ by means of neutrally gray light filters. The technique of sample preparation and its irradiation is similar to the technique described in Refs. [4,5]. The SW pressure was calculated by the formula given in Ref. [6].

The concentration dependence of the nonequilibrium charge carriers (NCC) on the SW pressure is shown in Fig. 1. At low SW pressures the concentration of the NCC exponentially increases, achieving saturation at a SW pressure higher than 3 kbar. In addition, an increase in conductivity of the CdTe was observed when the crystals were irradiated with ruby laser pulses, and then the conductivity returned to its initial magnitude. The kinetics of the conductivity change ($\Delta\sigma/\sigma_0$) of p-CdTe under the action of the SW is shown in the inset in Fig. 1. The relaxation time of the conductivity change under different SW pressures has two components. These are a fast component, which occurs exponentially with relaxation time constant $\tau_1 = 1.56 \times 10^{-4}$ s, and a slow component during which (over time $\tau_2 = 3$ –4 min) the conductivity decreases by several factors and then stabilizes. The residual conductivity of the crystal drops below the initial σ_0 value. The amplitude of the residual conductivity change versus the SW pressure is shown in Fig. 2. At first, the residual conductivity decreases and then saturates.

Fig. 1. The dependence of the NCC concentration in the p-CdTe crystal on the SW pressure. Inset: relaxation time of the NCC in a p-CdTe crystal at the SW passage.

Fig. 2. The dependence of the residual conductivity (σ) in p-CdTe on SW pressure.

The photocurrent of the initial crystals depends weakly on temperature in the 100–300 K range. At the limit of this range, the photocurrent becomes thermally activated and the dependence I_{ph} versus $1/T$ follows the Arrhenius law with activation energy $E_i = 0.8$ – 0.9 eV (Fig. 3, curve 1). Quenching of the photocurrent with activation energy $E_{vi} = 0.13$ eV is observed in the low-temperature region after the SW passage with $P < 2$ kbar. The thermal activation region of the photocurrent remains unchanged above room temperature, and the photocurrent decreases almost by an order of magnitude (Fig. 3, curve 2). The appearance of the temperature range of the photocurrent quenching subsequent to the SW passage with $P < 2$ kbar can be related to the formation of shallow-level centers with the activation energy of ~ 0.13 eV. At low temperatures and at low excitation levels in the region of the fundamental light absorption, a strong optical charge redistribution between r-centers ($E_r = 0.9$ eV) and shallow acceptors ($E_{vi} = 0.13$ eV) proceeds in the CdTe crystals. Namely, photoholes are trapped by the shallow levels, and the hole population of the r-centers is decreased, i.e. quasi-dark formation of the center population by minority carriers with a concentration of N_r^0 takes place [7,8]. Consequently, the N_r^0 rise causes a decrease in τ ($\tau \propto 1/N_r^0$) and in the photocurrent. The photocurrent decreases further by an order of magnitude after repeated SW passage with $P > 2$ kbar. In this case, the temperature dependence form is retained, excluding the region of the temperature quenching of photocurrents, which disappears.

Fig. 3. The temperature dependences of (1, 2) photocurrent and (3–5) dark current in p-CdTe (1, 3) up to and (2, 4, 5) after the SW passage.

A region with activation energy $E_1 = 0.6$ eV in the temperature dependence of the dark current of the p-CdTe crystal is observed (Fig. 3, curve 3). The dark current remains unchanged after the SW passage with $P < 2$ kbar. However, an additional region with $E_2 = 0.14$ eV appears (Fig. 3, curve 4). The dark current decreases with further increase of the SW pressure, and activation energies E_1 and E_2 disappear in the temperature dependence of the dark current. However, the level with energy $E_3 = 0.8$ eV corresponding to the deep r-centers is observed (Fig. 3, curve 5). It indicates that after the SW passage with $P > 2$ kbar, charge carriers are generated from deeper levels in comparison with the initial crystal. The level $E_2 = 0.14$ eV in the CdTe crystals corresponds to the energy position of acceptors, the cadmium vacancy [9], and $E_1 = 0.6$ eV corresponds to the double-charged cadmium vacancy [10].

The dislocation densities of the initial crystals were equal to 10^2 cm^{-2} . For the laser radiation power densities used, the SW did not lead to the appearance of visible damage at the entrance and exit surface of the crystals. However, after selective etching, the number of dislocation etch pits increased and its total amount increased with increasing radiation power density or number of pulses (Fig. 4). We note that the threshold laser irradiation power density for which dislocation multiplication is observed corresponds to the threshold of the SW formation.

Fig. 4. The distribution of the dislocation etch pits on the (111) surface of p-CdTe: 1—initial sample and 2, 3—after the SW passage.

3. Discussion

Increase of the concentration of the NCC of the p-CdTe single crystals, irradiated with nanosecond laser radiation pulses, is possible when additional carriers are generated as a result of the penetration of the thermal wave and laser SW.

The penetration depth of the thermal wave, which is formed under the irradiation of the samples, was $\sim 1.5 \mu\text{m}$, much less than the foil thickness. For this reason, changes in the concentration of the NCC in crystals cannot result from heating. The ionization energy of the defects decreases because of a decrease

of the band-gap energy (E_g) under the SW action. Estimation shows that the E_g change is equal to ~ 0.01 eV in the investigated range of the SW pressure, whereas the conductivity increases by a factor of 2–2.5. This indicates that the concentration of the NCC released from the traps is comparable to the equilibrium concentration. However, the slight change in E_g cannot bring about ionization of all the traps. In relation to the aforementioned, the increase of the NCC concentration at low (below 2 kbar) pressures can be explained by their generation from deep-level point defects (traps). The saturation of the NCC with the increase of the SW pressure above 3 kbar can be explained by accumulation of the residual defects generated by the SW [4].

The mechanism for the formation of the SW under the action of laser pulses is described in Ref. [4]. A thin layer of metal vapor and weakly ionized plasma forms at the interface when the surface of the foil is irradiated. It drives a wave of mechanical compression in front of itself at expansion into the volume. The SW can be considered as a directed flux of phonons which are scattered by the lattice irregularities. Here, the center of scattering acquires a momentum which is sufficient to form defects. These defects, in addition, can be ionized since the lattice, compressed by the SW, is close to the limit of stability.

Let us discuss the experimental results after the SW passage through the crystals. Since the metal vacancies (acceptors) manifest themselves in the equilibrium conductivity of a p-CdTe crystal, we can suppose that the decrease in the equilibrium conductivity after the SW passage with $P > 2$ kbar is related to a changing concentration of acceptor centers in the crystals. Let us consider the behavior of the acceptor centers after repeated SW passage. The Frenkel pairs, isolated vacancies, and interstitial atoms are formed in the crystal under SW action. They can interact with impurity atoms and form stable defect complexes [11]. At repeated SW passage, these steady defects accumulate from pulse to pulse, in a manner that is similar to high-energy radiation influence on a semiconductor [12]. It is possible that a cadmium vacancy forms during the first SW passage, verified by the appearance of the level with $E_2 = 0.14$ eV (Fig. 3, curve 4). The cadmium vacancies are transferred to the dislocations at the second SW passage with $P > 2$ kbar. The vacancy formation energy decreases because of the repeated SW passage through the crystal. For this reason, the large amount of excess vacancies formed brings about the additional distortion of the material [13]. In turn, this distortion can bring about concentration fluxes causing the phenomenon of “uphill” diffusion. Elastically strained layers formed in this case dramatically enhance vacancy diffusion in a bulk material. The enhanced diffusion can be related with: the crowdion mechanism of displacement of the lattice site atoms,

diffusion to sinks, diffusion along the dislocations with the enhanced diffusivity, or drift in the gradient of elastic strains, i.e. “uphill” diffusion [13]. The migration rate of atoms within the local volumes during “uphill” diffusion can be several orders of magnitude higher than the average mobility level of the atoms in crystals at a given temperature. As a result, the vacancies are localized in the compressed regions (formed by both the vacancies themselves and the SW) and form clusters. Depending on the number of vacancies, clusters take the form of a sphere or disk of monatomic thickness, i.e. a dislocation loop. We observe the formation of this dislocation loop in our experiment (Fig. 4). The appearance of the band $\lambda_{\text{max}} = 840$ nm in photoluminescence spectra connected to it was observed previously [5]. In many works of other authors, this dislocation-related band is associated with the point centers of recombination, which include cadmium vacancy [14]. The experimentally observed decrease of conductivity after the SW passage may be explained by an increase of the dislocation density [5].

4. Conclusion

Thus, the action of a laser SW on the p-CdTe single crystals at room temperature leads to the change in its conductivity and dislocation structures. The conductivity of the crystals is increased at the moment of the SW passage, and is decreased afterwards. The increase in conductivity could be explained by the generation of the NCC from deep-level point defects (traps) under the SW action. The increase in the dislocation density, i.e. decrease of the acceptors that determine the value of the conductivity could be an explanation of the conductivity decrease after the SW passage. It has been assumed that the mechanism of dislocation formation is the creation of a large amount of excess vacancies and its formation of clusters under a laser SW action.

Magnetic resonance studies of ZnO

W.E. Carlos^{a,*}, E.R. Glaser^a, D.C. Look^b^aNaval Research Laboratory, Code 6862, Washington, DC 20375, USA^bWright State University, Dayton, OH 45435, USA

Abstract

We have used EPR and ODMR to study state-of-the-art bulk ZnO single crystals. Most of the samples are n-type; however, under certain conditions (e-irradiated or annealed), we observe a center due to residual nitrogen ($g = 1.9953$, $g_{\perp} = 1.9633$ and $A_{\text{iso}} = 1.225$ mT, $A_{\text{aniso}} = 0.864$ mT). The N center is a nitrogen p-orbital along the c -axis, very similar to P or As in ZnSe, which have a Jahn-Teller distorted, deep state, seen in EPR. The intensity of the N center is strongly anisotropic, as would be expected for shallow heavy-hole acceptors with $m_J = \pm \frac{3}{2}$ in which the magnetic dipole transition is forbidden for $\mathbf{B} \parallel c$ and becomes allowed away from that orientation due to mixing with $m_J = \pm \frac{1}{2}$ states. The EPR spectra for the n-type samples are dominated by delocalized donors ($g = 1.9570$ and $g_{\perp} = 1.9551$). In one sample, the donor appears to be localized. These crystals also exhibit a broad PL band at 2.5 eV. ODMR on the 2.5 eV "green" PL band reveals an $S = 1$ triplet center (not seen in EPR) with spin-Hamiltonian parameters of $D = 0.763$ GHz, $g = 1.9710$, and $g_{\perp} = 2.0224$. ODMR of shallow donors is also observed as a luminescence-decreasing feature on the 2.5 eV green emission band. Published by Elsevier Science B.V.

1. Introduction

There has been renewed interest in ZnO both as a potential substrate for nitride epitaxy and as an active electro-optical material for near-UV applications in its own right [1,2]. It has the obvious advantage over GaN of being readily grown as bulk crystals. The primary impediment to its development is the lack of a p-type dopant. The crystals are invariably n-type due to an as-yet unidentified donor and while there have been some reports of p-type doping [3,4], they are still somewhat sporadic and not well understood. One potential acceptor is nitrogen and in this work, we use electron paramagnetic resonance (EPR) to examine residual, isolated nitrogen in high-quality bulk crystals and find that it is Jahn-Teller-distorted. We also examine the residual donor line and find no hint of hyperfine splitting, suggesting that an intrinsic defect rather than

an impurity may be responsible. Finally, we use optically detected magnetic resonance (ODMR) and observe an $S = 1$ triplet state and discuss its possible origin. The EPR measurements were all performed in a Bruker 9.5 GHz spectrometer, typically at 4.2 K. The ODMR experiments were performed on the 2.5 eV green photoluminescence (PL) at 24 GHz and 1.6 K using the 351 nm line of an Ar⁺ laser for excitation.

2. Nitrogen

In two samples (one annealed at 850°C and a second e-irradiated), we observe a three-line spectrum due to nitrogen (the only 100% abundant $I = 1$ nucleus), illustrated in Fig. 1 for several rotations about the $(1\bar{1}\bar{2}0)$ axis. In addition to the set of three relatively strong lines, there are several weaker lines, which we shall not discuss further in this paper. These three lines have nearly axial symmetry (rotation about the c -axis does little to either their splitting or their central position) and equal integrated intensities. The EPR parameters are (assuming axial symmetry which fits

*Corresponding author. Tel.: +1-202-404-4573; fax: +1-202-767-0546.

Fig. 1. The EPR signal of the N center at selected orientations. The lineshapes of the signal for $B \parallel c$ are shown in the inset.

Fig. 2. The integrated intensity of the N center as a function of orientation. The error bars give the range of intensities for the three lines.

very well) $g_{\perp} = 1.9633$ and $g_{\parallel} = 1.9953$ and $A_{\text{iso}} = 1.225$ mT and $A_{\text{aniso}} = 0.864$ mT. The large anisotropy in the hyperfine interaction suggests a p-orbital and an atomic orbital analysis yields a center that is 96% p and 4% s and 45% localized on the N atom. This is very similar to the deep state of As or P in ZnSe [5]—a p-orbital on the impurity atom which is Jahn-Teller-distorted, along the c -axis away from the substitutional site. A qualitative physical argument for the behavior of group V acceptors substituting for S or Se in other II–VI compounds has been given by Chadi [6]. He argued that the acceptor atom must have significantly higher ionization energy than the host anion to avoid a deep Jahn-Teller distorted state. Hence, N does not have a deep state in ZnSe, while As and P do. Extending this argument to ZnO:N, the ionization energies of N and O are similar, suggesting that it may be deep, consistent with our observations. Of course, As and P have even smaller ionization energies [7] and one would expect a deep state for them as well. Recent calculations by Yamamoto and Katayama-Yoshida have also indicated that isolated N forms a deep state [8].

The biggest puzzle with these lines is the variation of intensity with orientation. In Fig. 2, we see that the integrated intensity of all the three lines vary by an order of magnitude with angle (also noticeable in Fig. 1). However, all the three have very similar intensities. (The departure around 85° is an artifact due to one of the weaker resonances mentioned above overlapping with the low field line.) This is more typical of a heavy hole ($m_j = \pm \frac{3}{2}$) in which the EPR transition is forbidden for

$B \parallel c$ but becomes allowed away from that orientation due to mixing with the $m_j = \pm \frac{1}{2}$ states [9].

Note that the linewidth of the high field line is always smaller than that of the low field line. We argue that some of the linewidth is due to inhomogeneities in the g shift and hyperfine interaction. Consider the following argument. A site that is a little more (less) p-like will have a larger (smaller) g shift and a smaller (larger) hyperfine splitting. This will tend to increase the width of the $m_1 = -1$ (low field) line and decrease the width of the $m_1 = +1$ (high field). The central $m_1 = 0$ line is, of course, not affected by a distribution in A but only by a distribution in g values. Near 0° or 90° , we have minimums or maximums in the g shift and the hyperfine parameter A , hence, small variations in the character of the wave function are less important and linewidths become equal to each other. Note that near $B \parallel c$, the spectra are extremely sharp, as seen in the inset to Fig. 1. The g value is near 2 here and so, since the g shift is small, there is virtually no inhomogeneous broadening due to variations in g .

3. Donor resonance

Most of the samples show a strong donor line with an axial g tensor ($g_{\parallel} = 1.9570$ and $g_{\perp} = 1.9551$). The line is Lorentzian, not easily saturated, and approximately 200 μT wide, narrowing with increasing temperature to ~ 20 μT at 20 K. An isolated donor should have a long

relaxation time and is easily saturated—Ga or In in ZnO are easily saturated (at microwave powers of $\sim 1 \mu\text{W}$ vs. 1 mW used for these resonances) [10]. This indicates that the electron is not isolated at a single site but rather in an impurity band, possibly physically hopping from one site to another. This would average out any hyperfine interaction and make identification difficult. The integrated intensity gives $\sim 10^{16}$ spins/cc. This result is somewhat surprising—in general, we observe impurity banding at higher concentrations, i.e., when Bohr orbitals start to overlap. For example, Si:P has two hyperfine split lines for concentrations up to the mid- 10^{17} range [11].

In the samples that show the nitrogen center (either after annealing or after e-irradiation), we do observe what appears to be an isolated donor. The donor line in this sample is badly saturated (i.e., probably due to isolated centers). The upper lineshape in Fig. 3, obtained using rapid passage conditions with low modulation frequencies, has an even sharper width ($\sim 100 \mu\text{T}$) than the delocalized donors more commonly seen. The line shows no splitting and has a significantly different g tensor. ($g = 1.9555$ and $g_{\perp} = 1.9540$) The difference in the g shift is about 3% compared to that of about 7% between isolated donors and impurity band electrons in Si [11].

Fig. 3. The EPR signals for the donor line with $B \parallel c$ for an unannealed sample and a sample annealed at 850°C . As mentioned in the text, the spectrum for the annealed sample was taken using rapid passage techniques.

There are two classes of ideas for the residual donor: intrinsic defects and impurities. We have not been able to resolve any hyperfine structure due to the 4% abundant ^{67}Zn isotope ($I = 5/2$) which might give us some indication that we are looking at a Zn-interstitial or O-vacancy based center. (The isolated O_V has been observed in e-irradiated material and is thought to be deep.) In either case, hyperfine satellites would be weak ($\sim 1\%$ of the central line). The second class of ideas are impurities, such as hydrogen, as Van de Walle has suggested [12], or a simple impurity such as Ga. All these involve 100% abundant $I \neq 0$ nuclei, which would give a hyperfine splitting. A simple substitutional donor would certainly give observable hyperfine splitting or broadening. However, Van de Walle's calculations indicate that the hydrogen atom would sit in a bond-centered site and muon spin rotation (μSR) studies on other semiconductors do indicate that such a site would have a much smaller central hyperfine interaction. Recent μSR experiments on ZnO powder do indicate a small hyperfine interaction [13] which would not be resolved by ordinary EPR. Electron nuclear double resonance experiments could resolve hyperfine interactions (estimated to be on the order of 100 kHz) and reveal any anisotropy which would be expected for a bond-centered site. It, therefore, remains to be determined whether the dominant residual donor is H (or another impurity) or a lattice defect.

4. ODMR of triplet center

In these samples, there is a broad green PL band centered about 2.5 eV , very similar to that which has been previously observed from ZnO powders and platelets [14]. Several models have been proposed for this emission, including a Frenkel pair transition for a Zn_i to a V_Zn , an electronic transition between an O vacancy and a free hole or an internal transition of Cu_Zn^{2+} . To better understand this emission, we have performed ODMR on this band [15]. The spectra at various orientations are shown in Fig. 4 for an unannealed n-type sample. (Similar spectra were observed for annealed and lightly e-irradiated samples.) In addition to the shallow donor (and the N center in the annealed sample), we observe an $S = 1$ triplet center with resonance parameters of $D = 0.763 \text{ GHz}$, $g = 1.9710$ and $g_{\perp} = 2.0224$. This center is not observed in our EPR measurements. We have performed modulation frequency and excitation power studies, but do not resolve any additional pairs of exchange split lines, as are observed, for example, in ZnSe [16]. This seems to argue for a defect with a more unique electron-hole separation such as an impurity or a simple lattice defect.

As mentioned above, we also observe the shallow donor resonance as a PL-decreasing signal in the

Fig. 4. The ODMR spectrum of the unannealed sample as a function of angle. The dashed line traces the orientation dependence of the triplet center.

ODMR. This suggests a competition for the donor electrons in the optical processes. For example, the donors can trap e–h pairs (“donor-bound excitonic recombination”) and also provide carriers (“spin-dependent electron transfer”) that help to form the $S = 1$ triplet center.

5. Summary

We have discussed three centers in state-of-the-art bulk ZnO single crystals: one due to isolated residual nitrogen, another due to residual donors and the last due to an $S = 1$ triplet center which is only observed using ODMR and is currently unidentified.

Abstract

The electric field gradients (EFG) caused by group V acceptors, group Ib acceptors and the cadmium vacancy in CdTe are calculated using the linearised augmented plane wave method and compared to the corresponding experimental values. Experimentally, the EFG are determined by the perturbed $\gamma\gamma$ -angular correlation spectroscopy with the radioactive probe isotopes ^{111}In and ^{77}Br . Besides the chemical nature, information about the charge state and the lattice relaxation associated with each defect is obtained. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Electric field gradients; Perturbed $\gamma\gamma$ -angular correlation; Density functional theory; II–VI semiconductors

1. Introduction

Defects in semiconductors induce characteristic electric field gradients (EFG) at neighbouring lattice sites. The EFG is measured via its interaction with the nuclear electric quadrupole moment of a suitable probe atom by different experimental techniques, such as perturbed $\gamma\gamma$ -angular correlation (PAC), Mössbauer spectroscopy, nuclear quadrupole resonance or electron nuclear double resonance. Defect-related EFG have been successfully used as ‘fingerprints’ of the respective defects in the past, because they are very sensitive to an anisotropic charge distribution about the probe nucleus, caused, for example, by a neighbouring defect [1,2]. However, the EFG by itself does not tell much about its microscopic origin so that due to the lack of appropriate theories for predicting the EFG of a distinct defect, lots of defects, though experimentally well characterised via their EFG, have remained unidentified.

The EFG discussed in this paper, are experimentally determined by PAC spectroscopy, using the radioactive PAC probe atoms ^{111}In and ^{77}Br . The investigation of defects in semiconductors using PAC spectroscopy is described in detail in Ref. [2]. In the II–VI semiconductor CdTe, both ^{111}In and ^{77}Br are donor atoms, which can form close donor–acceptor (D–A) pairs with stable acceptors, driven by the Coulomb attraction of ionised donors and acceptors. The actual PAC measurement takes place after the radioactive decay of the parent probes ^{111}In and ^{77}Br at the $I = 5/2$ excited state of the daughter isotopes ^{111}Cd and ^{77}Se , respectively, and yields the quadrupole coupling constant ν_Q , related to the EFG by $\nu_Q = |eQV_{zz}/h|$, along with the asymmetry parameter $\eta = (V_{xx} - V_{yy})/V_{zz}$ ($|V_{xx}| \leq |V_{yy}| \leq |V_{zz}|$). The component V_{zz} is calculated from ν_Q using the quadrupole moments $Q = 0.83 \text{ b}$ for ^{111}Cd [3] and 0.76 b for ^{77}Se ($I = 5/2$) [4]. It is noted that the daughter isotope ^{111}Cd of the PAC probe ^{111}In is a host atom in CdTe, and the EFG characterises the isolated defect originally trapped at the ^{111}In donor. In the case of ^{77}Br , the daughter isotope ^{77}Se is isoelectronic to the Te host and consequently, the EFG characterises the defect pair, consisting of a stable acceptor and the isoelectronic ^{77}Se

isotope. Exemplified for the group V acceptor N and the group Ib acceptor Ag, the local defect structure after the radioactive decay of the employed PAC probes is sketched in Fig. 1.

By the detection of the fraction of probe nuclei, which are exposed to the characteristic EFG of a distinct defect, the presence of this defect is immediately proven and, at the same time, thermodynamic parameters of the involved defects, such as binding and migration energies, can be determined. If fluctuation rates become comparable to the spin precession frequencies induced by the EFG, electronic as well as geometrical changes of the complex formed with the (daughter) probe can be observed (cf. [2]). Since this kind of information is useful only if the observed EFG is assigned to the correct defect model, the reliable EFG calculation is an appreciated complement to the PAC spectroscopy.

For more than a decade, calculations based on the density functional theory (DFT) formalism have been used for determining, theoretically, the properties of defects in semiconductors (e.g. [5]), but calculations yielding also the EFG caused by impurities, came up only recently [6,7]. In the present work, the linearised augmented plane wave (LAPW) code WIEN97 [8] is employed for EFG calculation. Exchange and correlation effects are treated in the generalised gradient approximation as described in Ref. [9], being a development based on the local density approximation (LDA). The general treatment of a defect in a semiconductor host lattice within this method is performed according to Ref. [7], where a BCC supercell with a 32 atom basis and the tetrahedral symmetry of the T_d point group was used. Here, we are also dealing with cases in which two impurity atoms are introduced into the supercell and consequently, the symmetry is lowered to C_{3v} .

2. Donor–acceptor pairs with ^{111}In in CdTe

For the D–A pairing of ^{111}In donors with group V acceptors in CdTe, the experimental EFG obtained by

Fig. 1. Local defect structure after the radioactive decay of the parent PAC probe: (a) N acceptor trapped at a ^{111}In donor which decays to ^{111}Cd (tetrahedral symmetry); (b) Ag acceptor trapped at a ^{77}Br donor which decays to ^{77}Se (trigonal symmetry). Arrows indicate structural relaxation.

Table 1

Experimental EFG, calculated EFG, and calculated relaxation of the NN-Cd shell for the group V acceptors in CdTe^a

Acceptor	Experiment [10]	Theory [7]	
	V_{zz} [10^{21}V/m^2]	V_{zz} [10^{21}V/m^2]	Relaxation [%]
N_{Te}^-	$\pm 13.95(5)$	-13.7	21.7
P_{Te}^-	$\pm 10.56(9)$	-11.2	11.0
As_{Te}^-	$\pm 9.27(5)$	-9.5	8.3
Sb_{Te}^-	$\pm 7.62(5)$	-8.1	3.3

^aThe EFG refer to the NN-Cd site and to the ionised acceptor (e.g. N_{Te}^-). The experimental EFG obtained with the ^{111}In PAC probe is axially symmetric ($\eta = 0$), in all cases, as expected for the tetrahedral symmetry of the defect. Relaxation values are given in percent of the NN distance in CdTe (2.81 Å) and refer to the atomic movement indicated by the arrows in Fig. 1a.

PAC is compared to the calculated EFG in Table 1 [10,7]. Here, the use of T_d symmetry in the calculation implies $\eta = 0$. The LAPW calculations yield excellent agreement of the EFG at a nearest neighbour (NN) Cd site with the experimental data in the case of the ionised group V acceptors [7]. Structural relaxation (cf. Fig. 1a) is found to be crucial for an accurate EFG calculation: The relaxation of the NN-Cd atoms towards the group V acceptor by 1% of the undisturbed Cd–Te bondlength increases the calculated EFG by about 10^{21}V/m^2 , i.e. by about 10%. Regarding the strong relaxation of more than 20% for the N acceptor (cf. Table 1), it is clear that without taking into account the relaxation, a calculated EFG is meaningless. The high accuracy of the calculated EFG gives also evidence of the accuracy of the calculated lattice relaxation in the context of the high sensitivity of the EFG to the local structure. The occurrence of a second EFG, experimentally observed after As and additional Li doping, is interpreted in terms of the neutral As acceptor As^0 [7]. The agreement with the calculated value for As^0 shows that the calculation of EFG for non-ionised acceptor states can be reliable even for the rather small cell size of 32 atoms, where the spatial expansion of the bound hole exceeds the size of the supercell. Thus, in cases where the EFG depends significantly on the charge state of the defect, the EFG calculation can be used to determine the actual charge state observed in an experiment.

3. Donor–acceptor pairs with ^{77}Br in CdTe

The implantation of the radioactive ^{77}Br isotopes into CdTe crystals was performed at the ISOLDE mass separator at CERN (Geneva, CH). The experimental results obtained for the D–A pairs of ^{77}Br donors with stable group Ib elements are briefly summarised in

Table 2

Experimental and calculated EFG for group Ib acceptors and V_{Cd}^a

Acceptor	Experiment	Theory
	V_{zz} [10^{21} V/m ²]	V_{zz} [10^{21} V/m ²]
Cu _{Cd}	$\pm 5.3(2)$	-3.6
Ag _{Cd}	$\pm 6.7(2)$	-6.7
Au _{Cd}	$\pm 2.6(3)$	-1.1
V_{Cd}^2	$\pm 10.2(2)$	-10.8

^a The EFG refer to the NN-Se_{Te} site and to the ionised state of the defect. The experimental EFG obtained with the ⁷⁷Br PAC probe is axially symmetric ($\eta = 0$) in all cases.

Table 2. A more detailed discussion of the experiments is given in Ref. [11]. Due to the relatively weak EFG for the Au acceptor, the corresponding experimental data are difficult to interpret in a unique way. The assumption that the ⁷⁷Se probes are located in a disturbed lattice environment, would also be consistent with the PAC spectra observed after Au doping. Thus, the value for the Au acceptor given in Table 2 is obtained by assuming an axially symmetric EFG tensor, as it is measured for the Cu and Ag acceptors. Attributed to the ⁷⁷Se_{Te}-Au_{Cd} configuration, the EFG is unexpectedly small for an NN pair if it is compared to the EFG for the Cu and Ag acceptors or, for example, with the EFG for the group V acceptors (Table 1). It has rather a strength that is typical for cases where the probe and the trapped defect form more distant next nearest neighbour (NNN) pairs [2]. Thus, based solely on experimental observations, the interpretation of the PAC data obtained with the ⁷⁷Br probe is particularly difficult regarding Au-doped CdTe crystals, and support from theoretical tools is highly appreciated.

After implantation of ⁷⁷Br into undoped CdTe samples, an EFG, characterised by $\nu_Q = 188(4)$ MHz, $\eta = 0.0(1)$ is observed [11]. Based on the annealing behaviour under Cd vapour pressure, this EFG is interpreted with the formation of bromine A centres, i.e. close pairs of ⁷⁷Br donors with the acceptor-like cadmium vacancy. The theoretical determination of EFG is particularly interesting in the case of intrinsic defects, such as the present example of V_{Cd} in CdTe, because here, the defect identification is generally more difficult than in the previous examples where the ⁷⁷Br donors form D-A pairs with deliberately introduced dopants.

As mentioned above, the calculation of the EFG at a Se_{Te} site in CdTe, induced by a neighbouring group Ib acceptor, requires that two impurity atoms are introduced into the supercell used for the LAPW calculation, leading to a C_{3v} symmetry. Compared to the T_d symmetry, the calculation becomes more demanding: First, less symmetry operations can be exploited in order

to reduce the computational effort. Second, there are more degrees of freedom for structural relaxation (cf. Fig. 1b) so that finding the equilibrium positions of the atoms in the supercell becomes a lengthy task. Including relaxation of all atoms in the supercell, the calculated EFG for the ionised group Ib acceptors, i.e. Cu_{Cd}⁺, Ag_{Cd}⁺ and Au_{Cd}⁺, and for the ionised cadmium vacancy V_{Cd}^+ are compared to the experimental data in Table 2. Here, the use of C_{3v} symmetry in the calculation implies $\eta = 0$. The detailed results for the relaxation of the ⁷⁷Se probe, the group Ib acceptor, and the neighbouring atoms—i.e. all atomic positions shown in Fig. 1b—are listed separately in Table 3. For the Ag acceptor and the cadmium vacancy, the EFG calculation reaches the high degree of agreement as in the case of the group V acceptors. For the Cu and Au acceptors, the calculated EFG differ from the experimental values by about 1.5×10^{21} V/m², but are still close enough to confirm the proposed defect model, i.e. ⁷⁷Se_{Te}-Cu_{Cd} and ⁷⁷Se_{Te}-Au_{Cd} complexes. (Note that absolute differences between calculated and experimental EFG should be regarded rather than relative ones, because V_{zz} can assume negative and positive values including zero.) In particular, the unusually low magnitude of the EFG caused by the Au acceptor at an NN site, is clearly reproduced. For the neutral state of the group Ib acceptors, the EFG is calculated to be more positive by up to 2.5×10^{21} V/m², yielding less agreement with the experimental data. Consequently, the measured EFG are attributed to the ionised state, in accordance with the observation for the group V acceptors [7]. In contrast, the calculated EFG for the neutral and the singly charged Cd vacancy do not differ much from the value for V_{Cd}^0 (-9.6×10^{21} and -9.1×10^{21} V/m² for V_{Cd}^0 and V_{Cd}^+), so that the EFG calculation supports the identification of V_{Cd} , but the assignment of the measured EFG to a specific charge state cannot be made definitively. It is noted, that the trigonal symmetry used for the calculation of the Se_{Te}- V_{Cd} defect complex in principle allows the Jahn-Teller relaxation which is expected for V_{Cd}^0 and V_{Cd}^+ . However, the LAPW calculations give no indication for a Jahn-Teller effect. The properties of both the anion and cation vacancy in CdTe are discussed in detail in a parallel paper [12].

Table 3

Calculated relaxation of the local environment about the group Ib acceptors and V_{Cd} . Values are given in percent of the NN distance in CdTe (2.81 Å) and refer to the relaxations indicated by the arrows along the Te-Ag-Se-Cd chain in Fig. 1b.

	Te	Acceptor	Se	Cd
Cu _{Cd} Se _{Te}	8.7	4.9	7.6	8.0
Ag _{Cd} Se _{Te}	3.2	5.4	0.6	6.0
Au _{Cd} Se _{Te}	3.9	4.6	1.4	6.2
V_{Cd} Se _{Te}	13.4	—	8.6	9.3

Fig. 2. (a) Total DOS for a CdTe 32 atom supercell containing a $\text{Se}_{\text{Te}}\text{--Cu}_{\text{Cd}}$ pair. The dominant characters of the wavefunctions are indicated; (b) site-projected DOS for Cu_{Cd} , d ($l=2$) contribution; (c) site-projected DOS for Se_{Te} , p ($l=1$) contribution.

Though very useful for the interpretation of the experimental data, the EFG calculations yield somewhat lesser agreement with experiment for the group Ib acceptors, compared to the group V acceptors. This is probably a consequence of the LDA used in DFT calculations, which does not exactly describe the outer d electrons of the group Ib elements. In Fig. 2a, the calculated electronic density of states (DOS) for a supercell containing a $\text{Se}_{\text{Te}}\text{--Cu}_{\text{Cd}}$ pair is shown, and the predominant character of the wavefunctions in the different sections of the spectrum is indicated. In IIb–VI compounds, the outer cation d electrons (e.g. the Cd- $4d$ electrons in CdTe) interact with the anion p states making up the upper part of the valence band [13]. The d states of the group Ib elements in CdTe are more loosely bound than the Cd- d states and lie in an energy region which coincides with the energetic position of the Se- p states. This is clearly visible in Figs. 2b and c, where the site-projected and angular-momentum-decomposed DOS is plotted for Cu- d and Se- p states. The smaller energy separation between the Cu- d and the Se- p states compared to the Cd- d and the Te- p states leads to a stronger interaction, where the Se- p_z orbital (directed towards Cu_{Cd}) is affected rather than the Se- p_x and Se- p_y orbitals due to symmetry. It is well known that the LDA underestimates the binding energy of the cation d electrons (e.g. [13]) and a similar effect can be expected for the outer d electrons of the group Ib acceptors. This means, however, that the coupling between the Se- p states and, e.g. the Cu- d states is not estimated exactly and an error can be introduced in the calculated EFG, because of the anisotropic influence of the Cu- d

electrons from the point of view of the Se atom. This argument holds for all the three group Ib acceptors, so that the exact agreement with the experimental value for the Ag acceptor seems to be rather fortuitous. In general, it should be emphasised that the EFG calculations have proven to be very helpful for defect identification even in the case of the group Ib acceptors in CdTe, which is a rather difficult case for EFG calculations based on the DFT–LDA formalism due to the energetically high-lying d orbitals.

4. Summary and outlook

LAPW calculations are presented for isolated group V acceptors and for defect complexes consisting of a group Ib acceptor and a Se neighbour in the II–VI semiconductor CdTe. The theoretically determined EFG are used to support the identification of defects. In particular for the Au acceptor, where the experimental situation is ambiguous, a clear interpretation is achieved only by support of the EFG calculation. Furthermore, the assignment of an experimentally observed EFG to the Cd vacancy is confirmed by means of the LAPW calculations. Future work will focus on cases, where the PAC probe and the investigated defect are next nearest neighbours, on self-compensation mechanisms such as DX and AX centre formation, and on defects in other II–VI semiconductors than CdTe, such as ZnSe.

In general, it has been shown that by comparing the experimentally and theoretically determined, defect-related EFG, information about the chemical nature, the charge state, and the lattice relaxation associated with each defect is obtained. This is more important as for more than 50 defect complexes, studied in different semiconductors, experimental EFG are available.

Photoluminescence studies in ZnO samples

C. Boemare^{a,*}, T. Monteiro^a, M.J. Soares^a, J.G. Guilherme^b, E. Alves^b^a *Departamento de Física, Universidade de Aveiro, 3800 Aveiro, Portugal*^b *Instituto Tecnológico e Nuclear, Sacavém, Portugal*

Abstract

The similarities between ZnO and GaN samples reveal that the semiconductor oxide is a potential material as a promising material for optoelectronic devices. In this work, we study by spectroscopic and RBS techniques the characteristics of bulk ZnO. A comparison between the energy separation of the several groups of near band edge photoluminescence emission bands and the energy separation between the free exciton resonances observed in reflectivity is made. We report on the luminescence dependence from temperature and the variation of the relative intensities of the lines. From the data, an assignment of recombination centers is discussed. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: PL; TRPL; RBS; ZnO

1. Introduction

Due to its wide-gap of 3.37 eV at room temperature and its strong exciton binding energy of 60 meV the binary ZnO have many potential applications in short-wavelength light-emitting devices. Recent development in growth techniques has enabled the growth of ZnO epilayers on a wide variety of substrate, even with large lattice mismatch [1,2]. For this reason, there has been a renewed interest in ZnO. The studies of ZnO epilayers has its base on knowledge of the bulk crystal properties, i.e., the band gap evolution with temperature, the binding energies, the transitions of the un-doped crystal including shallow and deep emission levels.

In this paper, we study the photoluminescence and reflectivity of bulk ZnO as a function of temperature. The near band edge is studied in terms of energy separation to the free excitons evolution with temperature. The assignment of the emission centers is made, comparing between excited states, rotator states or binding with the different excitons. Parameters are

obtained for the gap evolution in temperature using three models.

2. Experimental details

PL measurements were carried out with a 325 nm CW He–Cd laser and the excitation power density was typically $<0.6 \text{ W cm}^{-2}$. A 325 nm band pass filter was used to attenuate lines other than the 325 nm laser line and a low pass sharp cut off filter was used to stop the laser light. PL was measured at temperatures between 14 and 300 K using a closed cycle helium cryostat. The luminescence was dispersed by a Spex 1704 monochromator (1 m, 1200/mm) and detected by a cooled Hamamatsu R928 photomultiplier.

The samples were excited with incident light parallel to the *c*-axis of the crystal, i.e. with the electric field perpendicular to *c*. The emitted light was collected in two configuration, at an angle of 0° from excitation, i.e. $E \perp c$, and at 90° , i.e. \perp or \parallel to *c*-axis.

3. Results and discussion

The near band edge photoluminescence recorded at 15 K in the 0° configuration, electric field *E* of the

*Corresponding author. Departamento de Física, Universidade de Aveiro, 3810-193 Aveiro, Portugal. Tel.: +351-34-370-276; fax: +351-34-24965.

E-mail address: clauda@fis.ua.pt (C. Boemare).

emitted light perpendicular to the c -axis, exhibits 14 lines (Fig. 1). The emissions of A free exciton are presents; emission of the B and C band is not observed. The same spectrum was obtained in the 90° configuration. In that configuration the use of a polarizer, in any orientation (\perp or \parallel to c -axis), makes the photoluminescence of the near band edge to collapse, indicating the unexpected non-polarization of the emitted light [3]. Either the intensity of the free excitons relatively to the donor-bound exciton group or the relative intensity of the several bound excitons does not significantly change.

In fact, from group theoretic arguments and the direct product of the group representations of the band symmetries [4] (Γ_7 for the conduction band, Γ_9 for the first valence band, A, Γ_7 for the second and third valence bands, B and C) we obtain the following intrinsic excitons ground states symmetries:

$$\Gamma_7 \times \Gamma_9 \rightarrow \Gamma_5 + \Gamma_6,$$

$$\Gamma_7 \times \Gamma_7 \rightarrow \Gamma_5 + \Gamma_1 + \Gamma_2.$$

In ZnO the donor bound excitons have been attributed to defect-pairs that have the properties of neutral donors [5]. Due to the preferentially incorporation of the defects in a certain crystallographic orientation local strains oriented in the direction of the pair will result, and the electric vector will orient in the strain direction inducing polarization effects. Similarly, free excitons would be expected to show polarization effect since Γ_5 and Γ_1 are allowed transitions with $E \perp c$ and $E \parallel c$, respectively, and Γ_6 and Γ_2 are unallowed. In fact, the Γ_6 and Γ_5 lines are observed in all polarization and this is likely due to the finite momentum of the photon.

Fig. 2 shows the random and $\langle 0001 \rangle$ aligned RBS spectra of the wurtzite ZnO sample. The minimum yield (ratio between the random and aligned spectra) along this direction is 4%, which is an indication of the excellent crystalline quality of the single crystals. More-

over the smooth dechanneling rate over all the probed thickness (about $3 \mu\text{m}$ for the $3 \text{ MeV } ^4\text{He}^+$) reveals a nearly defect free crystal over the entire depth also confirmed by the presence of free excitons.

At low temperature the spectrum is dominated by two donor-bound excitons at 3.3653 and 3.3622 eV. As the temperature rises above 50 K, (Figs. 3 and 4), most of the donor lines disappear and above 70 K only the donor lines that were located at 3.3653 and 3.3704 eV at 15 K remain. The line located at 3.3704 eV at 15 K, the A and B free excitons relative intensities increase (Fig. 3). We separate the bound exciton in three groups. The low-energy group is generally accepted to be neutral donor bound excitons, defect pairs or ordinary bound excitons. The second and the third sets of lines on the high-energy side of the neutral donor bound excitons (Fig. 1), between 3.3668 and 3.3725 eV, has been attributed to excited states of these complexes or excited rotator states [5].

Several models were proposed for the rotator states [6-9]: in a model the hole is excited to rotate around the fixed donor, in another one the exciton rather than the hole is rotating. Using the energy separation given by [5] one could identify some of the lines between the neutral donor bound excitons and the free A excitons as rotator states of the dominant neutral bound excitons. But the increase of the relative intensity of the 3.3693 line with temperature rather suggest an exciton bound to ionized defect, here a ionized donor. Furthermore taking into account the energy separation between the A and B exciton $\sim 12 \text{ meV}$, we can attribute these transitions to the same neutral donors now bound to B excitons (Table 1).

In reflectivity both the ground- and excited-states of the A and B free excitons are observed (Fig. 5). The excited states rapidly became unresolved with increasing temperature, whereas the A and B grown-states remain up to 200 K and room temperature, respectively. At low

temperature in the reflectivity spectra a resonance is visible near the minimum of the B exciton. This is attributed to a resonance with $E \parallel c$, in fact that the angle of reflectivity is not exactly 0 and when increasing the angle its amplitude increases. This feature rapidly became unresolved but can lead to a wrong measurement of the oscillation energy of the B exciton at low temperature. In Fig. 4 the open triangles are the

3.3592	3.3693 (Γ_6), 3.3707 (Γ_5)	3.3707
3.3622	3.3741 (Γ_5)	3.3741
3.3632	—	3.3754
3.3653	3.3754	3.3772

Fig. 5. Reflection and emission spectra in the intrinsic region, at 15 K.

positions of the A and B excitons obtain from reflectivity assuming the inflection point of the resonance as the energy of transition. For the A transition there is no ambiguity, since the splitting longitudinal-transversal is small (~ 1 meV), but this is not the case for the B exciton (~ 12 meV). In fact looking at the temperature evolution, the energy separation between the A and B excitons seems to decrease, from 14.9 meV at 15 K to 11.5 meV at 200 K. The energy separation between A and B exciton is due to the spin-orbit splitting which is not temperature dependent. The energy shift of the lines is due to the gap shrinkage effect in semiconductors that is caused by the cumulative effects of thermal lattice expansion and electron-phonon interaction. The decrease of the A-B splitting could have been attributed to a variation of the exciton binding energies but a weak temperature dependence for the effective Rydberg, R , is expected due the dependence of the exciton binding energy on the reduced effective mass μ and the static dielectric constant ϵ . For II-VI semiconductors the reduction of $R \propto \mu/\epsilon^2$ between 2 K and room temperature is expected to be inferior to 2 meV and be similar for both excitons [10]. At low temperature the binding energies obtained from Eq. (1) give 59.9 meV and 57.0 for the A and B excitons, respectively indicating similar effective masses and in

Fig. 6. Evolution of the energy position of the A exciton as function of temperature (●) data, (–) the fittings using the Eqs. (2)–(4).

good agreement with the literature [4]:

$$R = \frac{4}{3} [E_{2s} - E_{1s}]. \quad (1)$$

We performed numerical analyses of the energy position of the A exciton as function of temperature using three models. The Varshni' formula has shown limitations and various attempts have been made to improve the fitting. A modification of Varshni' equation [11] has been given [12] for the band gap temperature dependence:

$$E(T) = E(0) - \frac{\alpha T^2}{\beta + T}. \quad (2)$$

$$E(T) = E(0) - \frac{\alpha T^4}{(\beta + T)^3}. \quad (3)$$

In Ref. [13] the authors suggest a semi-empirical expression equivalent to the Bose–Einstein model proposed by Ref. [14] that provides us with good fitting and an estimative of the Debye temperature. Eq. (4) gives the best fitting to the data (Fig. 6), with a Debye temperature of $\Theta_D = 3/2\Theta = 305$ K, where Θ is the effective phonon temperature. The different values of the

parameters are given in the inset:

$$E(T) = E(0) - \frac{\alpha\Theta}{\exp(\Theta/T) - 1}. \quad (4)$$

4. Conclusion

We have shown the presence 14 transitions in the near band edge in ZnO at 15 K. These transitions are interpreted as transitions of: free excitons from the top valence band, ionized-donor bound exciton and neutral-donor bound either to the first and second top valence bands. We have determined the temperature dependence of the A exciton peak position in these high-quality ZnO crystals and obtained a value of the Debye temperature in good agreement the literature. The high quality of the samples studied is also demonstrated by the RBS measurements.

Abstract

Using β -radiation detected nuclear magnetic resonance (β -NMR), we investigated the microscopic behavior of implanted ^8Li in nominally undoped ZnSe crystals. From the temperature-dependent amplitudes of high-resolution NMR spectra we conclude a gradual interstitial-to-substitutional site change between 200 and 350 K. This is in accordance with earlier emission channeling results. We argue that this conversion proceeds via $\text{Li}_i^+ + V_{\text{Zn}}^{2-} \rightarrow \text{Li}_{\text{Zn}}^-$ and involves implantation related Zn vacancies. © 2001 Elsevier Science B.V. 1. Introduction

Li at substitutional Zn sites (Li_{Zn}) in ZnSe is a well-behaved shallow acceptor [1] at low dopant concentrations. The maximum achievable hole concentration is limited, however, to $p \approx 2 \times 10^{17} \text{ cm}^{-3}$ [2]. In order to explore the underlying “self-compensation” mechanism microscopically we applied β -radiation detected nuclear magnetic resonance (β -NMR) on implanted ^8Li probe nuclei. One advantage of this nuclear technique is a sensitivity high enough to work with negligible concentrations of probe atoms. This way we can “study dopants in undoped semiconductors”.

The final goal of our experiments is to see, whether Li compensation is tied to a low lying Fermi level, or if signs of an inherent instability of Li_{Zn} in ZnSe can be

detected already in intrinsic material. Here we report our first results in nominally undoped ZnSe in the limited temperature range of 150–380 K. An extension of this study to higher temperatures is currently underway. The investigation of pre-doped samples is intended for the future.

Microscopic information on the behavior of ^8Li in ZnSe is already available from Hofsäss and coworkers [3,4]. These authors employed the emission-channeling (EC) technique [5] to investigate the lattice sites of implanted ^8Li nuclei in the temperature regime of $T = 150$ –550 K. Their main results can be summarized as follows: (i) For $T \leq 200$ K Li is incorporated predominantly ($\geq 60\%$) at tetrahedral interstitial sites (T sites). (ii) A site change from interstitial Li_i to substitutional Li_s occurs at $T \approx 230$ K; the sublattice for Li_s was not determined. (iii) The fraction of Li atoms converting to substitutional sites (S sites) is affected by the implantation dose. The substitutional fraction increases if the total fluence of ^8Li exceeds $\sim 5 \times 10^{11} \text{ cm}^{-2}$. This suggests the involvement of implantation related vacancies in this site change. (iv) An

unidentified “random fraction” $f_r \geq 30\%$ is observed at all temperatures.

2. Experimental

The general principles of implantation- β -NMR have been described at various instances [6], here we applied the special variant of collinear laser polarization. The on-line separator ISOLDE at CERN provides a 60-keV beam of radioactive ^8Li ions ($\tau_\beta = 1.21$ s, nuclear spin $I = 2$). The beam is neutralized in a Na vapor cell and optically pumped by a collinear laser beam. The resulting electronic polarization is transferred in flight to the nucleus before the atoms reach the sample, which is mounted in a transverse NMR field B_0 . The implanted ^8Li -probe nuclei can be depolarized by resonant radio frequency (RF) irradiation. The lifetime-averaged polarization is detected via the left/right asymmetry of the emitted β -radiation. More experimental details can be found in Ref. [7].

For an effective sample diameter (beam spot) of ~ 4 mm the implantation flux was $1.7 \times 10^6 \text{ cm}^{-2} \text{ s}^{-1}$. This corresponds to 2.5×10^5 probe nuclei simultaneously in the sample or an equilibrium concentration of $4 \times 10^{10} \text{ cm}^{-3}$ (the implantation profile simulated with the Monte-Carlo code TRIM [8,9] has a width of about 500 nm with a broad maximum at a depth of $d \approx 300$ nm). Up to 6×10^{10} probe nuclei are implanted during a whole run of a few days (not necessarily in the same sample). This is still well below those values where implantation-dose effects were observed in the EC experiments [4].

We used several nominally undoped bulk crystals ($\rho > 10^8 \Omega \text{ cm}$) from commercial sources. The size was typically $10 \times 10 \times 2 \text{ mm}^3$ with (100) or (110) planes as implantation surfaces. All samples used in this study were capped with a ~ 25 -nm layer of amorphous Si_3N_4 to prevent surface decomposition.

3. Measurements and results

A typical β -NMR spectrum of ^8Li in ZnSe, measured at $T = 172$ K, is shown in Fig. 1. The line is centered at the Larmor frequency, the corresponding Li atoms occupy lattice sites with full T_d symmetry. This finding is consistent with the EC result of Li at T sites at this temperature. The spectrum was recorded under saturating RF conditions. The line shape is a pure Lorentzian, its width is determined by the applied RF power. About 80% of the initial polarization is destroyed in the resonance, reflecting the corresponding fraction of Li at cubic lattice sites. The difference to 100% is probably caused by ^8Li stopped in the amorphous Si_3N_4 capping

Fig. 1. β -NMR spectrum of ^8Li in ZnSe. $T = 172$ K. $B_0 = 3$ kG, $\langle 110 \rangle \parallel B_0$. The resonance was recorded with a saturating RF intensity of $B_{1,\text{rot}} = 1.0$ G and occurs at the Larmor frequency. The solid line is a Lorentzian fit.

Fig. 2. Larmor resonances recorded at a reduced RF intensity of $B_{1,\text{rot}} = 25$ mG. $B_0 = 3$ kG, $\langle 110 \rangle \parallel B_0$. (a): $T = 172$ K, (b): $T = 223$ K, (c): $T = 284$ K.

layer: in earlier experiments with uncapped samples we observed an almost complete depolarization.

The saturation of this type of resonances was almost independent of temperature in the investigated range. The situation changes, however, if the RF intensity is reduced. The spectra of Fig. 2 were recorded with $B_{1,\text{rot}} = 25$ mG; the corresponding power broadening is only 31 Hz (FWHM), in this case. The observed line shapes are no longer Lorentzians, now, but reflect an inhomogeneous distribution of local magnetic fields.

One reason for this is the random distribution of host nuclei with non-vanishing magnetic moments. This contribution can be estimated by the well-known Van Vleck formula [10]. For our case of $\langle 110 \rangle \parallel B_0$, we obtain second moments M_2 of 119–145 Hz for the ^8Li resonance, depending on which of the four cubic sites is considered. Assuming a Gaussian line shape (admittedly questionable for a dilute spin system like ZnSe) this means FWHM's of 281–343 Hz. These numbers are only estimates of the real situation, however, since the local lattice relaxation around the Li impurity, the influence of impurity induced electric field gradients, or

the contributions of indirect interactions (“pseudo exchange”) are not known. For the moment it may be sufficient to say that the experimental linewidths of Fig. 2 are of the order of the Van Vleck estimates.

The asymmetric line shape of all three spectra of Fig. 2 is currently not understood. An instrumental effect is unlikely but cannot be excluded for certain. Our following conclusions should not be affected by this question, however.

Another prominent feature of Fig. 2 is the reduced baseline polarization of the spectrum measured at $T = 284$ K. This is caused by spin-lattice relaxation and indicates dynamical processes involving substitutional Li. This finding is rather surprising at such a low temperature but we have to postpone its discussion to a future publication. The baseline reduction was also observed in a short β -NMR report on recoil implanted ^8Li in ZnSe by Miyake et al. [11]. These authors discussed a substitutional-to-interstitial site change around $T = 300$ K. Our own (see below) as well as the EC results [3,4] clearly contradict such an interpretation.

The physically most important point of Fig. 2 is the temperature dependence of the signal intensity. Amplitudes and widths of a series of low RF resonances are plotted vs temperature in Fig. 3. The amplitudes have a marked maximum at $T \approx 210$ K while the variation of the linewidths with temperature is less pronounced.

The integrated area of an inhomogeneous spectrum reflects in many cases the number of contributing entities. If we integrate the 223-K spectrum of Fig. 2(c), however, and normalize it properly taking the given RF conditions into account, we obtain a corresponding probe fraction of several hundred percent. We also know from Fig. 1 and other saturated resonances (not shown) that the total fraction of Larmor resonant ^8Li nuclei is $\approx 80\%$ for all temperatures in the investigated regime, which appears to contradict Fig. 2. The solution of this puzzle is diffusion. If probe nuclei move in a

spatially inhomogeneous environment they sense a different local field, hence a different resonance frequency, after each jump: physical diffusion causes “spectral diffusion”. An individual probe spin can be depolarized at several different frequencies, therefore. The other way around, we can depolarize more than the initially present number of probe nuclei by just irradiating a fixed frequency and waiting for new spins to become resonant. The physical consequence of this somewhat technical effect is a correlation between signal enhancement and diffusion. What Fig. 3 actually shows us is a peak of the average probe mobility at around 210 K.

In a given configuration, the jump frequency of a mobile atomic species is expected to increase exponentially with temperature. We, in contrast, observe a slowly decreasing mobility for $T > 200$ K. This is the signature of a gradual transition from a mobile to an immobile configuration, i.e., a change from interstitial to substitutional lattice sites. At low temperatures we have only diffusing Li_i but between 200 and ~ 350 K the site conversion occurs.

Qualitatively, these results are in perfect agreement with the EC data of Refs. [3,4]. Only concerning the end temperature of the conversion process we have a minor discrepancy. In the EC experiments conversion is completed at $T \approx 275$ K while in our data the Li_i survive up to higher temperatures. The most probable explanation for this difference is the lower implantation fluence in our case. This means a lower concentration of implantation related vacancies, which are obviously needed to promote the site change.

The nature of the S site, Li_{Zn} or Li_{Se} , cannot be read directly from the β -NMR spectra. There are strong arguments, however, in favor of Li_{Zn} . A hypothetical Li at a Se site had to adopt a $\text{Li}_{\text{Se}}^{5-}$ charge state, in order to fill its electronic shell. Such an extreme assumption can certainly be discarded. In any less negative state, however, the defect had a partially filled p shell, hence should undergo a Jahn–Teller distortion to remove its orbital degeneracy, and have no longer T_d symmetry [12]. The narrow Larmor resonance of Fig. 2(c) shows clearly that this is not the case. In the same manner, we can argue that Li_{Zn} has to be in the negative charge state as has to be expected for a shallow acceptor.

Another reason to exclude the Li_{Se} hypothesis is the $T \rightarrow S$ conversion process. We have seen already, that vacancies are involved in this reaction according to $\text{Li}_i + V \rightarrow \text{Li}_s$. Li_i should be positively charged [13] (from our own data Li_i^- and Li_i^+ were both possible, only the paramagnetic neutral state is ruled out). The vacancies in ZnSe are double acceptors (V_{Zn}) or double donors (V_{Se}) [12], in intrinsic ZnSe we had V_{Zn}^{2-} and V_{Se}^{2+} . Therefore, simple Coulomb repulsion prevents a reaction $\text{Li}_i^+ + V_{\text{Se}}^{2+} \rightarrow \text{Li}_{\text{Se}}^{3-}$.

Fig. 3. Temperature dependence of (a) amplitudes and (b) widths (FWHM) of a series of β -NMR resonances. Measuring conditions like in Fig. 2. The parameters were obtained by Gaussian fits to the original spectra.

Control of the electric and magnetic properties of ZnO films

H. Tabata*, M. Saeki, S.L. Guo, J.H. Choi, T. Kawai

ISIR-Sanken, Osaka University, 8-1 Mihogaoka, Ibaraki, Osaka 567-0047, Japan

Abstract

We have demonstrated a possibility of the growth of p-type ZnO films by a pulsed laser deposition technique combined with a plasma gas source. The p-type ZnO film has been fabricated by passing N₂O gas through an ECR or RF plasma source. N₂O gas is effective in preventing “O” vacancies from occurring and introducing “N” as an acceptor, at the same time. Two-step growth, with a thin ZnO template layer formed at high temperature, is quite effective to realize a well-crystallized growth at low temperature. This non-equilibrium film formation process enables us to produce other new ZnO films which show ferromagnetic properties which means that a transparent magnet is realized with this technique. These various types of ZnO films will open the door for practical applications in various oxide electronic devices. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Zinc oxide (ZnO) is one of the promising materials which is well matched for human being and environment and it is expected to apply across various fields due to its potential applications [1–7]. The problem of p-type doping of ZnO can arise for various reasons such as, the acceptors level may be sufficiently deep such that there are low thermal excitations in the valence band, low solubility of the dopant or inducing self-compensating processes on doping. Recently, a theoretical idea has been proposed, the so-called codoping approach (simultaneous doping of donor and acceptor), to realize the p-type electrical conduction in ZnO. In our experiments, the non-equilibrium process is essential. To do that, we have produced the ZnO films under the condition of excited N and O atmosphere. The active N is formed by passing N₂O gas through an RF plasma source. Furthermore, the two-step growth, with a thin ZnO template layer formed at high temperature, is quite effective to realize a well-crystallized growth at low

temperature. By this technique, transition metals such as Co and V have been substituted into the ZnO films by more than 15%. Eventually, ferromagnetic properties can be observed at room temperature in these highly doped ZnO films. The above-observed new type of ZnO films will open the door for practical applications in various oxide electronic devices.

1.1. Non-equilibrium process

The naturally occurring ZnO has an n-type conductivity which can be enhanced by doping with Al, Ga, etc. The problem of p-type doping in ZnO can arise for various reasons such as, the location of the acceptor level may be sufficiently deep such that there is low thermal excitations in the valence band, low solubility of the dopant or inducing self-compensating processes on doping. Recently, Yamamoto and Katayama-Yoshida [8] have proposed that by adopting a codoping approach (simultaneous doping of donor and acceptor) one can realize the p-type electrical conduction in ZnO. The proposed choice of donors are Al, Ga or In with N as the acceptor. We tried to adopt this method for obtaining p-type ZnO. Thermodynamically, Ga₂O₃

Fig. 1. Energy diagram for Ga_2O_3 , GaN and N-Ga-N.

and GaN are stable phases. To introduce N and Ga at the same time in the ZnO lattice, N-Ga-N binding state must be frizzed. Therefore, the non-equilibrium process is an essential approach (Fig. 1).

2. Experimental

The ZnO films are formed by a pulsed laser deposition technique. The details of the experimental facility are reported elsewhere [9,10]. The films are produced in a vacuum chamber having a base pressure of 1×10^{-8} mbar. An ArF excimer laser is operated at 1 Hz at a fluence of about 0.5 J/cm^2 and the typical deposition rate is about 10 Å/min . During the deposition, the substrates (ZnO single crystals and sapphire single crystals) are kept at $280\text{--}400^\circ\text{C}$ and the required N atmosphere is maintained by passing N_2O with or without plasma source.

The crystal orientation is examined by X-ray diffraction (XRD) and pole figure measurements, using Cu K_α radiation (Rigaku). The electrical resistivity, carrier concentration and mobility are measured using a four-point probe van der Pauw method. The optical transmission through the film is measured using a Vis-UV spectrometer. The major conduction type (either p- or n-type) is confirmed by the measurement of Hall, Seebeck coefficients as well as by electrochemical measurements. X-ray photoelectron spectroscopic (XPS) measurements are carried out by using a VG Scientific ESCALAB 220I-XL spectrometer with monochromatized Al K_α radiation source.

3. Results and discussion

3.1. Electrical properties

3.1.1. Conducting properties

Initially, experiments were conducted on pure (undoped) ZnO with N_2O gas, with and without the use of

Fig. 2. Temperature versus conductivities of p- and n-type ZnO films.

plasma source. When the plasma source is off (i.e. N_2O is introduced into the vacuum chamber without any pre-ionization), at a pressure of 1×10^{-3} mbar, the obtained film showed a low resistance of $4 \times 10^{-2} \Omega \text{ cm}$ and is clear n-type with properties close to that of a natural n-type ZnO thin film. On increasing the pressure to 3 mbar, the resistivity of the film increased to $1 \times 10^3 \Omega \text{ cm}$ (carrier concentration is $2 \times 10^{14} \text{ cm}^{-3}$). Both Hall and Seebeck coefficient measurements did not clearly indicate the type of carrier—the Hall measurements sometimes showed p-type with very low signal-to-noise ratio, while the Seebeck voltage was almost zero. But with plasma source on, at a pressure of 1×10^{-3} mbar, the maximum operating pressure with our plasma source, the resistivity increased to $1 \times 10^5 \Omega \text{ cm}$ with a corresponding carrier concentration of $2 \times 10^{10} \text{ cm}^{-3}$ and showed a clear p-type behavior by both Hall and Seebeck measurements.

Fig. 2 shows the temperature-dependent electrical conductivity for lowest resistance p-type and n-type films obtained by the codoping method. The p-type film shows a typical semiconductor behavior with an estimated activation energy of $\approx 13 \text{ meV}$ in the high temperature region, whereas, the n-type sample shows a degenerate semiconductor behavior. This type of metallic-like n-type transparent conducting oxide can substitute the expansive commercially used indium-tin-oxide (ITO) films in various applications.

3.1.2. Chemical bonding state [7]

Figs. 3(a) and (b) show the XPS results with and without Ga in the ZnO films which are formed in the N_2O atmosphere through plasma source. Without Ga, the N1s peak occurs close to the position which is observed with neutral N (406 eV, Fig. 3(b)). In the Ga-doped case, on the other hand, the N1s peak is located at around 396–398 eV, which corresponds to the Ga-N

Fig. 3. XPS N1s spectrum of ZnO films formed with and without Ga dopant.

type of bonding [11]. Furthermore, the N1s peak is a build-up peak (Fig. 4). One is well matched for the N peak of GaN (N is nearest neighbor) and the other for second nearest neighbor Ga–N. It is quite evident that an N–Ga–N bond occurs in the ZnO films.

From these observed peak areas and the corresponding sensitivity factors, the approximate relative intensity ratio of Ga : N is obtained as 1 : 6. It is reported [12] that such a relative intensity ratio, by XPS, for GaN film (1Ga:1N) is about 1:3.2. This suggests that in the codoped film, the N:Ga ratio is 2:1. This is one of the basic requirements for observing p-type activity in ZnO by the codoping process as predicted by theoretical calculations.

3.1.3. Structural characterization

Fig. 4(a) shows a typical X-ray diffraction pattern obtained for an N–Ga codoped ZnO film on sapphire (1120) substrate at 400°C. N doping is carried out under N₂O at a pressure of 1×10^{-3} mbar with ECR and using the target containing Ga of 0.1 wt%. Sapphire with its plane of orientation is expected to give minimum lattice mismatch for the ZnO. We could obtain epitaxial growth as confirmed by the Φ scan for the (101) planes of ZnO film as shown in Fig. 4(b). The Φ scan obtained for the (104) planes of the substrate is also shown in Fig. 4(c).

As indicated above, the presence of a well-defined columnar structure and a possible defect structure (due

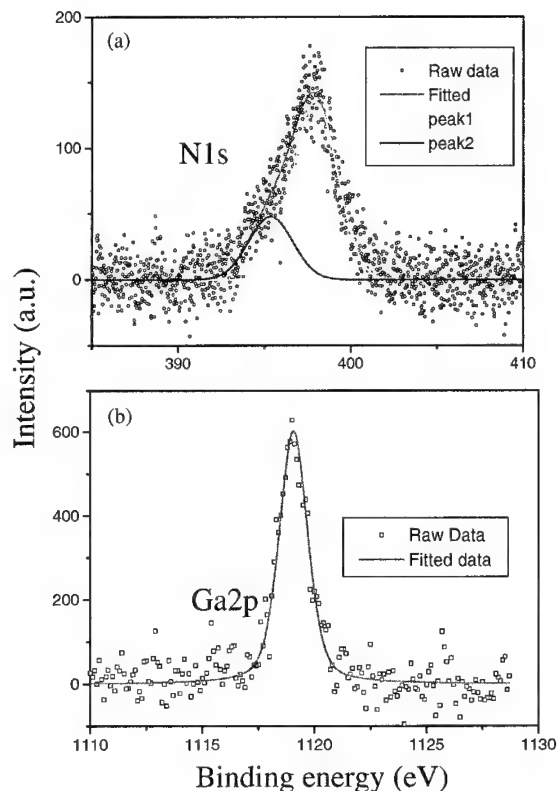

Fig. 4. XPS spectra of N1s and Ga2p in the ZnO films.

to doping processes) can act as scattering centers for the carriers, resulting in low mobility for most of the films. Also, the mobility obtained for the codoped p-type films are much lower than those obtained for the n-type films. However, the mobility of the p-type films on the sapphire substrate is higher than that of the p-type films on glass; this may be attributed to the difference in grain size—on sapphire the average size is ≈ 500 nm, whereas on glass it is ≈ 100 nm, as measured by atomic force microscopy.

3.2. Optical properties

3.2.1. Two-step growth [13]

3.2.1.1. Effect of the high temperature buffer layer.

From the thermodynamic point of view, Ga₂O₃ is the most stable phase when we mix “O”, “N” and “Ga” at the same time. The second stable phase is GaN. If we want to obtain the N–Ga–N complex, low temperature formation is very important. But the ZnO film, formed at a low temperature of 400°C, for example, shows a weak free exciton peak and strong one of deficiency in the PL spectrum. Of course, if it is formed at high temperatures above 600°C, a clear free exciton peak [14–16] is observed at 3.3 eV and the O-vacancy peak

Fig. 5. PL spectrum measured at RT of ZnO film formed at 300 °C.

(around 2.2–2.4 eV) decreases dramatically. There is a dilemma. The higher temperature formation is better for the crystal growth. The low temperature, on the other hand, is better for non-equilibrium growth. The cross point is located at around 550–600 °C. But here, we have the proposed tricky idea: two-step growth. At first, the thin ZnO film (5–10 nm) is deposited at high temperatures of around 600–700 °C. Then, the second ZnO layer (> 200 nm) is successively formed at a low temperature (< 400 °C) on the first template layer. This two-step growth, with a high temperature template layer, is quite effective in improving the crystallinity of the film at a low substrate temperature as low as 300 °C. The PL spectrum changes dramatically as shown in Fig. 5. It shows quality similar to that formed at high temperatures of 600–700 °C.

3.2.2. Optical behavior

Fig. 6 shows a typical visible-UV transmission spectra obtained for films having 5 wt% Ga in ZnO, codoped with N from N₂O (p-type, S.No. 11 of table III) and N₂ with plasma at a pressure of 1×10^{-3} mbar. The transmittance in the visible region is about 90% and this value is almost the same as that reported for the only Ga doped n-type ZnO and higher than the recently reported [17] p-type CuAlO₂. The slight absorption at 550–600 nm could be due to an interference effect. In Fig. 6, the blue shift of the absorption edge for the n-type film is due to high carrier concentration in accordance with the Burstein–Moss shift.

3.2.3. Electro-luminescence [18]

The electrical and photoluminescence properties of the p(or I)-ZnO layer produced on the ZnO single crystal seems to provide another possibility to explain

Fig. 6. Optical transmission spectra for: (a) 5 wt% of Ga codoped in ZnO under N₂O atmosphere {p-type}; (b) 5 wt% of Ga codoped in ZnO under N₂.

the light-emitting mechanism with the structure of metal/insulator/semiconductor (MIS) LEDs.

Fig. 7(a) shows the EL spectra of the ZnO homo-structural LED operating under a forward bias voltage with injection currents of 40, 80 and 120 mA, respectively, at room temperature. For comparison and emission analysis, the photoluminescence (PL) spectra excited from the surface of a p(or I)-ZnO layer grown on an Al₂O₃ (1120) substrate and an n-ZnO wafer irradiated by a 325 nm He–Cd laser at 77 K and room temperature (RT) are shown in Figs. 3(b) and (c). The current injection emission was generated when a forward biasing voltage of around 5–10 V was applied to the ZnO LED at room temperature. The light emission increases in the region of 300–900 nm when the injection current is increased from 40 mA to 80 and 120 mA.

Compared with those of the PL spectra in Figs. 7(b) and (c), there are abrupt emission increases in the region of 600–800 nm with the increase of injection current. A broad emission in the region of 370–380 nm is also slightly excited in the EL spectra, which corresponds to the free-exciton band. These broad PL peaks were repeatedly observed in the single nitrogen doped ZnO film. Since the isolated nitrogen dopant is unstable in the ZnO film, the oxygen vacancy is generated to reduce the film energy. In the cases of undoped ZnO and codoped ZnO [7], they show a clear and sharp free-exciton peak at around 380 nm. Similar broad and weak emissions are also observed in the PL spectra of Figs. 7(b) and (c), and occur due to defects such as oxygen vacancies and imperfection of crystallinity due to the low temperature formation (< 390 °C) [19]. The broad EL band emission in the region of 400–1000 nm is most likely due to defect states in the LED structure.

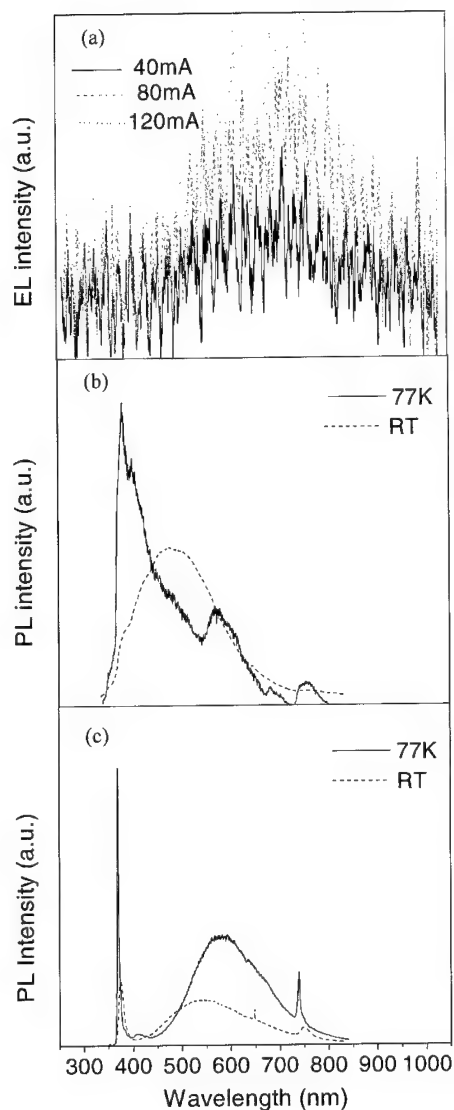

Fig. 7. (a) EL spectra of a ZnO homostructural LED operated at 5–10 V with injection currents of and 40, 80, 120 mA, respectively, at room temperature, (b) PL spectra of an n-ZnO single crystal wafer excited at 77 K and RT, and (c) PL spectra of a ZnO/Al₂O₃ film excited at 77 K and RT.

3.3. Magnetic properties

3.3.1. Cobalt (Co) doped-ZnO [20]

3d-transition metal doped ZnO films (n-type Zn_{1-x}M_xO ($x = 0.05 - 0.25$); M = Co, Mn, Cr, Ni) are formed on sapphire substrates using a PLD technique, and their magnetic and electric properties have been examined. The Co-doped ZnO films showed the maximum solubility limit. Some of the Co-doped ZnO films exhibit ferromagnetic behaviors with the Curie temperature higher than room temperature. The magnetic

Fig. 8. Magnetization versus temperature curves measured in the field of 0.1 T. Zn_{1-x}Co_xO films ($x = 0.05$ (Δ), 0.15 (\blacklozenge), 0.25 (\bullet)).

properties of Co-doped ZnO films depend on the concentration of Co ions and carriers.

The temperature dependence of magnetization for the Zn_{1-x}Co_xO films ($x = 0.05 - 0.25$) is shown in Fig. 8. A magnetic field of 0.1 T was applied parallel to the surface of the substrate. In the case of the Zn_{0.95}Co_{0.05}O and Zn_{0.75}Co_{0.25}O samples, the abrupt increase of magnetization, which corresponds to the T_C , appeared at 280 K. The $M-H$ curve (field dependence of magnetization) of Zn_{0.95}Co_{0.05}O films measured at 6 K showed a hysteresis shape with the coercive field (H_C) of 50 Oe. The saturation magnetization (M_S) of the film is estimated to be $1.8 \mu_B/\text{Co-site}$ from the $M-H$ curve. These $M-T$ and $M-H$ curves indicate that these films showed ferromagnetic features. The Zn_{0.85}Co_{0.15}O film also showed ferromagnetic behaviors. The T_C appeared at around 300 K, which is 20 K higher than that of Zn_{0.95}Co_{0.05}O film and the M_S is estimated to be $2 \mu_B/\text{Co-site}$ from the $M-H$ curve, which is $0.2 \mu_B$ higher than that of the Zn_{0.95}Co_{0.05}O film. (Fig. 8).

In the Zn_{1-x}Co_xO, only a few films showed ferromagnetic features, while the others showed spin glass-like behaviors. The reproducibility of the method was poor (less than 10%). We should adjust the conditions to make ferromagnetic films with high reproducibility in the near future.

We also produced Cr-, Ni-, or Mn-doped ZnO films and performed magnetic measurements. These films did not show ferromagnetic behaviors. However, we need to perform further experiments to determine their magnetic and electric properties.

3.3.2. Vanadium (V)-doped ZnO

Vanadium-doped ZnO films (n-type Zn_{1-x}V_xO ($x = 0.05 - 0.15$)) were formed on sapphire substrates using a pulsed laser deposition (PLD) technique, and their magnetic and electric properties were examined. Some of the V-doped ZnO films exhibited ferromagnetic behavior with a Curie temperature higher than 350 K. The magnetic properties of V-doped ZnO films were

Fig. 9. Hysteresis curves measured at 300 K of $\text{Zn}_{0.85}\text{V}_{0.15}\text{O}$ films (conductive sample (●), insulative sample (△)).

found to depend on the concentration of V ions and carriers. The results of optical transmission spectra indicated that they are transparent ferromagnets at room temperature. The M – H curve (field dependence of magnetization) of $\text{Zn}_{0.85}\text{V}_{0.15}\text{O}$ films measured at 300 K showed a hysteresis loop with the coercive field (H_C) of 200 Oe (Fig. 9(a)). The saturation magnetization (M_S) of the film is estimated to be $0.5 \mu_B/\text{V-site}$ from the M – H curve at 300 K. These M – T and M – H curves indicate that the films showed ferromagnetic features. The V concentration dependence of the M – H curve also showed a hysteresis shape. The $\text{Zn}_{0.90}\text{V}_{0.10}\text{O}$ and $\text{Zn}_{0.95}\text{V}_{0.05}\text{O}$ films also showed ferromagnetic behaviors. The M_S value of each film depends on the vanadium concentration from 5% to 15%. This indicates that ferromagnetism is more stable as the concentration of vanadium increases.

3.4. Conclusions

In summary, high resistivity p-type ZnO thin films have been obtained by doping with active N alone. This p-type conductivity is very much enhanced in terms of conductivity and carrier concentration by adopting a codoping method, using N as acceptor and Ga as donor dopants. The N doping is effective only with N_2O through an RF plasma source, but not with N_2 gas, and ZnO-based LED is also fabricated. EL property is observed. Furthermore, a room temperature ferromagnet has been developed for the first time in the ZnO films. To realize the local minimum phases, a non-equilibrium process is essential. Low temperature growth is one of the key techniques. The two-step growth, using a high temperature buffer layer, is a

powerful technique to obtain the well-crystallized ZnO films at a low temperature.

Modulation of deep level structures in SiO₂ upon nitrogen incorporation

Sukmin Jeong¹, Atsushi Oshiyama**Institute of Physics, University of Tsukuba, 1-1-1 Tennodai, Tsukuba 305-8571, Japan*

Abstract

We present first-principles total-energy calculations that provide energetics, charge states and electronic structures for various bond configurations around N in SiO₂ with and without hydrogen. It is found that the carrier traps are effectively removed near the energy gap upon coexistence of H and N. Effects of spin polarization around the defects are clarified. © 2001 Elsevier Science B.V. Keywords: Density functional theory; SiO₂; Carrier trap; Nitridation

1. Introduction

Leakage current across the ultrathin gate dielectrics is one of the major problems in miniaturization of metal-oxide-semiconductor devices. Generation of carrier traps is considered to be a principal cause for the leakage current in oxide films [1,2]. In the conventional oxides, O vacancies [3,4] and H bridges at the O vacancies [5] are proposed to be such carrier trap centers. The Si oxide films with N incorporation are now believed to be a candidate to replace the conventional Si oxides because they show better performances than the conventional oxides [6–13]. It is thus important to identify the carrier traps and their variances upon N incorporation in the Si oxynitride films.

We here explore a variety of bond configurations around N in SiO₂ using a first-principle total-energy method. We map out the energetics, charge states and electronic structures for the total-energy-optimized atomic configurations. We have found that N incor-

poration does not guarantee the improvement in electrical reliabilities of the Si oxynitride films, but that the *coexistence* of N and H is crucial for better electrical properties.

The density-functional theory (DFT) is used within the generalized-gradient approximation (GGA) [14]. The inclusion of spin degree of freedom is important in the structures without H. The nuclear potentials are simulated by ultrasoft pseudopotentials for O and N [15] and norm-conserving pseudopotentials for Si and H [16]. The cutoff energy of the plane-wave basis is 25 Ry. The super cell with 54 atomic sites possesses a triclinic symmetry and a special k point is used for integration in the Brillouin zone [4]. Geometries are optimized for all atoms until the remaining force on each atom is less than 5 mRy/Å.

2. Atomic structures

The bond configurations around the N atom in SiO₂ are not well identified. We thus consider possible atomic configurations containing N atoms in the network of α -quartz (Fig. 1): In the S₂ structure, an N atom substitutes for an O atom and then is bonded to two Si atoms (twofold N); in the S₃ structure, the central Si

Fig. 1. Structural models for N incorporation in α -quartz: (a) S_2 , (b) S_3 , (c) V_2 , (d) V_3 , (e) S_{2O} , and (f) α -quartz as a reference. Lightly grayed, darkly grayed, and black balls indicate Si, O, and N atoms, respectively. The arrow heads in panels (a)–(e) indicate the atoms that are bonded to an H atom in the corresponding H-terminated structures, labeled as S_{2H} , S_{3H} , V_{2H} , V_{3H} , and S_{2OH} , respectively.

moves leftward to form a threefold N atom, sacrificing the bond with its right O atom; the V_2 structure is the same as the S_2 structure except for the Si–Si dimer formation due to an O vacancy; in the V_3 structure, the threefold N is formed, by breaking the Si–Si dimer bond of the V_2 structure; in the S_{2O} structure, an O atom is added to the S_2 structure and an N–O bond is formed.

We then investigate the stability of the N-incorporated structures with respect to the SiO_2 matrix. We consider the reaction, $\text{NO} + X \rightarrow z\text{O}_2 + Y$, where X represents SiO_2 (perfect α -quartz crystal) or V_O (the α -quartz with an O vacancy). Y represents S_2 , S_3 , or S_{2O} when $X = \text{SiO}_2$, and V_2 or V_3 when $X = V_O$. The coefficient z is 1, except for $z = \frac{1}{2}$ when $Y = S_{2O}$. We choose the NO molecule since it is now widely used in oxynitridation of Si or is produced by dissociation of N_2O that is also another widely used reaction gas [17]. All the reactions are endothermic with reaction energies of 3.3, 4.4, 3.2, 2.8, and 2.1 eV for $Y = S_2$, S_3 , V_2 , V_3 , and S_{2O} ,² respectively, assuming both the reactant (NO) and product (O_2) gas molecules stay in the oxide film. The calculated reaction energies are consistent with most

experiments reporting only a few atomic percent of N concentration in Si oxynitrides. After the reactions, relative stability of the five structures is assessed by comparing the formation energies as a function of the oxygen chemical potential μ_O . For a wide range of physically relevant μ_O , the formation energy of S_{2O} is higher than those of the other four structures by more than 3 eV.

Chemically active dangling bonds (DBs) are likely in the five structures (arrow heads in Fig. 1). Hence, we further consider the H-terminated counterparts of the five structures, labeled as S_{2H} , S_{3H} , V_{2H} , V_{3H} , and S_{2OH} , respectively. The H termination would take place readily, since H is ubiquitous and diffuses very fast in SiO_2 with a barrier of 0.22 eV [18]. In this way, the present models include local arrangements experimentally observed: The most dominant $\text{N} \equiv \text{Si}_3$ species (in S_3 , V_3 , S_{3H} , and V_{3H}) and the minor species such as $\text{N} = \text{Si}_2$ (in S_2 and V_2) [9,11,12], $\text{O}=\text{N}=\text{Si}_2$ (in S_{2O}) [9–11], $\text{H}=\text{N}=\text{Si}_2$ (in S_{2H} and V_{2H}) [13], and $\text{HO}=\text{N}=\text{Si}_2$ (in S_{2OH}).

3. Thermodynamic levels

The stability among different charge states in their equilibria is obtained by comparing $\Omega(Q, \mu) \equiv E(Q) + Q\mu$, where $E(Q)$ is the total energy of the charge state Q , and μ is the electron chemical potential, i.e., the Fermi level in the energy gap. Figs. 2(a) and (b) show $\Omega(Q, \mu)$ for the N-incorporated structures as a function of μ for the doubly positive ($++$; $Q = 2$), positive ($+$; $Q = 1$), neutral (0 ; $Q = 0$), and negative ($-$; $Q = -1$) charge states. The μ value, $\mu_{th}(Q/Q + 1)$, at which $\Omega(Q, \mu) = \Omega(Q + 1, \mu)$, determines the relative stability of the Q and $(Q + 1)$ charge states. The μ_{th} values are also called thermodynamic levels [5]. The thermodynamic levels in Fig. 2 are aligned with respect to band edges, by matching the theoretical and experimental thermodynamic level related to the interstitial H in SiO_2 , located at 0.2 eV above the Si midgap (the energy reference hereafter), and by using the valence-band offset of 4.3 eV between SiO_2 and Si (refer to Ref. [5] for details).

The thermodynamic level defined above is not a single-electron level obtained by the Kohn–Sham equation. The Kohn–Sham (KS) level near μ_{th} , however, provides chemical understanding of changes in charge states since the charge-state changes are processes of carrier capture or emission through some electron state in the gap.

We begin with the V_2 structure since an O vacancy is proposed to be responsible for the leakage current in SiO_2 . The KS levels are originated from the lone-pair-like (LPL) and dangling-bond-like (DBL) states of N and from the Si–Si dimer bond. The LPL state of N with the minority spin, located at -2.4 eV, can capture an

²In evaluating the reaction energies for the structures, we consider their stablest charge states when the Fermi energy is at the Si midgap ($\mu = 0$ in Fig. 2).

Fig. 2. Relative formation energies $\Omega(Q, \mu)$ of the N-incorporated structures as a function of the electron chemical potential μ in the energy gap of α -quartz: The energies for the doubly positive ($++$), positive ($+$), neutral (0), and negative ($-$) charge states are shown. Both ends of μ in each panel are the experimental valence band maximum (VBM) and conduction band minimum (CBM) of α -quartz ($E_v^{\text{SiO}_2}$ and $E_c^{\text{SiO}_2}$), respectively. The VBM and CBM of bulk Si (E_v^{Si} and E_c^{Si}) are represented by vertical lines. The density-functional VBM and CBM of α -quartz are shown as a reference by vertical dotted lines near both ends of μ .

electron under electron injection since it is empty in the neutral state. The filled DBL state of N with the minority spin, located at -3.1 eV, can release an electron and then plays the role of a hole trap. The Si-Si dimer states of both spins are below the above two states. For the doubly positive charge state, the V_2 structure transforms to the V_3 structure with breaking of the Si-Si bond. This bistability is also observed for an O vacancy in SiO_2 [3,4].

The V_3 structure has different features in the KS levels from the V_2 structure. Instead of disappearance of the DB states of the N atom, the DB states of the right Si atom emerge at -1.7 eV for the majority spin and at 0.7 eV for the minority spin. The LP states of the N atom still remain in the SiO_2 energy gap. Thus the DB of the right Si atom can capture both an electron and a hole, depending on the position of the Fermi energy. The positively charged structure, in this case, is spin-unpolarized unlike the V_2 and S_2 structures.

Table 1 shows the charge-state dependent spin magnitude S for each geometry. The spin magnitude varies depending on the number of electrons accommodated in the corresponding electron states. It is noteworthy that high spin states ($S = 1$) are realized

Table 1

Calculated spin magnitudes S for possible charge states Q (see also Fig. 2) of each N-incorporated geometry. The calculated total-energy gain ΔE due to the spin polarization is also shown

Geometry	Q	S	ΔE (eV)
S_2	$+$	1	0.8
	0	1/2	0.4
	$-$	0	
S_3	$+$	1	0.5
	0	1/2	0.4
	$-$	0	
V_2	$+$	1	0.6
	0	1/2	0.4
	$-$	0	
V_3	$++$	1/2	0.2
	$+$	0	
	0	1/2	0.6
	$-$	0	

around defects in SiO_2 where non-magnetic elements alone exist. The total energy gain ΔE upon the spin polarization is also shown in Table 1 for each charge state. The energy gain is about a half eV. It is thus expected that the experiments such as EPR are capable of observing the high spin states in SiO_2 .

4. Coexistence of N and H

Figs. 2(a) and (b) clearly show that the N-incorporated structures induce the gap states that play roles of charge traps. The occupancy of the charge trap states is sensitive to the position of the Fermi energy that changes according to the external bias voltage across the oxide films. At the zero bias, corresponding roughly to $\mu = 0$, the negative charge states are the most stable except for V_3 . Within relatively small magnitudes of bias (0.2 – 1.8 V), the atomic structures change their charge states from negative to neutral. Larger biases then induce the charged states from neutral to positive. This manifests that the N incorporation in Si oxides itself is inadequate to erase carrier traps and then improve electrical reliabilities of the gate dielectrics.

The N-incorporated structures become much stabilized by capturing an H atom at the sites depicted in Fig. 1. The H-terminated structures have lower energies by 2.8 – 4.1 eV than the corresponding H-free structures (see footnote 2) plus H^+ in SiO_2 (see footnote 2).³ As shown in Figs. 2(c) and (d), the H termination gives rise to remarkable changes in electronic structures and consequently in structural stabilities. All the DB states

³For H in SiO_2 , the positive charge state has the lowest energy at $\mu = 0$ (see Ref. [19]).

disappear from the energy gap because of formation of strong bonds with H. As a result, we have only the gap states from the LP of N in S_{2H} , S_{3H} and V_{3H} and from the Si–Si dimer bond and the LP of N in V_{2H} . These remaining gap states are in the SiO_2 energy gap. However, they are practically inactive for a wide range of applied voltage due to their sufficiently deep positions in the energy gap [see Figs. 2(c) and (d)]. Further, since all the gap states are already occupied, electrons are unable to be trapped for the whole range of the Fermi energy. Therefore, in the H-terminated structures, S_{2H} , S_{3H} and V_{3H} , the carrier traps are effectively removed from the practical range of the Fermi-level position. This is in agreement with a recent voltage shift measurement for the gate dielectrics grown on the N-implanted Si substrate [8].

The $N \equiv Si_3$ unit, observed as the most dominant species in Si oxynitride, is found to be effective in reducing the charge traps, only if it is *terminated* by H (V_{3H} and S_{3H}). The $H-N = Si_2$ unit is also effective. The existence of N–O bonds, on the contrary, is not desirable for suppression of charge trapping: We have found that the anti-bonding states of LPs of the N and O atoms in the S_{2O} structure become hole traps that are still active for a bias as small as 2.7 V, even after H termination. Of course, it is impossible that the present models cover all the possible bond configurations around N, especially near the SiO_2/Si interface. But we argue that the calculated results are directly extended to other structures and that the charging characters can be predicted based on the generic features of the present model structures.

H termination (without N incorporation), although generally effective in removing the gap states of DBs from the energy gap, does not automatically guarantee suppression of charge trapping. A recent DFT calculation

has shown that the H-complexed O vacancy, where two Si atoms that were bonded to the removed O atom (O vacancy) are terminated by two H atoms, is susceptible to hole injection, through formation of an H_2 molecule [20]. Based on the present DFT calculations as well as this result, we argue that the improvement in electrical reliabilities of Si oxynitrides originates from the *coexistence* of N and H, neither from the presence of N alone nor from the presence of H alone.

Non-linear 2-mm waveband EPR spectroscopy of spin/charge excitations in organic semiconductors

V.I. Krinichnyi*

Institute of Problems of Chemical Physics, 16 Institutski Prospect, Chernogolovka, MD, 142432 Russia

Abstract

This report summarizes the basic aspects of an investigation at 2-mm waveband EPR of magnetic, relaxation and dynamics parameters of various low-dimensional solid-state organic semiconductors with mobile paramagnetic impurities. At high-registration frequency, all components of the g -tensor of such paramagnetic centers are determined. Relaxation and diffusion rates of paramagnetic impurities with different mobilities are determined by the method of steady-state saturation of spin packets. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: EPR; Organic semiconductors; Relaxation; Dynamics

1. Introduction

The recent years are characterized by a great attention to the synthesis and investigation of new electronic low-dimensional systems, organic polymer and fullerene semiconductors [1]. This happened since the investigation of these systems has generated entirely new scientific conceptions and a potential for its perspective application in molecular electronics.

Normally, these systems contain paramagnetic centers (PC) localized or/and delocalized along molecules, therefore EPR spectroscopy is a powerful method for investigation of different properties of organic semiconductors. However, at the usually used centimeter wavebands EPR, the signals of organic free radicals are registered in a narrow magnetic field range that leads to the overlapping of the lines of complex spectrum or spectra of different radicals with similar g -factors [1]. It was shown earlier [2], that transition to 2-mm waveband EPR and use of saturation methods enable the profound investigation of the structure, dynamics, other specific characteristics of paramagnetic impurities and their local environment, and charge transfer processes in different solid-state systems.

This report is devoted to the potentialities of non-linear 2-mm waveband EPR spectroscopy in the investigation of relaxation and dynamics properties of PC in various organic low-dimensional semiconductors, e.g. polyaniline, $(-\text{C}_6\text{H}_4-\text{NH}-)_x$ (PANI) slightly doped with sulfuric acid and in triphenylamine fullerene complex $(\text{C}_{60}^-\text{TPA}^+)$ irradiated by light with $\lambda > 400$ nm.

2. Polyaniline

Nearly symmetric Lorentzian signals are observed in the 3-cm EPR spectrum of the polyaniline slightly doped with sulfuric acid (Fig. 1a). At 2-mm waveband EPR, this sample demonstrates a more informative spectrum (Fig. 1b). Computer simulation of these EPR spectra showed that at least two types of PC are stabilized in the polymer semiconductor, namely localized polarons R_1 with $g_{xx} = 2.00535$, $g_{yy} = 2.00415$, $g_{zz} = 2.00238$, $A_{xx} = A_{yy} = 0.33$ mT, and $A_{zz} = 2.3$ mT, and polarons R_2 with $g_{\text{eff}} = 2.00395$ moving along polymer chains with a minimum rate $v_{1D}^0 \geq (g_{xx} - g_e)\mu_B B_0 / 2\pi\hbar \cong 5.7 \times 10^7 \text{ s}^{-1}$.

In both the dispersion components, the bell-like signals are detected due to an adiabatically fast passage of the inhomogeneously broadened line (Figs. 1c and d). This effect was not detected earlier at lower magnetic

Fig. 1. In phase (a–c) and $\pi/2$ -out-of-phase (d) absorption (a,b) and dispersion (c,d) spectra of polyaniline base detected at 3-cm (a) and 2-mm (b–d) wavebands EPR. Dotted lines show shown calculated PC R_1 and dispersion component u_3 registered at low temperature. The dispersion components u_2 and u_3 are shown.

fields. Indeed, the probability of interaction of the spin packets $P \propto \exp(-\hbar\omega_c/kT)$ decreases strongly at 2-mm waveband EPR such that the spin-packets become non-interacting and are saturated at lower RF power. This type of components is a result of rapid passage of PC as the conditions of the spin packets saturation $\gamma_c B_1 \sqrt{T_1 T_2} > 1$ and adiabatic passage of resonance $dB/dt = B_m \omega < \gamma_c^2 B_1^2$ hold (here T_1 and T_2 is, respectively, the spin-lattice and spin-spin relaxation time, dB/dt is the rate of passage of resonance, B_m and ω_m are the amplitude and angular frequency of magnetic field modulation, respectively, and B_1 is the magnetic component of the polarizing RF field. In this case, the dispersion signal consists of one linear and two non-linear terms [3]:

$$U = u_1 \sin(\omega_m t) + u_2 \sin(\omega_m t - \pi) + u_3 \sin(\omega_m t - \pi/2). \quad (1)$$

The dispersion signal of PANI is determined mainly by the two later terms of Eq. (1), so that both the relaxation times can be calculated from the u_2 and u_3 terms of Eq. (1) as was described earlier [4].

The relaxation times calculated from the dispersion spectra of PC in PANI sample are shown in Fig. 2 as a function of temperature.

The amplitude and shape of the components of the dispersion signal depend not only on the intensity of spin exchange and the rate of electronic relaxation, but also on the relatively slow macromolecular reorientations or torsional librations in the polymer semiconductor. Such motions are usually studied by the saturation transfer EPR spectroscopy (ST-EPR) [5]. Fig. 1 shows that the shape of the u_3 component changes with temperature. It is a typical manifestation of intensification of superslow anisotropic librations of

Fig. 2. The temperature dependences of the effective relaxation times, the 1D and 3D translative diffusion coefficients of PC in polyaniline slightly doped with sulfuric acid. The dependences $D_{1D}(T) \propto \ln^4(10^{25} T^{-9.8})$ and $D_{3D}(T) \propto k_1 T \exp(-0.025 eV/kT) + k_2 T \exp(-0.048 eV/kT)$ are shown by a dashed and dash-dotted lines, respectively.

macromolecules with localized R_1 radicals near the main X -axis. The correlation time of such PC motions in PANI was determined from the equation $\tau_c^v = \tau_c^0 (u_3^v/u_3^i)^{-4.8}$ to be $2.7 \times 10^{-7} \exp(0.045 eV/kT)$. The calculated activation energies of macromolecular librations correspond to the energies of optical phonons and are close to the value obtained for poly(tetrathiafulvalene) and poly(bis-alkylthioacetylene) [2].

The experimental data obtained can be explained by the modulation of electron relaxation by 1D diffusion of mobile polarons along the polymer chains and by their 3D hopping between the chains with the diffusion coefficients D_{1D} and D_{3D} , respectively. Such spin motions induce an additional magnetic field at the sites of other PC. This leads to the increase of effective relaxation rates of the spin ensemble [6]

$$T_1^{-1} = \langle \omega^2 \rangle [2J_1(\omega_c) + 8J_2(2\omega_c)], \quad (2a)$$

$$T_2^{-1} = \langle \omega^2 \rangle [3J(0) + 5J_1(\omega_c) + 2J_2(2\omega_c)], \quad (2b)$$

where $\langle \omega^2 \rangle$ is the second momentum of the line, and $J(\omega_c) = (D_{1D}\omega_c)^{-1/2}$ at $D_{3D} \leq \omega_c \leq D_{1D}$ and $J(\omega_c) = (D_{1D}D_{3D})^{-1/2}$ at $\omega_c \leq D_{3D}$ are the spectral density functions at the spin precession frequency ω_c .

1D spin dynamics in PANI can be interpreted in the framework of the Kivelson–Heeger model [7] of isoenergetic electron transfer between the polymer chain involving optical phonons. According to this model, polarons should diffuse along the chain with a diffusion coefficient of

$$D_{1D}(T) \propto D_{1D}^0 \ln^4[k_1 T^{-n-1}], \quad (3)$$

Fig. 3. In phase (a–c) and $\pi/2$ -out-of-phase (d) absorption (a,b) and dispersion (c,d) spectra of $C_{60}TPA^+$ complex detected at 3-cm (a) and 2-mm (b–d) wavebands EPR. The first derivative of quadrature dispersion signal (insert d) is shown by a dashed line (insert b). The dispersion components u_2 and u_3 are shown.

where k_1 is constant and $n \approx 10$. Fig. 2 shows that this function $k_1 = 10^{25} K^{9.8}$ and $n = 8.8$ fit well with the experimental data.

As in case of inorganic semiconductors, 3D spin dynamics in PANI can be explained by activated hopping through a barrier E_a , $D_{3D}(T) \propto T \exp(-E_a/kT)$. It is seen from Fig. 2, that spins and charges hop between polymer chains with $E_a = 0.025$ eV at $T \leq 200$ K and with $E_a = 0.048$ eV at higher temperatures. The latter value lies near the energy of lattice phonons determined above. This leads to a conclusion of modulation of interchain spin/charge transfer by macromolecular motion.

3. Fullerene complex

PC in $C_{60}TPA^+$ demonstrate a single spectrum with $g = 2.0023$ and linewidth of 0.15 and 1.18 mT at 3-cm and 2-mm wavebands EPR, respectively (Fig. 3). At 2-mm waveband, the EPR linewidth decreases down to 1.08 mT for the temperature decreasing down to 100 K. The spin susceptibility follows the Curie law for 100–250 K and it decreases sharply at higher temperatures (Fig. 4).

As in the case of PANI, in both dispersion components, the bell-like signal are detected due to an adiabatically fast passage of the inhomogeneously broadened line (Figs. 3c and d), so that the relaxation times of the sample can be determined from its dispersion components as well.

The temperature dependencies of the effective relaxation times of PC in $C_{60}TPA^+$ are present in Fig. 4. The figure shows that $T_1(T)$ and $T_2(T)$ functions differ on those of some metals and compounds of lower dimension. The break in the curves could be attributed to the structural conformation transition in the system at

Fig. 4. The temperature dependences of the effective relaxation times, the rotational diffusion coefficient and relative susceptibility of PC in $C_{60}TPA^+$ complex. The dependence $D_r = D_r^0 + k_1 T \exp(-0.027/kT)$ is shown by dashed line.

$T_c \approx 250$ K. The T_c value is closer to that of phase transition in C_{60} single crystal. It is accompanied with the librative reorientation of preferable axis of some C_{60} molecules by 22° and the change of the crystal unit volume.

The temperature dependence of the D_r value calculated for $C_{60}TPA^+$ from Eq. (2) with $J(\omega_c) = 2D_r/(D_r^2 + \omega_c^2)$ is also shown in Fig. 4. The figure shows that the spin rotation frequency increases monotonically with the temperature increase from 100 K up to $T_c \approx 250$ K and then increases sharply up to $\sim 10^{13} s^{-1}$ at 300 K. As in the case of single crystal C_{60} , such a drop is probably caused by the phase transition accompanied by the change of the sample unit size. This process decreases the energy barrier of the molecular rotation that leads to an the increase of the motion rate in the complex. The D_r value was determined to be $D_r = D_r^0 \exp(-0.024/kT)$ at $T \leq T_c$. $D_r^0 = 1.2 \times 10^{12} rad s^{-1}$ corresponds to an upper frequency limit for optical phonons in solids. The activation energy E_a is near to the phonon energy of C_{60} single crystal, 0.025 eV [8]; however, it is less than that of C_{60} rotation, 0.052 eV determined by X-ray structure analysis [9]. Such a discrepancy can be explained by the larger size of elemental unit of $C_{60}TPA^+$ complex that should lead to a decrease in the rotational barrier for PC.

The first derivative of $\pi/2$ -out-of-phase component of the dispersion signal shown in Fig. 3d is presented by a dotted line in Fig. 3b. The comparison of this spectrum with the normal absorption one (Fig. 3b) shows that, two PC, R_1 and R_2 with ratio 80:1 and equal g -factors but with different relaxation and dynamics parameters are stabilized in the complex. The singlet attributed to radical R_1 has $\Delta B_{PP} = 1.08$ mT, whereas PC R_2 demonstrates a doublet with $\Delta B_{PP} = 0.19$ mT splitted by $D = 1.37$ mT (Fig. 3b). The shape of the latter

spectrum should be attributed to triplet pairs stabilized in the sample. The distance r_{12} between PC in this triplet can be calculated in the framework of an interaction of two point-like dipoles, $D = 1.5\gamma_e\hbar r_{12}^{-3}$ to be 1.22 nm. This value is lesser than the distances between C_{60}^- anions (1.8334 nm) and that between C_{60}^- anion and TPA^+ cation (1.5394 nm), however, but exceeds another anion–cation distance (0.9953 nm) obtained for the complex by X-ray spectroscopy. This discrepancy can be explained by a more planar conformation of cation in triplet pairs.

As Fig. 3 shows, the spectrum of PC R_2 is manifested only in $\pi/2$ -out-of-phase dispersion signal. This means that the effective relaxation and consequently the rotation rate of this center exceeds at least by order of the value for R_1 . Indeed, the evaluation of D_r from Eq. (2) with $\langle\omega^2\rangle = 1/30\gamma_e^2 D^2$ for the triplet radical pair [10] gives $D_r \sim 10^{15} s^{-1}$ at room temperature that is higher than that estimated for R_1 radical with higher linewidth.

4. Conclusions

Two types of PC with different relaxation and dynamics parameters are stabilized at doped PANI and $C_{60}^-TPA^+$ complex irradiated by visible light. C_{60} molecules rotate actively at low temperatures and the rate of motion increases sharply at phase transition. This is accompanied by a change in the electron relaxation and in the paramagnetic susceptibility of the system. The change in the conformation of the cation complex also leads to a considerable increase in the rotation frequency.

The data obtained show the evident advantages of non-linear 2-mm waveband EPR spectroscopy in the investigation of different organic semiconductors of low dimensionality. The method allows to analyze completely and correctly the magnetic and relaxation parameters of PC of different mobilities in order to obtain fine peculiarities of molecular and spin dynamics in these and other systems.

Abstract

We investigated the effects of the incorporation of Na and O into p-type Cu-deficient CuInS₂. Codoping of Na and O leads to the formation of a complex containing Na_{Cu} and O_S, where they occupy nearest-neighbor sites, causing the annihilation of the deep level in the band gap due to the n-type Cu–S divacancy. © 2001 Elsevier Science B.V. 1. Introduction

The ternary semiconductor CuInS₂ with a chalcopyrite structure is a promising material for high-efficiency solar cells because its band gap of 1.5 eV matches the solar spectrum well. We have demonstrated that Na incorporation into p-type Cu-deficient CuInS₂ thin films is essential for fabricating high-efficiency CuInS₂-based solar cells without employing the KCN process [1–4]. The achieved efficiencies are 10.6% and 11.2% for CuInS₂ and Cu(In,Ga)S₂ solar cells, respectively [4]. We have reported that the Na incorporation annihilates the donor states generated in Na-free CuInS₂ films and, consequently, significantly enhances the electric conductivity of the film [3]. The calculated results using an *ab initio* electronic-band-structure calculation method suggests that the Na atoms move easily toward the Cu-vacancy (V_{Cu}) sites near the surface, where the material becomes more Cu deficient [5,6]. Moreover, we calculated the enthalpies of migration via V_{Cu} of Cu and Na

atoms in Cu-deficient CuInS₂ to be 1.12 and 0.42 eV, respectively [7]. There have been various investigations on defect structures for CuInS₂. It was reported that an acceptor level with 70–105 meV corresponds to V_{Cu} [8–11] and the three donor levels with 35–55, 70–72, and 140–200 meV correspond to sulfur vacancy (V_S) [8–10], interstitial In (In_i) or In at Cu sites (In_{Cu}) [10], and In_{Cu} [9,10,12], respectively. For p-type Cu-deficient CuInS₂ thin films fabricated by us, from the PL measurement, we find a deep donor level with 270 meV. This decreases the conductivity of the thin films, as discussed below.

The purpose of this work is to propose a model regarding the defect structure of Cu-deficient CuInS₂ by a codoping method using Na and oxygen (O) atoms, giving the origin of the defect which behaves as the p-type killer.

2. Methodology

The preparation process of CuInS₂ thin films is given elsewhere [13]. Low-temperature PL was performed using an Ar gas laser with a wavelength of 514.5 nm as the excitation source. PL spectra were obtained for the samples cooled to 9 K inside an optical cryostat. PL

signals were processed by means of a liquid-nitrogen-cooled Ge detector and a lock-in amplifier. For excitation intensity dependence measurements, different kinds of optical neutral-density (ND) filters were used to vary the intensity by setting them in the optical path. The SIMS analysis was performed with Cs primary ions to investigate the distribution of Na and O in the films. The measurement area was $100 \times 140 \mu\text{m}^2$. We monitored the $^{149}\text{NaCs}$ ion for positive ion detection and the ^{18}O ion for negative ion detection since the distribution of the ^{16}O overlaps that of the double-charged ion of ^{32}S . Details concerning the preparation for SIMS measurements are given elsewhere [13].

The results of our band-structure calculations for CuInS_2 doped with Na, V_{Cu} or oxygen atoms at S sites (O_S) are based on the local-density treatment of electronic exchange and correlation [14–16] and on the augmented-spherical-wave (ASW) [17] formalism. Further details are given elsewhere [5,7,13].

3. Results and discussion

First, we show the PL spectra for CuInS_2 films codoped with Na and O and without them in Fig. 1. We found four peaks at 1.52, 1.44, 1.40 and 1.20 eV. The most significant difference in the PL spectra between codoped and undoped CuInS_2 films is the intensity of the peak at 1.20 eV. This emission, related to a deep defect level, could be reduced in intensity by the incorporation of both Na and O. In order to investigate

Fig. 1. PL spectra for Na-free and Na-added CuInS_2 thin films.

the origin of the emission peaks, the dependence of the emission peak on both the excitation power and temperature was measured for the Na-free CuInS_2 film as a standard reference.

From the measurement of the dependence of the emission peak energies (E_p) for peaks B, C and D on the excitation power (P), as shown in Fig. 2, we find that the three emission peaks shift towards high energies with increasing excitation intensity. We interpret that all the shifts in terms of the excitation can be considered to be the characteristic criteria of donor–acceptor (DA) pair transitions. For peaks B and C, the increase of E_p with increasing excitation power can be explained for the ratio of only a few meV, ΔE_p to ΔP , on the basis of a decrease of the mean value of the distance between the acceptor and donor atoms at higher excitation levels [18]. On the other hand, for peak D, Fig. 2(c) indicates another mechanism which causes larger values ($> 10 \text{ meV}$) of the ratio. The mechanism may be band perturbation due to high concentrations of defects [19].

For Cu-deficient CuInS_2 , we focus on the idea that a Cu-vacancy (V_{Cu}) is considered to be a dominant defect as acceptor. Hence there are three different donor

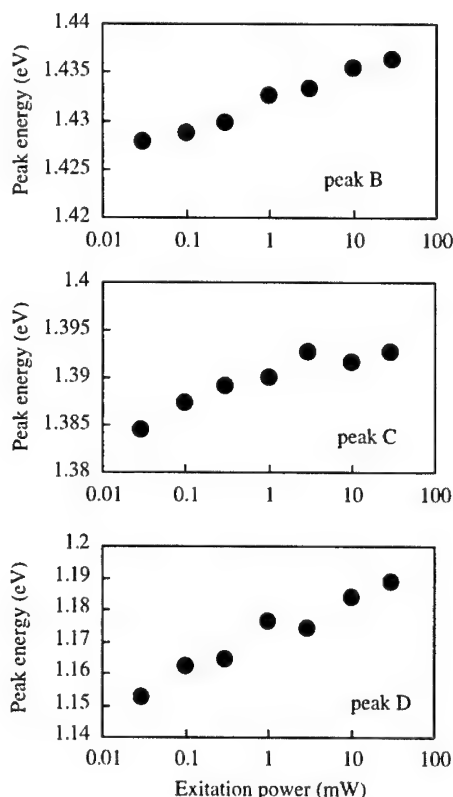

Fig. 2. The dependence of the emission peaks (peaks B–D) on excitation intensity at 9 K for Cu-deficient CuInS_2 undoped film.

defects, such as V_S , indium interstitial (In_i) and In at Cu sites (In_{Cu}), in the $CuInS_2$ films. It was reported that the origins of emissions at 1.447 and 1.41 eV were the DA transitions between a sulfur vacancy (V_S) and V_{Cu} , and that between indium interstitial (In_i) and V_{Cu} , respectively [20]. Our measurements of PL concerning both peaks B and C are in good agreement with those of the above report. Here, we can deduce that the 30 meV level corresponds to V_S , whereas V_{Cu} generates an 80 meV level, based on the measurement of the PL intensity as a function of temperature [13].

We note the origin of the near-edge emission peak at 1.52 eV. The possible recombination origins include both the donor-to-valence-band and the conduction-band-to-acceptor transitions. Two groups reported identifying the origin to be a donor-to-valence-band emission [11,20]. In this work, we have little information concerning the nature of the defects.

With regard to the emission peak at 1.20 eV for undoped $CuInS_2$, which changes significantly in this work, to our knowledge, there has been as yet no investigation. For Cu-deficient $CuInS_2$, the copper and sulfur vacancies are the most probable defects. We predict that the single intrinsic defect levels of $CuInS_2$ will be relatively shallow from the band-structure calculations [21]. Thus, we discuss the possibility of the occurrence of the complex defects including V_S and V_{Cu} . In Table 1, we summarize the difference in the calculated lattice energy (Madelung energy), ΔE_M , between undoped and doped $CuInS_2$. Table 1 shows that as the number of V_{Cu} increases, the Madelung energy increases. This gives rise to a shift in S 3p levels towards higher energy, resulting in the instability of S in the vicinity of the V_{Cu} site [22]. This suggests that the formation of n-type divacancies (V_{Cu-S}), which include V_{Cu} and vacancies of sulfur close to the V_{Cu} site (V_{Cu-S}) will be more favorable with increasing V_{Cu} concentration. Actually, for $CuInSe_2$ with a narrower band gap of 1.04 eV, Kimura et al. suggest that the origin of the deep donor level with 220 meV is the V_{Cu-Se} divacancy [23]. On the other hand, from Table 1, we find that the incorporation of Na, which occupies Cu-vacancy sites, causes a decrease in the Madelung energy. From the analysis of the S 3p levels in the vicinity of the sites of Na for Na-incorporated $CuInS_2$, we find that the Na incorporation stabilizes the S atoms close to the Na

sites. This gives us a solution for the problem concerning the formation of the Cu–S divacancies; a codoping using Na and other elements that strongly correlates with Na atoms. From the band-structure calculations under the condition of minimum total energy, we find that the formation of the complex of Na_{Cu} and O_S that occupy nearest-neighbor sites is energetically favorable. We note that the formation of the complex of Na and O plays an important role in the decrease of the concentrations of the n-type V_{Cu-S} divacancy. Moreover, as shown in Table 1, there is a decrease in the Madelung energy of $CuInS_2:(Na_{Cu} \text{ and } O_S)$ compared with that of undoped $CuInS_2$.

We carried out SIMS after removing secondary phase $NaInS_2$ [2,3,24] by HCl treatment, in order to investigate the distribution of Na and O codoped in the $CuInS_2$ crystal. Considering the above findings based on the calculated results, it is of interest to study the SIMS data shown in Fig. 3, which shows SIMS depth profiles of Na and O after removing the $NaInS_2$ phase. We confirmed that the Na concentration near the film surface was reduced by removing the $NaInS_2$ phase. Even after etching $NaInS_2$, we established high concentration of Na of the order of 10^{19} – 10^{20} cm^{-3} , as determined by SIMS. Note that the shape of the O profile closely resembles that of the Na profile. This indicates that the Na atoms strongly correlate with the O atoms within $CuInS_2$. The SIMS profile shows that both Na and O are incorporated in almost equal amounts. Based on the above results and discussion, we propose a model of the defect structure which includes the complex of Na_{Cu} and O_S which occupy the nearest-neighbor sites for $CuInS_2:(-Na, O)$. That is, the Na–O complex annihilates n-type V_{Cu-S} divacancies existing in the Na-free films.

4. Conclusion

The following conclusions are derived from the experimental and theoretical results and discussion.

Fig. 3. SIMS depth profiles for $CuInS_2:(Na, O)$ film after removing $NaInS_2$.

Table 1
Calculated difference in the Madelung energy, ΔE_{Mad} , between undoped and doped $CuInS_2$ crystals

Defects	$2V_{Cu}$	V_{Cu}	$Na_{Cu}V_{Cu}$	$2Na_{Cu}$	$Na_{Cu}O_S^a$
ΔE_{Mad}	+11.22	+5.82	+2.81	−9.82	−10.55

^aComplex of Na and O which occupy nearest-neighbor sites.

We succeeded in controlling n-type defects, particularly the defects causing deep levels, by the incorporation of both Na and O species into p-type CuInS_2 thin films. We propose a model of the defect structure for CuInS_2 codoped with Na and O. That is, Na_{Cu} and O_{S} form a complex in which they occupy nearest-neighbor sites. That annihilates the deep level due to the n-type V_{Cu} s divacancy.

Abstract

Defect formation processes in chalcogenide vitreous semiconductors of the ternary As–Ge–S system, induced by the ⁶⁰Co γ -irradiation with 2.82 MGy absorbed dose, are studied using positron lifetime measurements. The obtained results are explained at the level of both short- and medium-range ordering in the framework of coordination topological defects model modified with free-volume microvoids formation. © 2001 Elsevier Science B.V. 1. Introduction

Positron annihilation method is a powerful instrument for the experimental study of solids at different levels of their structural hierarchy [1]. It is characterized by a high sensitivity to local changes associated with point and linear defects, impurities and inhomogeneities, crystallites and phase incorporates, microvoids and atomic clusters.

The application of this method for disordered solids, such as chalcogenide vitreous semiconductors (ChVS), gives very important and sometimes exclusive information on their structural features as well as on microstructural transformations, induced by different kinds of high-energetic ionizing irradiation. The coordination topological defects (CTD) model for these radiation-induced effects in the binary ChVS was created [2,3] in the framework of well-known D^+D^- point charged defects concept developed by Mott et al. [4]. As a rule, only data of vibrational spectroscopy methods (such as

the Raman, IR Fourier spectroscopy) were obtained on the basis of the above model.

The aim of the present investigations is to obtain additional data on the CTD in the ternary As–Ge–S ChVS of stoichiometric As_2S_3 – GeS_2 and non-stoichiometric As_2S_3 – Ge_2S_3 cross-sections using positron annihilation lifetime technique.

2. Experimental

The investigated bulk samples of ternary stoichiometric $(As_2S_3)_y(GeS_2)_{1-y}$ ($y=0.1$ – 0.6) and non-stoichiometric $(As_2S_3)_x(Ge_2S_3)_{1-x}$ ($x=0.2$ – 0.4) systems were prepared by a well-known melt quenching method described previously elsewhere [5].

The prepared ChVS samples were irradiated by γ -quanta with an accumulated dose of 2.82 MGy and a dose power of 20 Gy/s in the normal conditions of stationary radiation field, created in the closed cylindrical cavity owing to concentrically established ⁶⁰Co ($E = 1.25$ MeV) sources.

The measurements of positron annihilation lifetimes were carried out using an ORTEC spectrometer with the FWHM (full-width at half-maximum) resolution of

0.270 ns. The ^{22}Na isotope with 0.74 MBq activity was used as a positron source placed between two identical samples, forming a “sandwich” system. The positron lifetimes were calculated from the LT computer program [6] using a single exponential function as well as a sum of two weighted exponential functions fittings.

3. Results and discussion

The positron lifetime characteristics of the investigated ChVS samples before and after γ -irradiation are presented in Table 1. Let us try to explain these results taking into account the previously obtained experimental data of other authors [7–10].

There are two principally different approaches to the interpretation of the positron lifetime measurements in the ChVS.

The first one, developed by Kobrin and Shantarovich with co-workers in the 1980s [7–9] on the basis of the CTD concept, prefers the positron annihilation processes in the ChVS at the negatively charged “dangling” bonds. It was assumed on the basis of numerous experimental data for the various ChVS systems (however, without strong theoretical calculations) that the main types of these CTD were characterized by the following lifetimes—0.32 ns (S_1^-), 0.37 ns (As_1^-) and 0.42 ns (Ge_1^-). The upper index in the CTD signature indicates the charged electrical state, and the lower one,

the number of neighbouring atoms. The experimentally observed positron annihilation lifetime components were treated as a superposition of various combinations of these lifetimes with each other, as well as lifetimes of positron annihilation on non-localized free electrons (0.2 ns) or microcrystalline inclusions (0.5 ns). Thus, only topological changes at the short-range ordering level were taken into account in this consideration. However, in this way it is difficult to explain the positron annihilation lifetimes less than 0.32 ns, because the free-electron concentration is typically too low in the ChVS [11].

The second approach is based on the theoretical lifetime calculations for the positrons trapped by the so-called open volume defects (vacancies and vacancy clusters) in crystalline As_2Se_3 . It was carried out by Jensen et al. at the beginning of the 1990 in order to explain the experimentally observed results on positron lifetime measurements in glassy As_2Se_3 [10]. It was stated that not intrinsic negatively charged CTD, but only microvoids of $25\text{--}100 \text{ \AA}^3$ volume in the form of As- (0.262 ns) and Se-monovacancies (0.274 ns), As–Se divacancy (0.316 ns) and As–Se₃ quadruple vacancy (0.368 ns) were responsible for the positron trapping. The lowest value of the positron lifetime (0.240 ns) was attributed to non-trapped positron annihilation in defect-free bulk crystalline As_2Se_3 . Apart from this, the experimental evidences for the CTD formation processes in the ChVS

Table 1

Positron lifetime characteristics for boundary compositions of the investigated stoichiometric $(\text{As}_2\text{S}_3)_x(\text{GeS}_2)_{1-x}$ and non-stoichiometric $(\text{As}_2\text{S}_3)_x(\text{Ge}_2\text{S}_3)_{1-x}$ ChVS systems before and after γ -irradiation with 2.82 MGy dose

Glass composition	Before γ -irradiation (ns)	After γ -irradiation with 2.82 MGy dose	
		Experimental values (ns)	Mean lifetime (ns)
$y = 0.6$	$\tau_1 = 0.3638 \pm 0.0002$	$\tau_1 = 0.277 \pm 0.002$; $I_1 = 0.67 \pm 0.01$; $\tau_2 = 0.386 \pm 0.003$; $I_2 = 0.33 \pm 0.01$	$\tau = 0.313 \pm 0.003$
$y = 0.1$	$\tau_1 = 0.3644 \pm 0.0004$	$\tau_1 = 0.282 \pm 0.009$; $I_1 = 0.53 \pm 0.05$; $\tau_2 = 0.397 \pm 0.010$; $I_2 = 0.47 \pm 0.05$	$\tau = 0.336 \pm 0.010$
$x = 0.4$	$\tau_1 = 0.3396 \pm 0.0003$	$\tau_1 = 0.275 \pm 0.010$; $I_1 = 0.55 \pm 0.06$; $\tau_2 = 0.392 \pm 0.013$; $I_2 = 0.45 \pm 0.06$	$\tau = 0.328 \pm 0.013$
$x = 0.2$	$\tau_1 = 0.239 \pm 0.006$; $I_1 = 0.43 \pm 0.02$; $\tau_2 = 0.385 \pm 0.005$; $I_2 = 0.57 \pm 0.02$	$\tau_1 = 0.243 \pm 0.017$; $I_1 = 0.33 \pm 0.05$; $\tau_2 = 0.387 \pm 0.009$; $I_2 = 0.67 \pm 0.05$	$\tau = 0.339 \pm 0.017$

are quite convincing [2,3,15] and, consequently, they cannot be rejected fully without any serious arguments.

So none of these approaches can be accepted entirely to explain the experimental results of the positron annihilation measurements in the ChVS.

We believe that positron trapping in the ChVS occurs on microvoids, but their association with the CTD must be taken into account too.

A part of the microvoids have a fluctuating nature and can be frozen technologically at melt quenching [12–15]. Their volumes in the ChVS are typically as high as $15\text{--}30\text{ \AA}^3$, which is less than the volumes of discrete atomic vacancies introduced in Ref. [10]. This value of $15\text{--}30\text{ \AA}^3$ can be reduced even to $5\text{--}10\text{ \AA}^3$ by accepting that fluctuation microvoids are probably connected with boundary shifts of bridge chalcogen atoms [15]. These native microvoids of atomic and sub-atomic sizes lead to a lower compactness of glassy-type atomic network in comparison with the crystalline structures. It means that these native free-volume microvoids can be the traps for positrons with characteristic lifetimes less than $0.25\text{--}0.30\text{ ns}$ (due to the dependence of the positron lifetimes on open volumes presented in Ref. [10]).

But the other part of the microvoids can be created in the ChVS structure by external influences as a result of atomic transformations at the medium-range ordering level in the nearest vicinity of the negatively charged CTD (CTD-based microvoids). This process is shown schematically in Fig. 1 in the example of (S_1^-, As_4^+) CTD formation in amorphous As_2S_3 , caused by photoexposure [16]. It is clear that the appearance of an additional As–As covalent chemical bond instead of the destructed As–S one at the positively charged As_4^+ defect leads to the local densification of the atomic package, while near the negatively charged S_1^- CTD the atomic network is distorted with free-volume microvoid formation (which is crosshatched in Fig. 1).

Fig. 1. A topological scheme illustrating the process of additional free-volume formation in the vicinity of the negatively charged S_1^- coordination defect.

It is difficult to quantitatively estimate the real volume of the created CTD-based microvoids for different kinds of the negatively charged CTD, but their appearance in the vicinity of the negatively charged CTD provides the effective positron trapping with characteristic lifetimes given by Kobrin and Shantarovich with co-workers [7–9].

The positron annihilation lifetime measurements show that before the γ -irradiation, all the ChVS samples of the stoichiometric system (the experimental data for two of them with maximal content of As_2S_3 and GeS_2 are presented in Table 1) are characterized by one mean positron lifetime of $\sim 0.36\text{ ns}$.

The fulfilled computer treatment of the obtained results shows the existence of two lifetime components after γ -irradiation: short- and long-lived ones. The first one ($\tau_1 \sim 0.28\text{ ns}$) seems to be responsible for positron annihilation on the native free-volume microvoids and S_1^- CTD with an associated free volume. The second lifetime ($\tau_2 \sim 0.39\text{ ns}$) is attributed to the superposition of lifetimes for positrons trapped on Ge_3^- and As_2^- CTD (with associated microvoids). According to the ratio of these short- and long-lived components (see Table 1), it can be concluded that the S_1^- CTD are dominant in the As_2S_3 -enriched ChVS compositions. On the contrary, the role of the Ge_3^- CTD becomes more essential with GeS_2 content in the investigated stoichiometric ChVS.

The results of the positron annihilation measurements for two-boundary non-stoichiometric ChVS compositions are also presented in Table 1. It is established that the As-enriched non-irradiated glasses are characterized by a lone mean lifetime of positrons ($\sim 0.34\text{ ns}$), while two lifetime components (with average lifetime $\tau = 0.322\text{ ns}$) appear with high Ge content in the $(As_2S_3)_{0.2}(Ge_2S_3)_{0.8}$ sample. The short-lived component ($\tau_1 \sim 0.24\text{ ns}$) can be explained similarly as in the case of the irradiated stoichiometric ChVS. The same interpretation is proper for a long-lived component of $\tau_2 \sim 0.39\text{ ns}$. We treat the latter by positron annihilation on the trapping sites of the Ge_3^- and As_2^- CTD. Such a separation of short- and long-lived components is observed only in the Ge-enriched non-stoichiometric ChVS. It is well known that these samples have a very small atomic compactness [11] and, finally, a high level of structural defectiveness. So, we conclude that a large concentration of the electrically charged CTD with extremely great amount of associated CTD-based microvoids initially exist as positron traps in these glasses.

The structure of the non-stoichiometric ChVS (similar to stoichiometric ones) becomes more defective after the γ -irradiation. As a result, two positron lifetime components with the above attributions to traps on the negatively charged CTD (with associated microvoids) and native free-volume microvoids appear. It is clear that the role of long-lived positron trapping is enhanced

with Ge content in the investigated ChVS owing to the Ge_3^- CTD ($\tau \sim 0.42$ ns) in good accordance with the previously studied concentration dependence of radiation-induced optical effects in this system [5].

4. Conclusions

The obtained results on the positron annihilation lifetime measurements in the ternary As–Ge–S ChVS of stoichiometric As_2S_3 – GeS_2 and non-stoichiometric As_2S_3 – Ge_2S_3 cross-sections prove the essential role of the CTD formation processes in the observed radiation-induced effects. The developed modified model of the CTD formation associated with free-volume microvoids at the levels of both short- and medium-range ordering describes well the compositional features of these effects.

Energy levels of native defects in zinc germanium diphosphide

W. Gehlhoff^{a,*}, R.N. Pereira^{a,1}, D. Azamat^a, A. Hoffmann^a, N. Dietz^b^a *Institute for Solid State Physics, Technical University Berlin, Sekr. PN5-2, Hardenbergstr. 36, D-10623 Berlin, Germany*^b *Department of Physics & Astronomy, Georgia State University, Atlanta GA 30303, USA*

Abstract

Electron paramagnetic resonance (EPR) and photo-EPR investigations of as-grown, post-growth annealed and electron irradiated zinc germanium diphosphide (ZnGeP_2) crystals allowed the determination of native acceptor- and donor-related defect levels in the ZnGeP_2 bandgap. From the photoinduced generation of the V_{Zn}^- EPR spectrum for electron-irradiated samples with the Fermi-level above the recharging level it is inferred that the $V_{\text{Zn}}^{-/-}$ acceptor state is located at 1.02 ± 0.03 eV below the conduction band. Observation of the recharging process in as-grown and post-growth annealed samples yields the localization of the Ge anti-site donor level $\text{Ge}_{\text{Zn}}^{+/++}$ at $E_{\text{opt}} = E_{\text{V}} + 1.70 \pm 0.03$ eV. Moreover, photoinduced processes involving the quenching and generation of the V_{Zn}^- and V_{P}^0 EPR spectra, respectively, are observed with an energy of $E_{\text{opt}} = 0.64 \pm 0.03$ eV. A model that can explain the complementary changes of the V_{Zn}^- and V_{P}^0 EPR intensities is briefly discussed. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: ZnGeP_2 ; Photo-EPR; Native defects; Energy levels

1. Introduction

Zinc germanium diphosphide (ZnGeP_2) is one of the most technologically important materials among the ternary II–IV–V₂ compounds due to its promising applications for non-linear optical devices such as tunable mid-infrared optical parametric oscillator (OPO) laser systems. However, up to now the performances of such OPOs are affected by a broad absorption band extending from the fundamental edge near 625 nm up to 2.5 μm , which overlaps with the desirable OPO pump wavelengths. This unwanted absorption with a pronounced plateau near 1 μm is mainly attributed to the photoionization of a deep acceptor center associated with the negatively charged state of the zinc vacancy (V_{Zn}^-) [1]. A large reduction of this unwanted absorption could be obtained by high-energy electron irradiation of the crystals. Electron

paramagnetic resonance (EPR) and photo-EPR investigations of as-grown, electron-irradiated and annealed ZnGeP_2 samples have shown strong differences in the V_{Zn}^- -related EPR signal intensity, which are mainly caused by a meta-stable recharging of the V_{Zn}^- centers owing to the preparation induced shift of the Fermi-level [2]. Photoinduced EPR studies of such highly compensated bulk ZnGeP_2 crystals have identified two donor centers, that have been attributed to the neutral P vacancy (V_{P}^0) [3] and the singly charged Ge_{Zn} anti-site (Ge_{Zn}^+) [4] centers, respectively. No clear defect assignments have been made for the usually broad photoluminescence bands in the range from 1.2 to 1.6 eV. However, a correlation with the concentration of the phosphorus vacancies was observed [5] and some parts of the broad infrared emission exhibit features of classical donor–acceptor recombination in dependence of the excitation density and time-decay character [2,6]. An assignment of the three identified native defects described above to energy levels in the ZnGeP_2 bandgap determined by electrical measurements [7] does not exist to date. In the present article, we report for the first time the wavelength dependence of the photoinduced changes in the EPR signal intensities associated with the acceptor

center V_{Zn}^- as well as the donors V_P^0 and Ge_{Zn}^+ in $ZnGeP_2$.

2. Experimental details

The $ZnGeP_2$ bulk crystals used in this work were grown by the gradient freezing Bridgman method. For the EPR studies, small samples with dimension $1 \times 1 \times 5 \text{ mm}^3$ were cut along the main crystallographic directions from as-grown, post-growth annealed and electron-irradiated samples. The EPR and photo-EPR measurements were performed at the Q-band ($\nu \approx 34 \text{ GHz}$) in the temperature region 4–50 K using a Bruker ESP 300E spectrometer. The samples could be irradiated with monochromatic light via a 0.4 mm optical fiber in the rod inserted into the helium cryostat, which had the sample mounted on the other end. Light from a 100 W Xenon or Halogen lamp was dispersed by a grating monochromator and coupled, after passing additional glass filters, into another 0.4 mm optical fiber at the end of which the spectral dependence of the photon flux was measured. When illuminating the samples, the two fibers were connected.

3. Experimental results and discussion

In the dark, both the as-grown and annealed $ZnGeP_2$ samples studied exhibit only the strong EPR spectrum described in Ref. [8], which has been identified as the single negatively charged zinc vacancy (V_{Zn}^-) by ENDOR measurements [9,10]. $ZnGeP_2$ has a tetragonal chalcopyrite crystal structure where the c direction is denoted as [001] and the two equivalent a directions are labeled [100] and [010]. The line positions of the electron spin transitions are given by the linear Zeeman interaction for $S = 1/2$ and the principal g -values $g_1 = 2.002$, $g_2 = 2.021$ and $g_3 = 2.074$ in the main directions [011], $[\bar{1}00]$, $[0\bar{1}1]$, respectively [3]. In the tetragonal crystal structure, there are four crystallographic equivalent center orientations. Every electron spin transition is split into a triplet with the intensity ratio 1:2:1 by the hyperfine interaction with two equivalent phosphorus nuclei ($I = 1/2$, 100% abundant) varying from 3.5 to 5.5 mT in magnitude. For an arbitrary direction of the magnetic field, an overlapping of the triplets belonging to the four center orientations is observed in the X-band, but a complete resolution of the hyperfine interaction of the different center positions can be obtained at least for some directions in the Q-band owing to the 3.5 times higher Zeeman splitting. Fig. 1(a)–(c) show typical Q-band EPR spectra for the negative charged zinc vacancy (V_{Zn}^-), together with the photoinduced spectra

Fig. 1. EPR and photoinduced EPR spectra of the negatively charged zinc vacancy (V_{Zn}^-), the neutral donor (V_P^0), and the anti-site center Ge_{Zn}^+ in as-grown and annealed $ZnGeP_2$ in the Q-band (34.2 GHz) at 15 K with the magnetic field B parallel to the directions (a) [001], (b) [011] and (c) [100]. (By a small misorientation of the sample the degeneracy of the inner V_{Zn}^- lines and of the V_P^0 lines is removed, see Fig. 1(b)).

related to the neutral phosphorus vacancy (V_P^0) and the anti-site center Ge_{Zn}^+ for the three directions of the external magnetic field B parallel to [001], [011] and [100]. The illumination of as-grown and annealed samples with monochromatic light changes the EPR signal intensity of the V_{Zn}^- centers and generates only the EPR spectrum of the neutral donor V_P^0 for photon energies from 0.6 to 1.5 eV. For photon energies between about 1.55 and 2.5 eV, the spectrum of the anti-site center Ge_{Zn}^+ is produced and a photoinduced enhancement of EPR signal intensities both of the V_{Zn}^- and neutral donor V_P^0 centers is observed. By avoiding saturation effects by corresponding choice of temperature and microwave power, we have determined the dependence of the EPR signal intensity on the photoexcitation energy normalized for a constant photon flux for the three centers (Fig. 2). The presentation establishes that the observed photoinduced quenching of the V_{Zn}^- signal in the low-energy region (0.6–1.5 eV) is always stronger than the photoinduced generation of the V_P^0 signal. For the higher energy

Fig. 2. Spectral dependence of the photoinduced changes of the EPR signal intensities at 15 K. The points (\bullet , \circ , $+$) represent the experimental values for the negatively charged zinc vacancy (V_{Zn}^-), the neutral donor (V_P^0) and the anti-site center Ge_{Zn}^+ , respectively. The corresponding lines are provided as a guide to the eye.

region (1.55–2.5 eV), the increase of the Ge_{Zn}^+ signal is always stronger than the sum of the increase of the intensities from the V_{Zn}^- and V_P^0 signals. Since all three centers are systems with spin $S = 1/2$ and both the anisotropy and differences between the g -values are small, the changes of the signal intensity are directly proportional to the number of recharged centers.

In order to monitor further the kinetics and the wavelength dependence of this photoinduced effect in detail, we fixed the external magnetic field \mathbf{B} at the position of maximum intensity of the first derivative of one of the non-overlapping EPR lines belonging to each one of the three centers and monitored the time dependence of the EPR signal intensity (I_{EPR}) upon an illumination sequence of increasing photon energies. As an example, the photoinduced changes of the intensity of the V_{Zn}^- EPR signal are shown for different photoexcitation energies $h\nu$ in Fig. 3. By fitting the time dependence of I_{EPR} by exponential decay functions, we have estimated the saturation value ΔI_{EPR} of the difference between the photoinduced EPR signal intensity and I_{EPR} measured prior to illumination for the different photoexcitations. The Ge_{Zn}^+ related spectral dependence of ΔI_{EPR} normalized to a constant photon flux is presented in Fig. 4(b). In this energy region (1.55–2.5 eV) identical spectral dependencies are observed for the V_{Zn}^- , Ge_{Zn}^+ and V_P^0 -related EPR spectra. This pointed to the fact that the photoionization process responsible for the enhancement of the EPR signals occurs on the same localized states in the $ZnGeP_2$ gap to the conduction (valence) band. In the low-energy region (0.6–1.5 eV) the same spectral dependence for the decrease of the V_{Zn}^- and the generation of the V_P^0 signal is observed. In the context of all the

Fig. 3. Time dependence of the EPR signal intensity I_{EPR} of the negatively charged zinc vacancy (V_{Zn}^-) at $T = 15$ K for different excitation photon energies $h\nu$ (eV) = 0.52 (I), 0.57 (II), 0.6 (III), 0.65 (IV), 0.70 (V), 0.75 (VI). The solid lines are experimental data and dashed curves are exponential fits. The horizontal lines represent the saturation values obtained from the fits. The vertical bars give the ΔI_{EPR} values used for the determination of the optical cross sections.

Fig. 4. Dependence of the enhancement of the EPR signal (ΔI_{EPR} as defined in Fig. 3) vs. the photon energy for (a) the V_P^0 center, (b) for the Ge_{Zn}^+ center, (c) photoinduced generation of the V_{Zn}^- EPR signal in an electron irradiated sample. The circles are experimental values and the solid lines are fits to the data by the extended Lucovsky formula, Eq. (1).

observed photoinduced recharging processes, it is unlikely that this process involved the valence band. Therefore, we infer that an electron from the V_{Zn}^- center is directly transferred to the positively charged

phosphorus vacancy (V_P^0), leaving behind the V_{Zn} center in the non-paramagnetic state V_{Zn}^0 .

The ionization energy E_{opt} of a defect involved in such PT is determined by the spectral dependence of the optical cross section, which must be determined from the photo-EPR data. The different methods for the determination of the optical cross section are discussed in Ref. [11]. How the relation between the ΔI_{EPR} values and the optical cross section can be obtained within the framework of the saturation value method is described in detail in Ref. [12]. This method has the advantage that different initial starting populations of the center under study prior to each subsequent photoexcitation can be considered. The $\Delta I_{EPR}(v)$ dependence of the optical cross section for a given PT is described by a system of kinetic equations that includes all excitation, recombination and captures processes in the sample. However, specific shifts of the Fermi-level in the initial samples can be very helpful in verifying the different dominant processes, and restricting the latter to only a few. Also, the complexity can be reduced using the fact that the light intensity I and the optical cross section σ always appear together in the form of $\alpha = I \times \sigma$ in the kinetic equations that describe the photoionization process. Using only values from the linear regime $\Delta I_{EPR}(v) \sim \alpha$ and assuming that only one dominant photoionization process is responsible for the decrease or enhancement of the studied EPR signal, we see that $\Delta I_{EPR}(v)$ is directly proportional to the corresponding optical cross section [12]. Fitting the spectral dependence $\sigma(v)$ of the considered photoexcitation by the modified Lucovsky formula extended to account for the electron-phonon interaction [11]

$$\sigma(v) \propto \int_{-\beta}^{\alpha} dz e^{-z^2} \frac{(hv - E_{opt} + \Gamma z)^{3/2}}{(hv + \Gamma z)^3} \left(1 + \frac{\Gamma z}{hv}\right)^{-1}, \quad (1)$$

where Γ describes the effect of broadening on the PT absorption band with the temperature, the ionization energy E_{opt} can be determined, see Fig. 4. For the recharging of the V_{Zn}^- , Ge_{Zn}^+ and V_P^0 centers we determine $E_{opt} = 1.70 \pm 0.03$ eV and for the decrease of the V_{Zn}^- and generation of the V_P^0 signal $E_{opt} = 0.64 \pm 0.03$ eV.

In agreement with [2], for samples irradiated with high-energy (2 MeV) electrons neither the V_{Zn} EPR signal nor the V_P^0 signal could be detected before optical excitation, if the samples are cooled down in the dark and infrared irradiation by black body emission from the resonator walls is avoided. However, illumination with infrared light simultaneously generates the V_{Zn}^- and the Ge_{Zn}^+ -related EPR signals. While, whether in the dark nor upon illumination the signal from the V_P^0 could be detected, a new center [13] could be observed with increasing signal intensity upon irradiation. The photo-induced generation of the V_{Zn}^- signal was recorded

for different excitation wavelengths. The determined spectral dependence ΔI_{EPR} normalized to a constant photon flux is presented in Fig. 4c. From the fitting procedure described above the photoionization energy $E_{opt} = 1.02 \pm 0.03$ eV is obtained. The observed process is interpreted as direct electron excitation from the doubly negative charged zinc vacancy (V_{Zn}^{2-}) to the conduction band, connected with a partial capture of the photoinduced electrons by the Ge_{Zn} centers recharging these to the paramagnetic state Ge_{Zn}^+ .

4. Conclusions

The present photo-EPR study reveals three photo-induced recharging levels connected with native defects in the bandgap of $ZnGeP_2$. The zinc vacancy acceptor level V_{Zn}^{2-} is established at $E_{opt} = E_C - 1.02 \pm 0.03$ eV and the Ge anti-site donor level Ge_{Zn}^{++} at $E_{opt} = E_V + 1.70 \pm 0.03$ eV. The excitation energy 0.64 ± 0.03 eV connected with the photoinduced decrease and increase of the EPR signals from the V_{Zn}^- and V_P^0 , respectively, seems to be caused by a direct recharging of weakly associated defects $V_{Zn}^-V_P^+$ to $V_{Zn}^0V_P^-$, which can be realized only for Fermi levels below the V_{Zn}^{2-} level at $E_C - 1.02 \pm 0.03$ eV. Above this level position a new center could be detected.

NMR investigation of $\text{CdF}_2:\text{Ga}$

D. Hilger^a, S.A. Kazanskii^b, A.I. Ryskin^b, W.W. Warren Jr.^{a,*}^aDepartment of Physics, Oregon State University, Weniger Hall 301, Corvallis, OR 97331-6507, USA^bS.S. Vavilov State Optical Institute, St. Petersburg, Russia

Abstract

^{113}Cd nuclear spin-lattice relaxation measurements have been carried out over the temperature range 200–500 K on semiconducting crystals of $\text{CdF}_2:\text{Ga}$ and co-doped $\text{CdF}_2:\text{Ga,Y}$. The relaxation rates $1/T_1$ in both crystals are found to be enhanced by two to three orders of magnitude relative to undoped CdF_2 . We attribute this enhanced relaxation to the effects of thermally excited conduction electrons. The rates in the Y co-doped crystal are systematically about a factor of two higher than are found in CdF_2 . Analysis of the temperature dependence yields a value $\Delta E = 141 \pm 10$ meV for both $\text{CdF}_2:\text{Ga}$ and $\text{CdF}_2:\text{Ga,Y}$. This result is unexpected in light of the value $\Delta E = 185 \pm 10$ meV found previously for $\text{CdF}_2:\text{In}$, and the expectation that the binding energies of the DX-like ground state of the trivalent impurity should lie deeper for $\text{CdF}_2:\text{Ga}$. © 2001 Elsevier Science B.V. 1. Introduction

Cadmium fluoride can be prepared as a wide-bandgap ($E_{\text{gap}} = 7.8$ eV) ionic semiconductor in which the trivalent transition metals and rare-earth elements (Sc, Y, La) act as conventional shallow donors [1,2]. Gallium and indium, in contrast, form bistable centers, which exhibit a variety of persistent photoinduced effects such as photorefractivity, photoconductivity, and photomagnetism [3–5]. Because of the relatively high temperatures for metastability of photo-induced changes in these materials, approaching 200 K for $\text{CdF}_2:\text{Ga}$, they are of interest for a variety of applications, including optical data storage.

The ineffective doping, bistability and metastability of $\text{CdF}_2:\text{M}$ ($\text{M} = \text{In, Ga}$) have been proposed to reflect ‘negative U, DX behavior’ [6–11]. In the deep ground state of the impurity, the active dopants undergo disproportionation to form $\text{M}^{1+}\text{--M}^{3+}$ pairs. The doubly occupied (M^{1+}) impurities are stabilized by a local lattice relaxation that compensates the extra coulomb repulsion energy. Calculations of Park and

Chadi [12] suggest that this can be accomplished by movement of the (M^{1+}) ion from a substitutional (Cd) site toward a nearby interstitial. Because of the vibronic barrier associated with the lattice distortion, optically excited shallow donor states are metastable at sufficiently low temperatures.

At temperatures well above the range of metastability, conduction electrons are thermally excited from the deep states. The excitation statistics are those of the three-level system consisting of the ground states, thermally generated, shallow donors, and the conduction band states [13]. The number of conduction electrons at a given temperature depends on both the binding energy of the deep state (0.25 eV for In and 0.7 eV for Ga [12], and the binding energy (~ 0.1 eV) of the shallow donor [14]. The temperature dependence of the carrier concentration should reflect both these binding energies.

In our previous nuclear magnetic resonance studies [15,16] of $\text{CdF}_2:\text{In}$, we found that the ^{113}Cd spin-lattice relaxation rate reflects the concentration of conduction electrons. Nuclei are relaxed by the fluctuating magnetic hyperfine fields of carriers and the temperature dependence of the relaxation rate can be related to that of the conduction electron density. The $\text{CdF}_2:\text{In}$ results are in good agreement with independent determinations of the carrier concentration in these materials. In the present

E-mail address: wwarren@physics.orst.edu (W.W. Warren Jr.).

work, we report first results for the ^{113}Cd spin-lattice relaxation in crystals of $\text{CdF}_2:\text{Ga}$ and $\text{CdF}_2:\text{Ga,Y}$. Co-doping with Y is known to increase the numbers of active dopants [17].

2. Experimental methods

The samples used in these experiments were converted to semiconductors by a high temperature anneal in a reducing atmosphere of cadmium vapor. The details are reported elsewhere (see, for example, Ref. [16]). This process removes many of the self-compensating fluorine interstitials, but it has been shown that their removal is not complete [18]. The concentration of active bistable impurities is therefore less than the total chemical concentration of the dopants. For $\text{CdF}_2:\text{Ga}$ crystals studied in these experiments, the concentration of active gallium was estimated to be approximately $0.7 \times 10^{18} \text{ Ga/cm}^3$ [19].

The NMR measurements were carried out using a Chemagnetics/Varian CMX-360 spectrometer in a magnetic field of 8 T. Sample temperatures were varied using a temperature-regulated gas-flow system. The spin-lattice relaxation times were determined from the rate of recovery of the equilibrium nuclear magnetization after an initial inverting radio-frequency pulse. The recovery curves were fit to a single exponential function characterized by a time-constant T_1 , the spin-lattice relaxation time.

3. Experimental results

The theory of nuclear spin-lattice relaxation by carriers in a semiconductor yields the following expression for the relaxation rate [20]:

$$\frac{1}{T_1} = \frac{16\pi}{9} n(T) |\Psi(\text{Cd})|^4 \gamma_e^2 \gamma_{113}^2 \left(\frac{m^3 k T}{2\pi} \right)^{1/2}, \quad (1)$$

where $n(T)$ is the temperature-dependent carrier density, $|\Psi(\text{Cd})|^2$ is the conduction electron probability density at the Cd nucleus, and γ_e and γ_{113} are, respectively, the electron and nuclear gyromagnetic ratios. Eq. (1) predicts $1/(T_1 T^{1/2}) \propto n(T)$.

In Fig. 1 we present an Arrhenius plot of the ^{113}Cd spin lattice relaxation data plotted in the form $1/(T_1 T^{1/2})$ versus inverse T . Data are presented for co-doped $\text{CdF}_2:\text{Ga,Y}$ and $\text{CdF}_2:\text{Ga}$ together with our previous results for $\text{CdF}_2:\text{In}$ [15,16]. The temperature dependence of $1/(T_1 T^{1/2})$ in each case can be characterized by an activation energy ΔE where $\Delta E = 185 \pm 10 \text{ meV}$ for $\text{CdF}_2:\text{In}$ and, within the experimental uncertainty, the $\text{CdF}_2:\text{Ga,Y}$ and the

Fig. 1. Arrhenius plot of $1/(T_1 T^{1/2})$ for ^{113}Cd in $\text{CdF}_2:\text{In}$ (solid squares), $\text{CdF}_2:\text{Ga}$ (open circles), and $\text{CdF}_2:\text{Ga,Y}$ (solid circles).

$\text{CdF}_2:\text{Ga}$ crystals exhibit the same value, $\Delta E = 141 \pm 10 \text{ meV}$.

4. Discussion

Previous work [15,16] has shown that the temperature dependence of $1/(T_1 T^{1/2})$ is essentially the same as that of the conduction electron concentration in $\text{CdF}_2:\text{In}$. As noted above, the activation energy of $1/(T_1 T^{1/2})$ is not reflective of single excitation energy. Rather, it represents the combined effects of the binding energies of the deep states ($E_{\text{bind}}^{\text{d}} = 250 \text{ meV}$ [12,13]) and the shallow donor states ($E_{\text{bind}}^{\text{s}} = 100 \text{ meV}$ [14]). A statistical analysis [13] indicates that the conduction electron concentration increases with temperature with an average value $\Delta E = 195 \text{ meV}$. This agrees well with the observed variation of $1/(T_1 T^{1/2})$, a result that is completely consistent with our expectation that the ^{113}Cd spin-lattice relaxation is governed by interactions with conduction electrons as expressed by Eq. (1).

Measurements [16] of the ^{19}F spin-lattice relaxation rates in $\text{CdF}_2:\text{In}$ provide further support for the DX model and the above binding energies in this system. ^{19}F spin-lattice relaxation is dominated by interactions with paramagnetic shallow donor states, rather than conduction electrons. The observed temperature dependence of $1/T_1$ for ^{19}F ($\Delta E = 70 \pm 10 \text{ meV}$) is in good agreement

with the model prediction [13] ($\Delta E = 74$ meV) for the concentration of shallow donors.

Previous work suggests that the deep state in $\text{CdF}_2:\text{Ga}$ is more strongly bound than in $\text{CdF}_2:\text{In}$. Park and Chadi's calculation gives $E_{\text{bind}}^{\text{d}} = 700$ meV for the binding energy of this state. Since the binding energy of the shallow donor is expected to approximately 100 meV in both $\text{CdF}_2:\text{In}$ and $\text{CdF}_2:\text{Ga}$, we might expect to find a larger value of ΔE for $\text{CdF}_2:\text{Ga}$. It is clear from the data in Fig. 1 that this is not the case.

The ^{113}Cd spin-lattice relaxation data in $\text{CdF}_2:\text{Ga}$ imply that the deep states do not play a role in the statistics of the carriers found in the bulk of the material. The conduction electrons appear to be thermally excited from shallower states than previously believed. At the present time, we do not know the identity of these states. Further studies, including ^{19}F relaxation rate measurements, are planned in hopes of resolving the energetics of the $\text{CdF}_2:\text{Ga}$ system.

Scattering of charge carriers in semiconductors: models and their criteria

V.V. Mikhnovich Jr.*

Ioffe Physicotechnical Institute, Russian Academy of Sciences, 194021 St. Petersburg, Russia

Abstract

Calculations of mobility of charge carriers in semiconductors are based on some theoretical approaches and models widely used for a long time. In the present work, three main approaches to this problem, the Born approximation as well as the approximation of isolated scattering centers and potential scattering are considered to deduce the criteria of their validity in an analytical form convenient for practical purposes. A comparison between the calculated and experimental data has shown that the adequate theoretical description is rather sensitive to a slight violation of the criterion of isolated scattering centers, in contrast to other approximations with lesser sensitivity to their breaking. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Mobility of charge carriers; Scattering of charge carriers

1. Introduction

The theory of scattering of charge carriers due to lattice vibrations and impurity centers in semiconductors has been developed in great detail, so the Hall and drift mobility of charge carriers in practically important materials can be calculated in wide regions of impurity concentrations and temperature; see for instance Refs. [1–3]. However, in many handbooks, a variety of empirical formulae for mobility calculations is still in use [4,5], since in the presence of several scattering mechanisms theoretical consideration of the resultant mobility of charge carriers becomes rather complicated. Up to now, a thorough analysis of the validity limits of the theoretical approaches and models adopted are lacking.

The purpose of the present work is to derive the validity limits for the main approaches in an analytical form.

2. Theoretical aspects of the problem

In general, several principal scattering mechanisms are usually taken into consideration when calculating the mobility of charge carriers in semiconductors: (i) scattering by acoustic phonons, (ii) scattering by optical phonons, (iii) scattering by charged centers, and (iv) scattering by neutral centers.

Let us first discuss a simple case of silicon. Then, we will show how a more complicated case of semiconductor compounds like n-GaN can be treated, too.

2.1. Silicon

It is well known that the scattering of charge carriers by acoustic-mode lattice vibrations is dominant over that by optical phonons at temperatures T

$$T \ll \hbar\omega_{\text{opt}}/k_B. \quad (1)$$

Here, k_B and \hbar are the Boltzmann and Planck constants, respectively; ω_{opt} is the frequency of optical phonons ($\hbar\omega_{\text{opt}} = 0.063 \text{ eV}$ [6]). In the subsequent discussion, the temperature interval of interest runs from cryogenic temperatures up to room temperature, so based on

*Fax: +7-95-552-07-03.

E-mail address: cleanair@cityline.ru (V.V. Mikhnovich Jr.).

condition (1) one can neglect the contribution of optical phonons to the scattering of charge carriers.

The next approximation used in calculations requires that the condition

$$l_{\text{eff}} \gg r_0 \quad (2)$$

is also satisfied, the so-called potential scattering. Here, $l_{\text{eff}} = [l_0^{-1} + l_{\text{ph}}^{-1}]^{-1}$, l_0 and l_{ph} are the free paths of charge carriers relative to the scattering by neutral centers and acoustic phonons, respectively; r_0 is the effective radius of potential scattering by a charged center. Under condition (2), all the scattering mechanisms mentioned above can be treated independently. Owing to this, the resultant momentum relaxation time τ of charge carriers is given by

$$\tau^{-1} = \tau_i^{-1} + \tau_0^{-1} + \tau_{\text{ph}}^{-1},$$

where τ_i , τ_0 , and τ_{ph} are the relaxation times relative to scattering by ionized centers, neutral centers, and acoustic phonons, respectively. The fulfillment of condition (2) allows the introduction of the cross-section of charge carrier scattering by ionized centers for calculations of τ .

Another important approximation in mobility calculations is the scattering by isolated charged and neutral centers. The concentrations of relevant centers must be not too high, so that the conditions

$$\tau_i \gg \tau_c, \quad \tau_0 \gg \tau_c, \quad (3)$$

were satisfied. Here τ_c is the time of collision of a charge carrier with a charged center and it is about $\hbar/k_B T$ [2].

The expressions for the drift and Hall mobilities have the form:

$$\mu_d = \frac{e}{m^*} \langle \tau \rangle, \quad \mu_H = \frac{e}{m^*} \frac{\langle \tau^2 \rangle}{\langle \tau \rangle}$$

for a parabolic band.

The energy-dependent relaxation times for the scattering by acoustic phonons τ_{ph} and neutral centers τ_0 can be given in the following form [6]:

$$\tau_{\text{ph}} = \frac{9\pi\rho v_0^2 \hbar^4 E^{-1/2}}{4\sqrt{2}E_1 m^{*3/2} (k_B T)}, \quad \tau_0 = \frac{m^{*2} e^2}{20\epsilon_0 \hbar^3 N_0}.$$

Here ρ is the crystal density, v_0 is the averaged velocity of sound, E_1 is the deformation potential, ϵ_0 is the crystal permittivity, m^* is the effective mass of charge carriers, e is the electron charge, and N_0 is the concentration of neutral centers.

For the description of scattering by charged centers, the Born approximation is widely used. In this approach, one takes into account only the charge carriers whose energy E is greater than the effective Bohr energy E_{Bohr} ($E_{\text{Bohr}} \approx 0.01$ eV) [2], i.e.

$$E \gg E_{\text{Bohr}} \quad \text{for} \quad kr_0 \gg 1, \quad (4)$$

where k is the wave number. Under such conditions $\tau_i(E)$ can be given by the Brooks–Herring expression:

$$\tau_i(E) = \sqrt{2m^* \epsilon_0^2} E^{3/2} / Z^2 e^4 \pi N_i \Phi(y), \quad (5)$$

where Ze is the charge of ionized centers; N_i is the concentration of charged centers:

$$\Phi(y) = \ln(1+y) - y/(1+y) \quad \text{and} \quad y = (2kr_0)^2.$$

It can be demonstrated that conditions (1)–(4) which are, in fact, the criteria for validity of the approximations can be given in the form convenient for practical purposes:

$$N_0 \ll 0.3 \times 10^{20} \left(\frac{m^*}{m_0} \right)^2 \left(\frac{T}{T_0} \right),$$

$$N_i \ll \frac{1.4 \times 10^{19}}{\ln [0.46 \times 10^{20} (T/T_0)^2 (m^*/m_0) (1/n)]} \times \left(\frac{m^*}{m_0} \right)^{1/2} \left(\frac{T}{T_0} \right)^{5/2},$$

$$n^{1/2} \gg 0.8 \times 10^9 \left(\frac{T}{T_0} \right)^{3/2} \left(\frac{m^*}{m_0} \right)^2 \times \left\{ 1 + 1.5 \times 10^{-19} N_0 \left(\frac{m_0}{m^*} \right)^{7/2} \left(\frac{T_0}{T} \right)^{3/2} \right\},$$

$$n^{1/2} \ll 0.3 \times 10^{10} \left(\frac{T}{T_0} \right) \left(\frac{m^*}{m_0} \right)^{1/2},$$

$$50 \text{ K} \ll T \ll 730 \text{ K}, \quad (6)$$

where n is the concentration of charge carriers in the conduction or valence band, m_0 is the free electron mass, and $T_0 = 300$ K.

Criteria (6) are deduced taking $\rho = 2.3$ g/cm³ [7], $v_0 = 6 \times 10^5$ cm/s [7], $\epsilon_0 = 11.8$ [7], $E_1 = 10$ eV, $m^* = 0.26m_0$ and $0.38m_0$ for electrons and holes, respectively [2], and $Z = 1$ for group-III and V impurities.

2.2. Gallium nitride

In this case, to the scattering mechanisms given above one should also add the piezoelectric-potential scattering of charge carriers by acoustic phonons as well as the scattering by optical phonons, deformation and polar ones. The energy-dependent relaxation times for the piezoelectric potential scattering, τ_{pe} , and the scattering by polar optical phonons, τ_{pol} , are determined by the following equations [6]:

$$\tau_{\text{pe}} = \frac{2\sqrt{2}\pi\hbar^2\epsilon_0 E^{1/2}}{(Pe)^2 m^{*1/2} (k_B T)},$$

$$\tau_{\text{pol}} = \frac{1}{2\alpha\omega_{\text{opt}}} \exp\left(\frac{\hbar\omega_{\text{opt}}}{k_B T}\right) \quad \text{for} \quad T \ll \hbar\omega_{\text{opt}}/k_B.$$

Here, P^2 is the piezoelectric coupling coefficient and α is the Fröhlich constant; other symbols have their usual meaning given in Section 2.1. P^2 and α can be expressed in terms of other crystal constants:

$$P^2 = \frac{E_p^2}{\chi \rho v_0^2}, \quad \alpha = \frac{e^2}{\hbar \chi} \left(\frac{m^*}{2 \hbar \omega_{\text{opt}}} \right)^{1/2},$$

$$\chi^{-1} = \varepsilon_{\infty}^{-1} - \varepsilon_0^{-1},$$

where E_p is the piezoelectric constant and ε_{∞} is the high frequency permittivity. In a way similar to that used for silicon, the criteria for validity of the approximation applied can be written in the form:

$$n^{1/2} \gg 0.7 \times 10^9 \left(\frac{T}{T_0} \right)^{3/2} \left(\frac{m^*}{m_0} \right)^2 \times \left\{ 1 + 1.3 \times 10^{-19} N_0 \left(\frac{m_0}{m^*} \right)^{7/2} \left(\frac{T_0}{T} \right)^{3/2} + 28.5 \left(\frac{m_0}{m^*} \right) \left(\frac{T_0}{T} \right)^{3/2} \exp \left(-\frac{\hbar \omega_{\text{opt}}}{k_B T} \right) \right\},$$

$$50 \text{ K} \ll T \ll 1065 \text{ K}. \quad (7)$$

The criteria (7) are identical to the criteria (6).

Criteria (7) are deduced taking $\rho = 6.1 \text{ g/cm}^3$ [5], $v_0 = 4.33 \times 10^5 \text{ cm/s}$ [5], $\varepsilon_0 = 10$ [8], $\hbar \omega_{\text{opt}} = 0.092 \text{ eV}$ [5], $E_p = 0.56 \times 10^{-4} \text{ C/cm}^2$ [5], $\varepsilon_{\infty} = 5.5$ [8], $P^2 = 1.8 \times 10^{-3}$, $\alpha = 0.87 (m^*/m_0)^{1/2}$ and $Z = 1$. The effective mass of electrons in n-GaN is taken $m^* = 0.22 m_0$. The deformation potential E_1 is assumed to be close to 10 eV ; cf. $E_1 = 7.8$ [5] and 9.2 eV [9].

3. Comparison between calculated and experimental data

As an illustration, in Fig. 1a comparison between the experimental and calculated mobilities of electrons in a sample of Si doped with As is given. The experimental data on the electron concentration and mobility were taken from Ref. [10]. The concentration of ionized impurity centers is equal to $N_i(T) = 2N_A + n(T)$ where N_A is the total concentration of compensating acceptors. As is seen from Fig. 1, there is a satisfactory agreement between the calculated and experimental curves of $\mu_H(T)$. It is interesting to note that the criteria for the validity of the Born approximation are not met throughout the entire temperature range; see Eqs. (6)_{4,5}. It means that the Born approximation appears to be valid beyond the strict limits given by these equations. However, analysis of the calculated mobilities of charged carriers in n-Si and p-Si over a wide range of concentrations of ionized centers showed that even a slight violation of the criteria expressed by Eqs. (6)_{1,2}, associated with the approxima-

Fig. 1. The electron Hall mobility in n-Si as a function of temperature for $N_A = 5 \times 10^{15} \text{ cm}^{-3}$. 1—experimental curve; 2—calculated curve.

Fig. 2. The electron Hall mobility in n-GaN as a function of temperature. 1—experimental curve [11]; 2—calculated curve.

tion of isolated charged centers, results in misfitting calculated and experimental curves. At concentrations of ionized centers in Si lower than 10^{14} cm^{-3} the criterion for the validity of potential scattering is broken; see Eq. (6)₃. However, at such low concentrations of scattering centers the mobility of charge carriers is mainly determined by the scattering due to acoustic phonons.

Similar conclusions can be drawn from calculations of the electron mobility in n-GaN; see Fig. 2. It can be shown that at $N_i \geq 10^{17} \text{ cm}^{-3}$ the criterion given by Eq. (7) is broken and the approximation of isolated charged centers is not valid any longer. As a consequence, the calculated mobility $\mu_H(T)$ does not fit the experimental one.

4. Conclusions

In the present work, the main approximations used in the calculations of mobility of charge carriers in Si and GaN have been analyzed. The criteria for validity of the approximations of potential scattering by isolated ionized centers as well as Born approximation are given in an analytical form which is convenient for practical purposes. It has been shown that mobility calculations are sensitive even to a slight violation of the approximation of isolated charged centers. In contrast, the Born approximation appears to be valid beyond the strict limits of its validity.

Mg–H and Be–H complexes in c-BN

N.M.C. Pinho^{a,b,1,*}, V.B. Torres^b, R. Jones^a, S. Öberg^c, P.R. Briddon^d^a School of Physics, The University of Exeter, Exeter EX4 4QL, UK^b Department of Physics, University of Aveiro, Campus Santiago, 3810 Aveiro, Portugal^c Department of Mathematics, Luleå University of Technology, S-97187 Luleå, Sweden^d Department of Physics, The University of Newcastle upon Tyne, Newcastle upon Tyne NE1 7RU, UK

Abstract

Ab initio calculations on hydrogen complexes with Mg and Be impurities in c-BN are reported. We find that both impurities are acceptors and bind H to form passive defects. However, their structures are different. For Be–H, the H atom lies at a puckered bond centre configuration similar to C–H in GaAs, while in Mg–H the H atom lies at an anti-bonding site to an N neighbour of the impurity. The hydrogen related vibrational modes of the two complexes are also reported. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: BN; Hydrogen; Magnesium; Beryllium

1. Introduction

Boron nitride's gap of 6.4 eV makes it the largest band gap in the nitride family. Although it has a very large gap it still shares many common properties with AlN and GaN. It has extreme hardness, high melting point, high thermal conductivity, low dielectric constant and is chemically inert. The zincblende phase is stable under high temperature and high pressure and is easily doped with Be and Mg [1,2]. The relative ease of doping has made p–n junction diodes possible. The most efficient dopants used are beryllium and silicon for p- and n-types. The ionisation energies of Be and Si have been given as 0.23 and 0.24 eV [2]. However, the Be (–/0) level varies with temperature, pressure and concentration. Values of 0.24, 0.31 and 0.35 eV at 7.7 GPa and 2100°C for Be concentrations of 2900, 4500 and 1700 ppm, respectively, have been reported [3].

Hydrogen is a common contaminant in almost all growth techniques, due to its presence in the majority of growth conditions, its high solubility and diffusibility. The existing hydrogen in as-grown material can form passive complexes with defects already present. It also can “tie off” dangling bonds on grain boundaries or dislocations. An example of this was the successful p-doping of GaN achieved with Mg. It is necessary to anneal the material grown by VPE, in order to eliminate hydrogen which forms passive complexes with Mg. Considering these aspects, we may expect hydrogen to passivate dopants in BN as it does in many other semiconductors [4–6].

In Si and GaAs, hydrogen lies at a bond centre near the acceptor [7]. However, in GaN, hydrogen lies at an anti-bonding site to a nitrogen neighbour of Be, which raises a question about the preferred site for H in BN. Park and Chadi [8] demonstrated, using a first-principles LDA method in a 32 atom super-cell, that Be lies at a B site in c-BN and is an acceptor. A full-potential linear augmented plane-wave study [9] showed an outward displacement of 3% for the nitrogen neighbours. It also showed the existence of a (–/0) level to be at $E_v + 0.4$ eV. Nevertheless, theoretical studies on the properties of hydrogen in BN are scarce. An ab initio

Hartree–Fock study concluded that neutral hydrogen prefers a bond-centred position in c-BN [10], while a local density-tight-binding method [11] found H^0 to be located on the centre of a rhombus formed by two neighbouring B–N bonds.

In view of these contradictory results, we have investigated the location of H in c-BN doped with Be and Mg.

2. Method

All results achieved in this paper have been found using a first-principle density functional method employing Gaussian orbitals (AIMPRO). Details of the method have been given previously [12,13]. 64 atom super-cells were used, together with a 2^3 Monkhorst–Pack Brillouin sampling scheme [14]. The Fourier expansion of the charge density was performed with energy cut-offs up to 100 Ry. Both the cut-off energy and the sampling scheme were checked to guaranty convergence of structure and total energy. Local vibrational modes (LVM) of defects were evaluated from the energy second derivatives between the neighbouring atoms of the defect. A Musgrave–Pople interatomic potential describing the bulk was first derived by fitting to a set of energy double derivatives for c-BN. These potentials could then be used to evaluate the entries to the dynamical matrix for host atoms surrounding a defect.

3. Results

The calculations of basic material properties such as lattice parameter, bulk modulus and its pressure derivative for c-BN, are presented in Table 1. These were found by using a fit to the Birch–Murnaghan equation of state [15]. The error in the calculated lattice parameter is about 1%. The second derivatives of the energy, with respect to atomic positions, were used to find a Musgrave–Pople interatomic potential between B and N [17]. This potential gave an optic phonon frequency at Γ of 1350 cm^{-1} , close to the experimental value of 1305 cm^{-1} [18]. However, the short range potential does not lead to a splitting of the LO and TO modes. Experimentally, the LO mode is at 1066 cm^{-1} .

Fig. 1. Configurations investigated for a hydrogen atom passivating Be and Mg in c-BN.

The second derivatives of the energy between these inner 8 atoms of a 64 atom cell were evaluated and fitted to the derivatives of a Musgrave–Pople potential where the potential for atom i is

$$V_i = 1/4 \sum_j k_r^{(i)} (\Delta r_{ij})^2 + r_0^2/2 \sum_{j>k} k_{\theta}^{(i)} (\Delta \theta_{jik})^2 \\ + r_0 \sum_{k>j} k_{r\theta}^{(i)} (\Delta r_{ij} + \Delta r_{ik}) \Delta \theta_{jik} + \sum_{k>j} k_{rr}^{(i)} \Delta r_{ij} \Delta r_{ik} \\ + r_0^2 \sum_{l>k>j} k_{\theta\theta}^{(i)} \Delta \theta_{jik} \Delta \theta_{kil}.$$

Here, Δr_{ij} and $\Delta \theta_{jik}$ represent the variations in the length of the i – j bond and angle, between the i – j and i – k bond, respectively. Only the nearest neighbours are considered for the sum. Table 2 gives the coefficients $k_r^{(i)}$, $k_{\theta}^{(i)}$, $k_{r\theta}^{(i)}$, $k_{rr}^{(i)}$ and $k_{\theta\theta}^{(i)}$.

The introduction of either Be or Mg at the boron site leads to an outward breathing displacement of 4.7% and 14.1%, respectively, in the N nearest neighbours. These values become 4.9% and 14.9% for the negatively charged complexes. We then studied the structure and vibrational modes of the Be–H and Mg–H complexes. Seven possible sites (Fig. 1) for H were investigated to ascertain the most stable defect. These include the bond centre (C), an anti-bonding site to the impurity or host atom (A, F), puckered bond centre sites (B, D), a site between two N neighbours (E) and a remote bond centre site (G). The relative energies for the fully relaxed Be–H and Mg–H defects are listed in Table 3. For Be–H, the

Table 3

Fig. 2. Kohn-Sham levels for BN, Be^- , Mg^- , Be–H, Mg–H defects.

lowest energy configuration corresponds to the puckered bond centre B, shown in Figs. 1 and 3, and is similar to a configuration found previously for hydrogen [10]. H is bonded to Be and an N neighbour, with a Be–N–H angle of 44° . The N–H, Be–H bond lengths are 1.07 and 1.45 Å, respectively. The Be–N bond is increased by 17% relative to that in the Be acceptor. The binding energy of H to Be was estimated to be 1.45 eV from the difference in energies of the dissociated and bound centres evaluated in the same super-cell.

Reorientation barriers were also calculated. The most straightforward reorientation (i) comes from rotating the hydrogen atom 120° around the (1 1 1) Be–N bond to which the hydrogen is attached. This barrier is only

Be–N–H

Fig. 3. Reorientations for the Be–N–H complex.

0.2 eV. The other reorientation path (ii) consists of the movement of the hydrogen atom, maintaining its C_{1h} plane, to an equivalent position. The barrier for this is also coincidentally 0.2 eV. These two processes are exemplified in Fig. 3.

The energies for the Mg–H complexes are also listed in Table 3. The stable configuration corresponds to an N anti-bonding site labelled F in Fig. 1. This is exactly the same structure found in GaN. The N–H and Mg–N bond lengths are, respectively, 1.01 and 1.79 Å. The binding energy of 1.48 eV H with Mg was found as described above for Be.

Fig. 2 shows the Kohn-Sham energy levels for BN, Be_B^- , Mg_B^- , Be–H and the Mg–H defects in the 64 atom cell corresponding to $\mathbf{k} = (0.25, 0.25, 0.25)$. It is clear that Be and Mg are acceptors and that the hydrogenated centres are passive.

The calculated H-related vibrational modes are given in Table 4. The stretch mode lies at 3315 cm^{-1} and is similar to the corresponding Mg–H defects in c- and w-GaN [19–21]. We also find a resonant E wag mode near the top of the one phonon maxima. This mode is IR-active and in principle might be observed.

4. Conclusions

The calculations made show that substitutional Be and Mg are acceptors in cubic BN and are passivated by hydrogen. The position of H is different in the two defects. In Be–H, the H atom lies at a puckered bond centre while in the Mg–H case it lies at the anti-bonding site to an N neighbour. This difference is undoubtedly due to the different sizes of the impurities. This configuration and its stretch local mode are similar to the corresponding complex in GaN. The awkward positioning of the hydrogen atom in the Be–H case, together with its low reorientation barrier, may prove to be as interesting as the oxygen interstitial in silicon. The

low relative energies for some configurations and the application of stress or strain on the crystal may lead to different conclusions relative to the equilibrium structure. Caution and further investigations are still necessary for the full understanding of these phenomena.

Influence of substitution of P by As on exciton and biexciton states in $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals

O.A. Yeshchenko*, M.M. Biliy, Z.Z. Yanchuk

Physics Faculty, Kyiv Taras Shevchenko University, 6 Akademik Glushkov prosp., 03127 Kyiv, Ukraine

Abstract

Low-temperature (1.8 K) excitonic absorption, reflection and photoluminescence spectra of mixed $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals have been studied at $x = 0.01, 0.02, 0.03$ and 0.05 . Energy gap and rydbergs of excitonic B, C and A-series decrease monotonically with the increase of x . Spectral half-widths of absorption $n = 1$ lines of B and A-series increase monotonically with the increase of x due to fluctuations of crystal potential. Emission lines of excitonic molecules have been observed in photoluminescence spectra of $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals. Binding energy of molecule increases with the increase of x due to the decrease of the electron-hole mass ratio. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Optical spectroscopy; Substitution of atoms; Energy gap variation; Exciton and biexciton binding energy variation

1. Introduction

β - ZnP_2 (further ZnP_2) and ZnAs_2 crystals are direct-gap semiconductors, which are characterized by the same symmetry group C_{2h}^5 . Besides symmetry of lattice, the similarity of ZnP_2 and ZnAs_2 exists in the structure of energy bands and exciton states as well. Namely, three excitonic series are observed in the absorption spectra of these crystals: dipole allowed C-series at $\mathbf{E} \parallel \mathbf{Z}(\mathbf{c})$ (C-exciton), forbidden B-series at $\mathbf{E} \perp \mathbf{Z}(\mathbf{c})$ (B-exciton) and partially allowed A-series at $\mathbf{E} \parallel \mathbf{X}$ (A-exciton) polarizations (see e.g. Refs. [1,2] for ZnP_2 and Refs. [3,4] for ZnAs_2). In the photoluminescence (PL) spectra of these crystals at $\mathbf{E} \parallel \mathbf{Z}(\mathbf{c})$ polarization, a series of lines caused by the radiative transitions from the ground $n = 1$ and excited $n = 2, 3$ states of allowed S-paraexciton (C-series) is observed (see e.g. Ref. [2] for β - ZnP_2 and Ref. [4] for ZnAs_2). Besides this emission series, the so-called B-line is observed in the PL spectra of ZnP_2 at $\mathbf{E} \perp \mathbf{Z}(\mathbf{c})$. The B-line occurs to the radiative transitions from the ground state of forbidden S-orthoexciton and corresponds to B_1 -line of absorption B-series.

In ZnP_2 crystals excitonic molecule (EM or biexciton) with rather high binding energy $E_{\text{bex}}^b = 6.7 \text{ meV} = 0.15 E_{\text{ex}}^b$ exists, where E_{ex}^b is the binding energy of the lowest-energy B-exciton. In ZnP_2 EMs manifest themselves in PL spectra due to two-electron and two-photon radiative transitions from the ground state of the molecule [5]. The experimental evidences of existence of the EMs in ZnAs_2 are absent at present, though by theoretical estimations they would have binding energy $\approx 1.6 \text{ meV}$.

In present work we study the mixed crystals (solid solutions) of isovalent substitution $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$, which, to our knowledge, were not studied earlier. In present work the low-temperature (1.8 K) optical spectra of $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals have been studied at small levels of substitution of P by As: $x \leq 0.05$. Experimental dependences of parameters of excitons and EMs on x were obtained.

2. Exciton spectra of $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals

Absorption, reflection and luminescence spectra of $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals at $x = 0.01, 0.02, 0.03$ and 0.05 and pure ZnP_2 ($x = 0$) are presented in Figs. 1–3. The $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals are direct-gap semiconductors as

Fig. 3. Photoluminescence spectra of $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals at temperature 1.8 K.

well as ZnP_2 . One can see from the figures that in the mixed crystals the same excitonic C, B and A-series are observed, as in pure ZnP_2 . Let's note, that in contrast to ZnP_2 crystals, where in optical spectra the lines up to $n = 7$ for B-series and to $n = 4$ for A and C-series are observed, in spectra of $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals of various thickness excitonic lines only with $n = 1, 2$ are observed. Probably, this fact is a result of "blurring" of band edges, which takes place owing to fluctuations of crystal potential and respective fluctuations of energy gap, caused by the statistical distribution of As atoms at P lattice sites. With the increase of concentration x the spectral lines shift to the low-energy side, a behaviour that is caused by decrease of energy gap (see Table 1). This shift could be expected, taking into account the fact, that in ZnAs_2 the energy gap is 0.55 eV smaller than in ZnP_2 . But besides the trivial decrease of E_g at increase of x , there is also decrease of the of excitonic series rydbergs (see Table 1). Values of E_g and rydbergs were obtained by fitting of excitonic series by simple hydrogenlike dependence: $E(n) = E_g - R_Y/n^2$.

Dependences of the half-widths of absorption $n = 1$ lines of B and A-series were also studied (see Table 1). It is seen, that half-widths of B_1 and A_1 -lines increase monotonously with the increase of x . It is known that the increase of the half-width of exciton lines is the result of fluctuations of crystal potential and respective

fluctuations of E_g . The theory of the influence of fluctuations of composition x on half-width of exciton absorption lines was developed in Ref. [6], where two extreme cases were considered. If the effective size of the crystal potential fluctuation $R_D = \hbar/(2MD)^{1/2}$, where M is the total mass of exciton and $D(x) = W(x) - W(0)$ ($W(x)$ is the half-width of exciton line), is much larger than exciton Bohr radius $R_D \gg a_{\text{ex}}$ then

$$D(x) = 0.08 \frac{\alpha^4 M^3 x^2 (1-x)^2}{\hbar^6 N^2}, \quad (1)$$

where $\alpha = dE_g/dx$, N is the concentration of sites of lattice, where the substituting atoms can "sit". If $R_D \ll a_{\text{ex}}$ then

$$D(x) = 0.5\alpha \left(\frac{x(1-x)}{Na_{\text{ex}}^3} \right)^{1/2}. \quad (2)$$

The experimental dependences $D(x)$ of absorption B_1 and A_1 -lines in $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals were fitted by functions (1) and (2). The experimental points are badly fitted both by an expression (1) and (2). Let us estimate the effective size of the crystal potential fluctuation R_D for different x in $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals. Estimations give: $R_D = 82 \text{ \AA}$ at $x = 0.01$, $R_D = 62 \text{ \AA}$ at $x = 0.02$ and $R_D = 30 \text{ \AA}$ at $x = 0.05$. In ZnP_2 the exciton Bohr radius is $a_{\text{ex}} = 15 \text{ \AA}$ (for B and C-excitons). Thus, for $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$: $R_D \sim a_{\text{ex}}$, i.e. both conditions $R_D \gg a_{\text{ex}}$ and $R_D \ll a_{\text{ex}}$ are not fulfilled. So, in studied crystals the intermediate case takes place which is, nevertheless, more close to (1) as $R_D > a_{\text{ex}}$. Therefore, since the intermediate case takes place, we tried to fit the experimental dependences by the function: $D(x) = (1-c)D_1(x) + cD_2(x)$, which is the superposition of functions $D_1(x)$ of type (1) and $D_2(x)$ of type (2), c is the weighting factor. We have obtained that the superposition function fits the experimental points very well. The fitting of dependences of the half-widths of absorption $n = 1$ lines of B and A-series on x gives: $c_B = 0.05$, $c_A = 0.32$. The fact, that c_A is considerably larger than c_B , indicates that for A_1 -line the function $D_2(x)$ of type (2) makes a considerably larger contribution, than for B_1 -line. It could be expected since the A-exciton has a considerably smaller binding energy than the B-exciton, and correspondingly larger Bohr radius. Thus,

B-exciton is closer to the case 1 ($R_D \gg a_{\text{ex}}$) than A-exciton.

3. Excitonic molecules in $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals

In PL spectra of mixed $\text{Zn}(\text{P}_{1-x}\text{As}_x)_2$ crystals, as well as in ZnP_2 crystals, there are M_C and M_A lines (Fig. 3). These lines are due to radiative transitions from the ground state of EM to the ground state of the C-exciton (M_C -line) and ground state of A-exciton (M_A -line). EMs are rather well investigated in pure ZnP_2 . As well as in pure ZnP_2 , the M-lines demonstrate a square-law character of the dependence of their intensity on excitation intensity, which confirms their biexcitonic nature. The binding energy of EM can be determined from PL spectrum as: $E_{\text{bex}}^b = 2E_{\text{ex}} - E_{C1} - \hbar\omega_{M_C}$, where E_{ex} is the energy of lowest B-exciton ground state (B_1 -line), E_{C1} is the energy of the ground state of allowed C-exciton, and $\hbar\omega_{M_C}$ is the energy of a photon of M_C -line. Contrary to rydbergs of excitonic series the binding energy of EM increases with the increase of x both by absolute value and in relation to the binding energy of the lowest B-exciton. The behaviour of E_{bex}^b with the increase of x can be explained as follows. As known (e.g. from Ref. [7]), the ratio $E_{\text{bex}}^b/E_{\text{ex}}^b$ is a function of the ratio of electron and hole masses $\sigma = m_e/m_h$, and with the decrease of σ the ratio of binding energies of EM and exciton increases. At substitution of atoms of one type by atoms of another type the variation of parameters of energy band structure occurs, in particular the variation of masses of carriers. Since the dielectric constant has close values in ZnP_2 and ZnAs_2 crystals, ϵ should not vary considerably in mixed crystals. Therefore, the decrease of exciton rydbergs with the increase of x is an evidence of the decrease of reduced effective mass of carriers μ . The reduced mass at small σ is $\mu \approx m_e$. Since in ZnP_2 crystals the ratio of electron and hole masses is rather small ($\sigma = 0.06$), the decrease of $\mu(x)$ reflects the decrease of $m_e(x)$. The dependence $m_h(x)$ can be estimated in such a way. Knowing the ratio of the reduced masses $\mu(x)/\mu(0) = Ry(x)/Ry(0)$ and the ratio $\sigma(x)/\sigma(0)$ (it can be obtained from the experimental dependence $[E_{\text{bex}}^b/E_{\text{ex}}^b](x)$), one can calculate the ratios

$m_e(x)/m_e(0)$ and $m_h(x)/m_h(0)$ (see Table 1). With the increase of x the electron mass decreases, and the hole mass increases. Thus, the increase of m_h occurs even faster than the decrease of m_e . This behaviour reflects the fact that in ZnP_2 conduction band originate mainly from Zn ions and valence band—from P ions [8]. Therefore, substitution of P atoms by As atoms should first of all have an influence on parameters of a valence band, in particular on hole mass. The simultaneous decrease of m_e and increase of m_h result in appreciable decrease of their ratio, and therefore in the respective increase of binding energy of EM.

Abstract

CdF₂ crystals doped with Ga or In are the most promising representative of new class of holographic materials, in which a photo-induced change in the density of bistable (DX center) states in a semiconductor crystal produces a local change of its refractive index. Mechanism of holographic gratings decay is considered. Analysis of the decay kinetics shows opportunities of CdF₂:Ga, CdF₂:In as materials of real-time holography with response times in the range of seconds to 1 ms in CdF₂:Ga or to 100 ns or less in CdF₂:In. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Holographic grating; Diffraction efficiency; Barrier

1. Introduction

Recently, a new class of holographic materials was proposed, in which a photo-induced change in the density of bistable (DX center) states in a semiconductor crystal produces a local change of its refractive index. (see Ref. [1] and references therein). The excited (“shallow” donor) state of the DX center has a metastable nature being separated from the ground (“deep”) state by a potential barrier due to a strong lattice relaxation in the latter state. Therefore, photo-induced gratings in such crystals are principally dynamic ones. Here, we consider two most promising representatives of this class of materials, CdF₂:Ga and CdF₂:In, having the highest barrier ~1 eV among crystals of this class and very low barrier ~0.1 eV, respectively [2].

Conversion of doped CdF₂ into semiconducting state is realized through an annealing of as grown crystals in reduction atmosphere of Cd vapor (a process called additive coloration), upon which procedure electrons introduced into the crystal locate at the donor levels or in the conduction band.

Together with donor ions, semiconducting CdF₂ crystals contain interstitial fluorine ions, F⁻, which play a function of acceptors in these ionic crystals; they

effectively decrease the concentration of donors, i.e. partly compensate them [3].

At sufficiently low *T*, below 200 K for CdF₂:Ga and 40 K for CdF₂:In, all electrons are associated with M ions (M = Ga, In), in pairs, forming the deep M centers (M¹⁺) [2]. The photo-induced conversion of bistable M centers from the ground state into the metastable donor state (M³⁺ + *e*_{hydr}, where *e*_{hydr} denotes an electron localized at the hydrogenic orbital), in accordance with the reaction

results in a noticeable change of the refractive index of the crystal, δn . This change creates the opportunity of writing phase holograms in the spectral gap between the photo-ionization absorption bands of the deep and shallow centers; these bands are located in the ultraviolet–visible (UV–VIS) and infrared (IR) ranges of the spectrum, respectively (Fig. 1). The refractive index change results from the transition of tightly bound electrons of the deep centers into the loosely bound hydrogenic or free state. Accordingly, δn is proportional to the shallow donor concentration, N_{sh}^0 [4].

2. Samples, details of experiment, and discussion of results

Techniques of growing the crystals and their conversion into a semiconducting state is described elsewhere [4,5].

E-mail address: alex@ryskin.spb.su (A.I. Ryskin).

Fig. 1. Absorption spectra of (a) CdF₂:In, (b) CdF₂:Ga, and (c) CdF₂:Ga,Y crystals cooled in the dark (solid line) and after UV-VIS illumination (dashed line) at temperature (a) 5 and (b, c) 77 K.

Along with singly doped CdF₂:Ga, crystals of CdF₂:Ga co-doped with Y were also studied. Co-doping increases the concentration of the optically active Ga and, simultaneously, significantly improves the optical quality of the crystal [5]. Fig. 1 shows the spectra of additively colored CdF₂:Ga, CdF₂:Ga,Y, at $T = 77$ K and CdF₂:In crystals at $T = 5$ K as cooled in the dark and after a strong illumination in the UV-VIS band.

The concentration of electrically and optically active impurity, N_M , in CdF₂:Ga, CdF₂:Ga,Y, and CdF₂:In crystals under investigation was 0.7×10^{18} , 1.7×10^{18} , and $2.7 \times 10^{18} \text{ cm}^{-3}$, respectively.

At $T > 200$ K for CdF₂:Ga and $T > 40$ K for CdF₂:In, the written hologram decays due to conversion of the photo-induced shallow centers in the antinodes of the grating into the deep centers:

This reaction includes the thermal release of an electron from the shallow donor center into the conduction band, its transport in the conduction band, and its capture by another shallow center with the subsequent formation of a deep center. The last stage also requires thermal activation due to the large lattice relaxation accompanying the deep center formation.

The rate equation, which describes the change with time of the shallow donor center concentration and includes the processes of thermal destruction (Eq. (2)) and formation as well as photo-induced formation

(Eq. (1)) of these centers, may be written as

$$\begin{aligned} dN_{\text{sh}}^0/dt = & -[c - (b/4)](N_{\text{sh}}^0)^2 - (b/2)N_M N_{\text{sh}}^0 \\ & + (b/4)(N_M^2 - N_F^2) + I\mu\sigma N_d^-. \end{aligned} \quad (3)$$

Here, c and b are kinetics constants of the shallow center thermal destruction and creation, respectively. N_d^- and N_F^- are concentration of the deep M centers and interstitial fluorine ions, respectively, I is the light intensity, and σ is the cross-section of photon absorption by the deep centers. Eq. (3) allows one to find, for finite T , the shallow center concentration in the dark ($I = 0$) or under illumination of the crystal, and the transient patterns.

Without specifying the details of the multi-stage processes of thermal destruction of the shallow (Eq. (2)) and deep centers, one may propose that these processes have a thermally activated nature, i.e. they are characterized by activation energies, $E_{\text{bar}}^{\text{sh}}$, $E_{\text{bar}}^{\text{d}}$:

$$c(T) = v_1 \exp(-E_{\text{bar}}^{\text{sh}}/kT),$$

$$b(T) = v_2 \exp(-E_{\text{bar}}^{\text{d}}/kT), \quad (4)$$

where v_1 , v_2 are frequency factors, $E_{\text{bar}}^{\text{sh}}$ and $E_{\text{bar}}^{\text{d}}$ may be considered as effective heights of the barriers separating the shallow state from the deep state and vice versa.

This pattern of the shallow center decay has the following appearance:

$$N_{\text{sh}}^0(t) = n_2 + (n_2 - n_1)/\{\exp[(t + t_0)/\tau] - 1\}. \quad (5)$$

Here, t_0 is an integration constant, $\tau = 1/[(c - b/4) \times (n_2 - n_1)]$ is a parameter which describes the rate of decay, and n_1 , n_2 are roots of the right-hand side of Eq. (3) (see Ref. [5]). The n_2 root is equal to the equilibrium concentration of the shallow donor centers in the dark. It is shown in Ref. [2] that at $N_{\text{sh}}^0 \ll N_M$ $b \ll c$, i.e.

$$\tau \cong 1/[c(n_2 - n_1)]. \quad (6)$$

Analysis of decay curves using Eq. (5) allows one to find the parameters n_2 , $(n_2 - n_1)$, and τ . Under the assumption that $N_F^- < N_M$ τ can be expressed as follows:

$$\tau \cong 1/(N_M \sqrt{cb}). \quad (7)$$

It is evident from Eq. (7) that an Arrhenius plot for τ allows one to find the quantity $\frac{1}{2}(E_{\text{bar}}^{\text{sh}} + E_{\text{bar}}^{\text{d}})$. Eq. (6) has a smaller temperature range of applicability as compared with Eq. (7). A criterion for its use is a weak dependence of n_2 on T , indicating a low rate of thermal decay of the deep center.

Thus, the shallow center decay is described by the hyperbolic cotangent type dependence of Eq. (5). This dependence converts to a simple exponential for $(t + t_0) \gg \tau$, and this inequality is satisfied either at the final stages of the decay (large t), or at higher temperatures (large n_2 , i.e. small τ).

Fig. 2. Temperature dependence of (i) decay time of photo-induced IR absorption ($\lambda = 1.3 \mu\text{m}$, black squares) and holographic gratings written in CdF₂:Ga,Y (square root of DE, open circles); the dashed line is the result of a calculation using Eq. (5) and (ii) initial DE of the hologram; the solid line shows the calculation (see [6]), the open triangle shows the experimental value.

Two techniques were used for the experimental study of the decay problem: (i) measurement of the photo-induced IR absorption, which is a direct measure of N_{sh}^0 , and (ii) measurement of the diffraction efficiency (DE), η , of gratings written in the crystal; the square root of this quantity is proportional to N_{sh}^0 for moderate values of $\eta \leq 0.7$ [4,5].

For absorption measurements, the crystals were mounted in a variable temperature cryostat and its transmissivity at $\lambda = 1.3$ or $1.5 \mu\text{m}$ was measured as a function of time following a saturating exposure. For DE measurements, gratings were written into the sample using two interfering beams (argon laser, $\lambda = 476 \text{ nm}$ for CdF₂:Ga, CdF₂:Ga,Y and ruby laser, $\lambda = 693 \text{ nm}$ for CdF₂:In) and the DE was determined versus time by comparing the strengths of the transmitted and diffracted beams using as a probe an attenuated 476 beam (CdF₂:Ga, CdF₂:Ga,Y) or beam of helium–neon laser, $\lambda = 628 \text{ nm}$ (CdF₂:In). Figs. 2 and 3 show temperature dependencies of decay time corresponding to decrease of DE down to 0.01 of the initial value and of initial DE of holograms written in CdF₂:Ga,Y and CdF₂:In. Decay patterns are described finely by Eq. (5). Analysis of these patterns with use of Eqs. (5)–(7) allows one to find the barrier height on the side of the shallow and deep centers as follows: CdF₂:Ga— $E_{bar}^{sh} = 0.95 \text{ eV}$, $E_{bar}^d = 0.73 \text{ eV}$; CdF₂:In— $E_{bar}^{sh} = 0.14 \text{ eV}$, $E_{bar}^d = 0.25 \text{ eV}$. Therefore, (i) the shallow-to-deep center conversion (Eq. (2)) proceeds with an overcoming of very high barrier for CdF₂:Ga and low barrier for CdF₂:In and (ii) for both Ga and In an activation energy of the deep-to-shallow center conversion practically coincides with a binding energy of the deep center, which is 0.70 eV for CdF₂:Ga and

Fig. 3. Temperature dependence of (i) decay time of holographic gratings written in CdF₂:In (square root of DE, open circles); the dashed line is the result of a calculation using Eq. (5) and (ii) initial DE of the hologram; the open triangles are experimental values, the solid line shows a trend.

0.25 eV for CdF₂:In [6]. The latter statement means that after thermal ionization of the deep center, reconstruction of the ionized center into the shallow center proceeds spontaneously.

3. Conclusions

The metastable nature of the photo-induced state of the Ga and In centers in CdF₂ crystals allows the application of these crystals as materials for real-time holography over a wide range of response times of seconds to 100 ns or less, with temperature as the controlling parameter.

Dielectric response of semiconducting and photochromic CdF_2 on microwaves

S.A. Kazanskii*, D.S. Rumyantsev, A.I. Ryskin

S.I. Vavilov State Optical Institute, 12 Birghevaya Line, St-Petersburg 199034, Russia

Abstract

CdF_2 is the only highly ionic dielectric crystal, which can be converted into n-type semiconductor via doping with column-III elements and annealing in the reduction atmosphere. Among donor impurities, Ga and In dopants form DX centers with the shallow metastable state and ground strongly localized state, making these crystals photochromic. We studied the dielectric permittivity, $\epsilon = \epsilon_1 - i\epsilon_2$, of $\text{CdF}_2:\text{Ga}$, $\text{CdF}_2:\text{In}$, and also non-photochromic $\text{CdF}_2:\text{Y}$ in the microwave range ($\lambda \approx 8 \text{ mm}$) at low temperatures (T) down to 1.8 K in the darkness and after illumination by the ultraviolet-visible light. Illumination of $\text{CdF}_2:\text{Ga}$ and $\text{CdF}_2:\text{In}$ results in increase of both the dielectric constant, ϵ_1 , by $\Delta\epsilon_1 = (0.5-1.4)$ and the dielectric loss factor, ϵ_2 , by about an order of magnitude. At $T = 1.8 \text{ K}$ the low-field dielectric loss factor in these crystals and also in $\text{CdF}_2:\text{Y}$, $\epsilon_2 = 0.1-0.3$, may be decreased by an order of magnitude with increase of the microwave field power; however, ϵ_2 ceases to depend on the field at $T > 4 \text{ K}$. These features are explained on the basis of Tanaka theory of resonant saturated absorption of ionized donor pairs, modified here to cover also far infrared range of spectrum. The study shows, that maximum available concentration of neutral donors in CdF_2 could never exceed $\sim 10^{19} \text{ cm}^{-3}$ and the compensation degree be less than 0.5 at any doping level because of the existence of impurity clusters. These clusters store an “excessive” impurity and are “inexhaustible” sources of interstitial F^- ions. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

CdF_2 is the fluorite-type crystal that can be converted into a semiconducting state via doping with column-III elements of the periodic table and subsequent annealing in reducing atmosphere [1,2]. During the coloration process interstitial fluorine ions F^- , which are charge compensators of the surplus $+1$ charge of the dopants, diffuse out of the volume of the crystal to the surface. An opposite current of electrons into its volume maintains charge neutrality of the crystal. These electrons localize in the conduction band or at hydrogenic donor orbitals centered on the dopant. The donor state in CdF_2 has a binding energy of $\sim 100 \text{ meV}$, and it is responsible for infrared (IR) photo-ionization absorption band

($\lambda_{\text{max}} \approx 7 \mu\text{m}$), which stretches into the visible range of the spectrum [3,4]. The room-temperature electronic conductivity of additively colored CdF_2 crystals reaches $10 \Omega^{-1} \text{ cm}^{-1}$. However, the maximum available concentration of free electrons does not exceed $\sim 10^{19} \text{ cm}^{-3}$ [1–3].

Among donor impurities in CdF_2 , Ga and In play a special part since these dopants form bistable centers in the reduced (semiconducting) crystals. Along with the “shallow” hydrogenic state, they also have a “deep”, strongly localized two-electron state characterized by large lattice relaxation [5]. Such large lattice relaxation is typical for two-electron metastable centers (DX-centers) in conventional semiconductors; it is responsible for the energy barrier separating the deep state from the metastable substitutional (shallow donor) state. The barrier height is $\sim 1 \text{ eV}$ for Ga and less than 0.1 eV for In [6].

Table 1
Dielectric permittivity of semiconducting CdF₂ crystals studied with $\lambda \approx 8$ mm low-field microwaves at $T = 1.8$ K.

Sample	Total electron concentration, N_e (cm ⁻³)	ϵ_1 in the dark	$\Delta\epsilon_1$ after illumination	ϵ_2	
				In the dark	After illumination
CdF ₂ :Ga	7×10^{17}	7.6 ± 0.1	0.5 ± 0.1	0.01 ± 0.005	0.1 ± 0.05
CdF ₂ :In	3×10^{18}	—	1.4 ± 0.4	0.02 ± 0.01	0.1 ± 0.05
CdF ₂ :Y	2×10^{18}	—	—	0.3 ± 0.1	

When cooled in the dark, the reduced CdF₂:Ga and CdF₂:In crystals are semi-insulating since electrons introduced in the crystals during the coloration are predominantly localized at the deep M¹⁺ centers (M=Ga, In). Illumination of the crystals in the ultra-violet-visible (UV-VIS) photo-ionization absorption band of deep centers results in release of the electron into the conduction band with its subsequent capture by an ionized (“empty”) center with formation of a neutral (shallow) donor. An ionized deep center also spontaneously converts into the shallow state. As a result of this “photo-decoloration process”, the UV-VIS band disappears and, instead, an IR band arises in the absorption spectrum of the crystals.

In this work we study the low-temperature complex permittivity of semiconducting CdF₂:Ga, CdF₂:In, and CdF₂:Y crystals in the microwave range ($\lambda \approx 8$ mm) and discuss an important role of the ionized donor pairs in formation of the dielectric response of these crystals in the microwave and far IR (FIR) ranges.

2. Samples, experimental technique, and results of measurements

Microwave measurements of the real, ϵ_1 , and imaginary, ϵ_2 , parts of the dielectric permittivity of CdF₂:In, CdF₂:Ga, and CdF₂:Y crystals over the frequency range of 34.0–37.5 GHz at temperatures 1.8–100 K were made with cylindrical samples of diameter 2.0–2.5 mm set in a cylindrical reflex resonator operating in TE₀₁₁ mode. The cavity perturbation technique used in the experiments is based on measurements of both the loaded quality factor and the frequency shift of the cavity occurring when a sample is inserted into the resonator.

Measurements were made both in the dark and after illumination of the samples with the UV-VIS light. Microwave dielectric properties of CdF₂:Y are independent of its illumination. In contrast, substantial increase of complex permittivity was detected during the process of illumination of photochromic CdF₂:Ga and CdF₂:In crystals. The dielectric permittivity of the samples under consideration at low microwave fields

and the extreme changes observed after illumination at $T = 1.8$ K are shown in Table 1.

At $T = 1.8$ K, a saturation of the dielectric losses with an increase in microwave power was observed for all semiconducting samples studied. The measured value of ϵ_2 could be decreased by about an order of magnitude with an increase of the input microwave power from the minimum level. Experimental $\epsilon_2(T)$ dependences for CdF₂:Ga are shown in Fig. 1.

3. Discussion of results

We assume that all observed phenomena are due to resonant absorption of the nearest pairs of neutral and ionized donors that are called the “ionized donor pairs” [7].

Provided that the nearest-neighbors donors are identical, the single electron of the ionized donor pair has an equal probability to be found at each of these donor centers. The situation is analogous to that for the molecular H₂⁺ ion. The doubly degenerate ground state of such a system splits to lower bonding and excited anti-bonding states separated by an energy interval W depending on the distance r_0 between the donors of the pair. The transitions between these two states are observed in the microwave and FIR absorption experiments. Based on the approach of Tanaka et al. [7], we propose [8] simple analytical expressions for the microwave and FIR absorption coefficient for the intermediate-compensation case over the frequency range in which the donor-pair theory is applicable.

Photo-decolored CdF₂:Ga and CdF₂:In crystals as well as CdF₂:Y may be considered as ordinary n-type semiconductors with donors partly compensated by the interstitial F⁻ ions. The experimental values of ϵ_2 in low microwave fields at $T = 1.8$ K (see Table 1), agree by an order of magnitude with this quantity calculated under condition of moderate compensation degree $0.1 \leq K \leq 0.9$ and reasonable assumptions of the concentration of the interstitial F⁻ ions in these crystals: $N_F \leq 2 \times 10^{19}$ cm⁻³. It follows then that the total concentration N_D of donors in CdF₂:Y, which is equal to the concentration of “isolated” Y³⁺ ions in CdF₂

Fig. 1. $\epsilon_2(T)$ -dependence for $\text{CdF}_2:\text{Ga}$ after its illumination, measured with 36 GHz microwaves. Attenuation of the input microwave power: (a) 0 dB, (b) 7 dB, (c) 15 dB, and (d) 25 dB.

lattice, is at least five times less than total concentration of this impurity in the crystal ($(1-3) \times 10^{20} \text{ cm}^{-3}$), that is more than 80% of Y^{3+} ions are bound into clusters. Similar reasoning shows that more than 70% of In and 30% of Ga ions are bound into clusters and do not participate in microwave and FIR resonant absorption. By analogy with Ca, Sr, and Ba fluorides one may assume for CdF_2 a limiting concentration of $\sim 10^{20} \text{ cm}^{-3}$ of RE and Y ions which can be introduced into CdF_2 as statistically distributed substitution centers. The “redundant” impurities, whose solubility in CdF_2 reaches 10 mol% and above, form impurity-fluorine clusters which are readily observed in the optical spectra of RE ions in all the fluorite-type crystals [9–11].

Further limit on K value was found by studying $\text{CdF}_2:\text{Ga}$ and $\text{CdF}_2:\text{In}$ crystals during their deep-to-shallow center conversion. The experimentally found monotonic increase of the dielectric loss factor and the dielectric constant under illumination of the photochromic crystals testify clearly to the fact that $K \geq 0.5$ in the photo-decolored crystals.

Eisenberger et al. [12] observed a FIR absorption band ($10\text{--}150 \text{ cm}^{-1}$) in semiconducting CdF_2 . Our calculations of FIR absorption for the degree of compensation $0.5 \leq K \leq 0.9$ (see Fig. 2(c–e)) agree well with their experimental spectra [12], both by shape of the band and values of absorption coefficient.

It is necessary to define a source of the appreciable increase of the real part of permittivity, $\Delta\epsilon_1$, after illumination of the photochromic $\text{CdF}_2:\text{Ga}$ and $\text{CdF}_2:\text{In}$ crystals (see Table 1). Using the Kramers–Kronig relations, it is possible to show, that the photoinduced buildup of their FIR absorption bands ($10\text{--}150 \text{ cm}^{-1}$) due to ionized donor pairs could result in $\Delta\epsilon_1(\omega \rightarrow 0) \sim 2$ (for $N_e \sim 10^{18} \text{ cm}^{-3}$ and $K = 0.5$) in agreement with the experimental data.

Fig. 2. Calculated in the modified Tanaka et al. approach, FIR absorption spectra of CdF_2 with concentration of neutral donors, $7 \times 10^{17} \text{ cm}^{-3}$, with Bohr radius, $a = 7 \text{ \AA}$ [4] and the degree of compensation: (a) $K = 0.1$, (b) $K = 0.3$, (c) $K = 0.5$, (d) $K = 0.7$, and (e) $K = 0.9$.

4. Conclusions

The occurrence of microwave and FIR broadband absorption, saturation of the microwave absorption in high electromagnetic fields, and significant increase of dielectric constant observed in semiconducting CdF_2 crystals are due to co-existence of neutral and charged donors, which form ionized donor pairs. The change of dielectric response upon illumination of photochromic $\text{CdF}_2:\text{Ga}$ and $\text{CdF}_2:\text{In}$ crystals at low temperature is caused by the photo-induced growth in concentration of donor electrons, and, consequently, the growth in concentration of donor pairs. The obtained limits on the degree of compensation $0.5 \leq K \leq 0.9$ for typical semiconducting CdF_2 are in good agreement with the results of the EPR study of Eisenberger and Pershan [13].

The results of this study show that with additive coloration of CdF_2 doped with column-III elements, total chemical reduction of the impurity and, consequently, total removal of interstitial F^- ions from the crystal lattice, is unachievable. It testifies to the presence of impurity-fluorine clusters [9–11] in the doped CdF_2 , which might supply the crystal with F ions during the process of chemical reduction of the impurity. A substantial part of the donor impurity is certainly collected in clusters, which makes it impossible to obtain a semiconducting CdF_2 crystal with the compensation degree less than 0.5 and with concentration, N_e , of free or weakly bound electrons exceeding $\sim 10^{19} \text{ cm}^{-3}$.

Stacking faults and excitons in AgI

S. Mochizuki*

Department of Physics, College of Humanities and Sciences, Nihon University, 3-25-40 Sakurajosui, Setagaya-ku, Tokyo 156-8550, Japan

Abstract

AgI powder is gradually evaporated in vacuum onto a substrate whose temperature is higher than the superionic transition point T_C . During the evaporation, the optical absorption spectrum of the film is measured as a function of time-elapsed after the beginning of evaporation. By increasing the time (i.e., with increasing film thickness), the shifts of the absorption edge and exciton energy are observed, which are due to exciton or carrier confinement effects in the averaged structure of α -AgI. Information as to the electronic structure of the averaged structure is deduced from analyzing the observed spectra. After stopping evaporation, the film is gradually cooled down to 131 K. Through the cooling process, the absorption spectrum is also measured as a function of temperature. New exciton absorption bands (H_1 , H_2 and H_3) appear, together with the $Z_{1,2}$ and Z_3 excitons in the γ -AgI. The H_1 , H_2 and H_3 excitons are assigned to a metastable disordered polytype structure of β -AgI, in the light of the X-ray diffraction data. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Silver iodide AgI is well known as a solid electrolyte and has three phases designated as α , β and γ at normal pressure in the order of decreasing temperature with the following properties [1]. At superionic transition point T_C (419 K), the superionic conductor α -phase transforms into semiconductor β -phase (wurtzite lattice). The α -phase has a body-centered cubic arrangement of I^- ion with highly mobile Ag^+ ions randomly distributed through the equivalent interstices, which has been known as the averaged structure. Extensive attention has been paid to the mechanisms of the superionic motion and to the electron–phonon interactions in the averaged structure for many years [2,3]. However, an in situ optical study on the electron states of α -AgI is limited in number and many basic problems remain to be solved. Moreover, the interest in AgI-based superionic conducting glasses and AgI:metal oxide composites has significantly grown and extreme conductivity enhancement has been observed at room temperature [4]. For this reason, also, it is necessary to clarify the

electronic and ionic structures of α -AgI. At 408 K, the β -phase transforms mostly into the second semiconductor γ -phase (zinc blende lattice) with a small amount of the β -phase [5]. However, at temperatures lower than T_C , the effects of stacking faults and metastable structures need to be pointed out [6]. It is said that, if annealed and aged, the structures may convert into the wurtzite lattice. Therefore, in order to clarify the details of such a transition between the wurtzite and zinc blende structures, any measurement must be carried out in situ. The exciton absorption spectrum of AgI is very sensitive to such a crystal modification and local structural change [7,8]. While high-temperature α -AgI is cooled down to low temperature, it is useful to measure spectral transition in the exciton absorption.

2. Experimental

Vacuum evaporation experiments are carried out under a base pressure of 10^{-4} Pa. Optically flat-plates of silica glass, sapphire (R-cut) and MgO (100) are used as substrates. The surface temperature of the substrate is monitored with an alumel–chromel thermocouple. A platinum crucible containing nominally pure AgI

E-mail address: motizuki@physics.chs.nihon-u.ac.jp (S. Mochizuki).

powder was gradually heated indirectly in an alumina crucible on which a tungsten-wire heater was wound. The thickness of AgI film on the substrate increases with time. During film deposition, the substrate temperature was maintained above T_C . The optical density spectrum of the film was measured as a function of the time t_d elapsed after the beginning of the evaporation with an optical multichannel analyzer system. The experimental procedure is almost the same as the experiments for microcrystals, except for introducing noble gas stream, which has been already reported [9]. After stopping the evaporation, the film is gradually cooled down to 131 K. Through the cooling process, the absorption spectrum of the film was also measured as a function of temperature.

3. Results and discussion

3.1. Optical absorption of α -AgI film

Fig. 1 shows the time evolution of the optical density spectrum of α -AgI. The substrate temperature is 453 K. Although one time-resolved spectrum consists of successive sixty-four spectra in this figure, only eight spectra are selected and presented in order to show clearly the time evolution. The time t_d is indicated in the plots. The final thickness of the film was about 300 nm. At the initial stage of the evaporation, a kink and an absorption edge appear at about 2.8 eV and at about 2.6 eV, respectively. With the progressing evaporation, the absorptions increase and the kink and the edge shift to lower energies, together with the growth of an absorption tail below 2.5 eV. In order to observe the

detail, as shown in Fig. 2, we compared the spectrum measured at $t_d = 48.88$ s (curve A) with that measured at $t_d = 123.63$ s (curve B), by scaling the curve A, so that the optical density at 3 eV coincides with that of curve B. The curve C obtained by such scaling coincides with the curve B not only at the energy region between 3 and 4 eV, but also at the lowest photon energy (1.549 eV). The result shows that, with progressing evaporation, namely, the increasing film thickness, the steepness of the optical density curve in the neighborhood of the absorption edge decreases and the absorption-edge shifts from 2.57 eV to a lower energy 2.52 eV. The red shift nature observed arises from a decrease in the quantum confinement of carriers or excitons in α -AgI film. We investigated the absorption tail below 2.5 eV by replacing the silica glass substrate with a MgO (100) plate and a R-cut sapphire plate, and changing the evaporation speed. The results can be summarized as follows:

- (1) With the increasing evaporation speed, the fabricated films become somewhat cloudy.
- (2) Films on the MgO- and sapphire single-crystal substrates do not show a prominent tail below 2.5 eV.

Therefore, the absorption tail observed below 2.5 eV is closely connected with surface roughness, and with crystalline defects at the film/substrate interface.

3.2. Optical absorption of AgI film below T_C

After stopping the evaporation, the specimen was gradually cooled to 131 K with an average cooling rate

Fig. 1. Time evolution of the optical density spectrum of α -AgI film on a silica glass at 453 K during vacuum evaporation.

Fig. 2. Comparison of the optical density spectra of AgI film between the early and middle stages of the vacuum evaporation.

of 0.03 K/s. During the cooling process, the optical density spectrum was measured as a function of temperature, at temperature intervals of 5 K. Only the four spectra are presented in order to show clearly the temperature dependence. The result is shown in Fig. 3. During cooling from 453 to 398 K, the optical density spectrum is almost independent of temperature. Urbach rule does not hold in α -AgI. This indicates that the contribution from the electron–phonon interaction characteristic of the α -phase counterbalances that from the temperature-shift of the band gap energy due to thermal contraction of α -AgI. No remarkable spectral change was observed near T_C . This is due to the hysteresis of the superionic conduction transition [8]. At 393 K, several weak exciton absorption peaks and a shoulder appear faintly at 2.934, 2.975 (shoulder), 3.058, 3.110, 3.766 and 3.977 eV. On further cooling, these absorption peaks become prominent. In order to show the detailed spectral structure, the spectrum measured at 131 K is shown, together with that measured at 453 K, in Fig. 4. The X-ray diffraction (XRD) pattern of the AgI film was measured at room temperature. The XRD result shows a considerable amount of γ -AgI and the broadening of the (h0l) diffraction lines of β -AgI. The broadening arises from the stacking disorder in β -AgI hexagonal stacking sequence (ababab...), as pointed out by Lee et al. [10]. Taking into account the X-ray diffraction data, as indicated in the figure, the peaks, the absorption peaks and the shoulder observed at 2.934, 2.975 (shoulder) and 3.766 eV are assigned to the Z_1 -, Z_2 - and Z_3 -exciton absorptions of γ -AgI [7,8], while the peaks observed at 3.058, 3.110 and 3.977 eV are assigned to the H_1 -, H_2 - and H_3 -exciton absorptions of some

Fig. 3. Optical density spectra of AgI film on a silica glass at different temperatures during cooling process.

Fig. 4. Optical density spectra of AgI film at 131 and 453 K.

stacking-disorder-induced polytype structure of AgI. Quite a similar exciton absorption due to the polytype structure was found in CuI film evaporated onto a room-temperature substrate [7].

3.3. Miscellaneous

In Fig. 5, the absorption intensity peak energy and photoluminescence intensity peak energy of AgI film at 9 K are plotted as a function of the substrate temperature during vacuum evaporation. The observed absorption and photoluminescence (PL) peaks are due to the $Z_{1,2}$ exciton. The PL intensity peak appears several tens of meV lower than the absorption one, which indicates the existence of shallow exciton traps due to electron–phonon interactions or defects. With the increasing substrate temperature above about 450 K, the redshift becomes prominent. Silica glass substrate, which has an extremely small thermal expansion coefficient, gives a larger shift than that of sapphire. The results are qualitatively explained by the asymmetric stress at the interface coming from thermal shrinking with different thermal expansion coefficients between AgI and substrate material. The stress affects the electronic structure of AgI and induces an additional shift of the $Z_{1,2}$ exciton energy. This thermal stress may be one of the candidates for the cause of polytype structure formation. Our experiments show that the H_1 , H_2 and H_3 absorptions are not observed in thick AgI films which were produced by the vacuum evaporation with a small evaporation rate. Thinner sample tends to be influenced by the thermal stress and, therefore, the H_1 , H_2 and H_3 absorptions become more prominent. In addition to this stress effect, the effect of the deviation from

Fig. 5. Substrate temperature dependence of the absorption intensity peak and PL intensity peak energies at 9 K for the silica glass and sapphire substrates.

stoichiometry, $\text{Ag}_x\text{I}_{1-x}$, should also be considered at a high temperature for further discussion.

Effect of the stacking disorder observed in film specimens appears frequently even in the absorption spectra of nanocrystal specimens. Nanocrystals both on a substrate [11] and in a matrix [12] show faint absorption bands between 3.0 and 3.2 eV, which are in the H_1 - and H_2 exciton energy region. This indicates that AgI nanocrystals contain a stacking disorder induced by some reconstruction of surface atoms and

by the stress at the nanocrystal/matrix interface similar to CuI nanocrystals [13].

Valence-change- and defect-induced white luminescence of Eu_2O_3

S. Mochizuki^{a,*}, Y. Suzuki^a, T. Nakanishi^a, K. Ishi^b^a *Department of Physics, College of Humanities and Sciences, Nihon University, 3-25-40 Sakurajosui, Setagaya-ku, Tokyo 156-8550, Japan*^b *Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Sendai 980-8577, Japan*

Abstract

Under irradiating with a CW UV laser light ($\lambda = 325\text{ nm}$) at room temperature in vacuum and oxygen gas atmosphere, the film, microcrystals and powder compacts of Eu_2O_3 exhibit a reversible photoluminescence (PL) spectral change between a red sharp-line structure and a white broad one. After stopping the UV irradiation, the ability of the white PL lasts for more than several months at room temperature under room light, in spite of changes of atmosphere. The reversible phenomena to be observed are interpreted as the results of both the valence-number change of europium ions ($\text{Eu}^{3+} \rightarrow \text{Eu}^{2+}$) and the oxygen vacancy formation. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Defect structures; Valence change; White-light emission

1. Introduction

Eu_2O_3 is stable in air and has five phases designated by X, H, A, B and C at atmospheric pressure in order of decreasing temperature as follows [1]. At about 2553 K, the X phase transforms into the H phase which transforms to the A phase at 2413 K. At 2313 K, the A phase (hexagonal structure: space group D_{3d}) transforms into the B phase (monoclinic structure: space group C_{2h}). In the A phase, the europium atoms are seven-coordinate with four oxygen atoms closer than the other three, while, in the B phase, the europium atoms are six- and seven-coordinate. At about 1373 K, the B phase transforms into the C phase (cubic structure: space group T_h) in which the europium atoms are six-coordinate. At room temperature, the present authors have recently observed the reversible UV-laser-light-induced spectral transitions between the red- and white-luminescence states in Eu_2O_3 -powder compacts and—films produced by the radio-frequency sputtering

method [2,3]. The interest in photoluminescent materials showing such photo-induced reversible spectral change at room temperature has significantly grown, because a combination of the reversible phenomenon and the near-field optical microscope [4] is very promising when applied to high-density optical storage with nanometer resolution. It is also the hope that we can find white PL material, which is useful for the wide-band tunable-laser medium. Very recently, we have also observed the similar photoinduced spectral transition in Eu_2O_3 films produced by the pulsed laser ablation method in vacuum and Eu_2O_3 microcrystal films produced by the laser ablation in low-pressure oxygen gas atmosphere.

In this paper, an overview of our results obtained in the past three years will be given, together with a phenomenal model of the photoinduced spectral transition.

2. Experimental

All specimens were made from Eu_2O_3 powder of 99.98% purity. Powder compact specimens were prepared by pressing the Eu_2O_3 powder under a pressure of 0.2 GPa for 1 h at room temperature. They were then

sintered at 1273 K in air for 24 h. First types of Eu_2O_3 films were grown on a silica glass substrate by the radio-frequency sputtering (RFS) method. They are named RFS films. Second-type of Eu_2O_3 films were grown on a silica glass substrate by the pulsed laser ablation (PLA) method in vacuum of 1.33×10^{-4} Pa. They are named PLA-films. Eu_2O_3 microcrystal-accumulated films were grown on a silica glass substrate by the PLA method in oxygen gas of the pressure lower than 100 Pa. They are named PLA-MC film. They are characterized by the X-ray diffraction (XRD) method and the scanning electron microscopy (SEM). Irradiations were carried out with a CW He–Cd laser line ($\lambda = 325$ nm) with power densities between 31438 and 840000 W/m^2 . The same He–Cd laser line excites luminescence. Emitted light is dispersed and detected using a grating spectrograph equipped with a multichannel photodetection system.

3. Results and discussion

The XRD analysis of the produced specimens indicates that the powder compact, RFS film, PLA film, and PLA-MC film are respectively, the C phase, the H phase [1], a mixture of predominantly C phase with a little B phase, and a mixture of predominantly B phase with a little C phase of Eu_2O_3 . The specimens were also examined by the SEM. The powder compacts consist of randomly oriented and connected rectangular-parallel-piped grains, as shown in Fig. 1(a). The RFS-films and the PLA ones have smooth surfaces and are optically transparent. The PLA-MC films consist of a lot of small particles whose sizes is approximately several hundred nanometers and little aggregates whose sizes can be several thousand nanometers, as shown in Fig. 1(b).

Figs. 2–5 show the photoinduced spectral changes at room temperature of the Eu_2O_3 -powder compact,

Eu_2O_3 -RFS film, Eu_2O_3 -PLA film and Eu_2O_3 -PLA-MC film, respectively. In the measurements of the powder compact, the RFS films, the PLA films and the PLA-MC films, their relative sensitivities of the detections are 1, 8, 170 and 34, respectively. Experiments were carried out in alphabetical order: (a) \rightarrow (b) \rightarrow (c). Irradiation time t_{ir} under a given atmosphere and the kind of

atmosphere are indicated in each plot, together with the relative sensitivity of the detection, SD. First, these as-produced Eu_2O_3 specimens are irradiated with a 325 nm laser line at room temperature under oxygen atmosphere of a pressure 1.01×10^5 Pa. Under 325 nm excitation, these specimens show the red sharp $^5\text{D}_0 \rightarrow ^7\text{F}_J$ ($J = 0, 1, 2, 3, 4$) emissions [5,6]. Depending on the crystal structure of the specimens, the detailed spectral structure of the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ emission differs each other [7,8]. Next, the specimen chamber is evacuated to 1.33×10^{-4} Pa. Under 325 nm irradiation in this vacuum, quite similar photoinduced spectral changes were observed in all the specimens. Namely, with increasing t_{ir} , the $^5\text{D}_0 \rightarrow ^7\text{F}_J$ ($J = 0, 1, 2, 3, 4$) emission intensity of Eu^{3+} ions becomes weak, while a very broad emission band appears and spreads all over the visible light region. The wavelength of the intensity peak of the white PL band observed in all the specimens is between 540 and 620 nm. Especially, the relative intensity decreases of the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ emission of the powder compact, RFS film, PLA film and PLA-MC film are 75.3%, 15.6%, 34.5% and 15.4%, respectively. The intensity decrease indicates the decrease of number of Eu^{3+} ion, which is

due to photoreduction ($\text{Eu}^{3+} \rightarrow \text{Eu}^{2+}$). At this stage, the bright white PL can be seen with the naked eye. The whitening speed of the PLA film specimen was the highest among all specimens. In addition, the wavelength of their intensity maximum of the white PL band is specimen-dependent. The spectral structures to be observed in the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ emission in the RFS film, PLA film and PLA-MC film, incidentally, differ from that for the powder compact specimen (C-phase Eu_2O_3) in which each Eu^{3+} ion is surrounded by six oxygen ions. Seven-coordinate Eu^{3+} ions account for the spectral difference [2,3,7,8].

Oxygen gas is again introduced into the chamber. The change from white PL emission to red emission can be seen with the naked eye. It is found through many successive experiments that the spectral changes as shown in these figures are reversible. Similar experiments were carried out by changing the wavelength of the irradiating laser light. For example, a CW He–Cd laser ($\lambda = 442$ nm), a CW Ar^+ laser ($\lambda = 528.7, 514.5, 501.7, 496.5, 488.0, 476.5, 472.2, 465.8$, and 457.9 nm), and a pulsed $\text{Nd}^{3+}:\text{YAG}$ laser ($\lambda = 266, 354.7, 532$, and 1064 nm) were used. No spectral change was observed with these lasers, which indicates that the CW UV laser light of the wavelength 325 nm is required to induce the spectral change. The speed of the spectral change is accelerated by increasing the power density of the activating light. The change to the white PL emission can also be observed at low temperatures down to 7 K, which indicates that the phenomenon does not arise from a phonon-assisted process and that it is a purely electronic mechanism. In spite of the changing atmosphere (for example, O_2 gas and air exposures), the white PL state lasts for more than several months at room temperature after the removal of the laser light under room light, and the red PL state re-appears only by irradiating with the same UV laser light under O_2 gas atmosphere of a pressure 1.01×10^5 Pa.

Finally, we turn to the observed photoinduced spectral change between the red- and white PL. Noting the result that the 325 nm photons are essential to induce the spectral change. The 325 nm irradiation in vacuum produces both valence change ($\text{Eu}^{3+} \rightarrow \text{Eu}^{2+}$) and oxygen vacancies. They then induce local structural relaxation (distortion) around photoexcited ions to form a metastable state. A simplified scheme is drawn in Fig. 6, omitting the detailed structure of the 4f electronic states of Eu^{3+} ions. The $^7\text{F}_0$ -MS and X represent the ground state of Eu^{3+} ions, the metastable state, and one of some 4f excited energy level of Eu^{3+} ions or charge-transfer state, respectively. The coordinate Q expresses some local structural change due to both the valence number change of Eu^{3+} ions and the oxygen vacancy formation. The potential barrier of the height ΔE separates the metastable state from the ground state. In oxidizing atmosphere, the 325 nm radiation produces

Fig. 4. Reversible spectral change of Eu_2O_3 film produced by the laser ablation method in vacuum.

Fig. 6. Schematic energy diagram of the photoinduced reversible spectral change of Eu_2O_3 .

the localized excitation of Eu^{3+} ions and the deexcitation of the photoexcited Eu^{3+} ions provides the red luminescence due to the $^5\text{D}_0 \rightarrow ^7\text{F}_J$ transitions, via the nonradiative transitions (NR) to the $^5\text{L}_6$, $^5\text{D}_J$ ($J = 3, 2, 1, 0$) states. When the photoexcitation is carried out in vacuum, the excited state is relaxed through both a radiative recombination and the local structural relaxation to the metastable state. The 325 nm excitation of the metastable state induces both the backward transition and the transition to the localized electronic state (LES) originating from the Eu^{2+} and oxygen vacancy formations. Since the photoproduced metastable state is extremely stable even at room temperature in oxygen, air and vacuum atmospheres after stopping 325 nm irradiation as described above, the potential barrier separating the ground state ($^7\text{F}_0$) from the MS must be high enough to suppress the thermal-forward and -backward transitions between the $^7\text{F}_0$ state and MS. The LES is a luminescence center strongly coupled with lattice vibrations and, therefore, gives a broadband luminescence as observed. Our PL-excitation spectra measurements on all the specimens show that the laser wavelength 325 nm corresponds the lower-energy

edge of the charge-transfer (CT) absorption band ($\text{Eu}^{3+} + \text{O}^{2-} \rightarrow \text{Eu}^{2+} + \text{O}^{1-}$) and the transition energy to higher excited states of Eu^{3+} ions; for example, $^7\text{F}_0 \rightarrow ^5\text{L}_J$ transitions. Therefore, the CT and $^5\text{L}_J$ states are candidates for the origin of the X state. However, the observed spectral change is thought to be a surface phenomenon. The detailed surface electronic structure should be clarified for further discussion.

Abstract

In this paper, the theory of dislocation density and curvature measurements from X-ray rocking curves is extended to the case of double oxide heteroepitaxial $\text{CeO}_2(001)/\text{YSZ}(001)/\text{Si}(001)$ films mainly by high-resolution X-ray diffraction. According to this theory, we have successfully resolved the rocking curves of CeO_2 and YSZ by two simple components. Thus, the dislocation density and radius of curvature of each layer can be calculated from the distribution of the square of measured FWHM versus $1/\sin^2\theta$. The results show that the YSZ layer has a higher dislocation density and a lower radius of curvature than CeO_2 . The high-resolution transmission electron microscopy (TEM) image of CeO_2/YSZ interface cross-section shows a high dislocation density along the interface with an average interval ~ 3.9 nm. © 2001 Elsevier Science B.V. Keywords: Dislocation density; Rocking curve; YSZ; CeO_2

1. Introduction

In recent years, the Yttria-stabilized ZrO_2 (YSZ) and double CeO_2/YSZ epitaxial films on $\text{Si}(001)$ substrates have attracted much attention due to their applications such as the buffer layers in electronic devices [1] and in high Tc superconductors [2,3]. The adding of a YSZ buffer layer between CeO_2 and $\text{Si}(001)$ is necessary to obtain the $\text{CeO}_2(001)/\text{YSZ}(001)/\text{Si}(001)$ epitaxial growth layer [4]. However, the lattice mismatches at interfaces, CeO_2/YSZ and YSZ/Si , (lattice constants of bulk CeO_2 is 0.541 nm, bulk YSZ is 0.514 nm and Si is 0.543 nm), are over 5.0% and will lead to an increase of lattice distortion, random strain and dislocation density as clarified in our previous work [5]. The measurement of dislocation density in heteroepitaxial semiconductor layers is important for the development of microwave

transistors and the integration of devices in dissimilar semiconductors. The X-ray rocking curves provide non-destructive measurements of dislocation densities with accuracy equal to crystallographic etches or TEM. Hordon and Averbach have described the theory of full-width at half-maximum (FWHM) of rocking curves and determined the dislocation densities of metal single crystals of copper and aluminum [6]. On the basis of this theory, Qadri and Dinan calculated the dislocation densities of alloy epitaxial $\text{ZnCdTe}/\text{InSb}$ films and which showed good agreement with TEM observation [7]. Ayers extended the calculation technique in $\text{GaAs}/\text{Si}(001)$ single semiconductor layers by the measurement of several rocking curves from different diffraction planes [8].

In this paper, the aforementioned theory is extended to the case of oxide heteroepitaxial film, $\text{CeO}_2/\text{YSZ}/\text{Si}(001)$, for the estimation of dislocation density and radius of curvature. The calculated result by high-resolution XRD is also compared with the observation of high-resolution TEM.

2. Experimental

Single YSZ (8 mol% Y_2O_3) and double CeO_2/YSZ layers were prepared by pulsed laser deposition (PLD) with a KrF (248 nm) excimer laser at 1073 K in 5.5×10^{-4} Torr on Si(001) substrates which were RCA cleaned [9] and dilute HF ($\text{HF}:\text{H}_2\text{O}=1:10$) treated. The experimental procedure is described in detail in Ref. [10]. The thickness of the CeO_2 layer was kept at about 78 nm (± 2 nm) and that of the YSZ layer was varied from 20 to 145 nm. Due to the measurement of the precise thickness being quite difficult, we used several techniques for comparison including energy dispersive spectroscopy, a surface profile detector and the glazing X-ray reflectivity measurement and which showed good agreement with each other [11]. The rocking curves from (002), (113), (004), (224), (115), (006), (335) and (226) diffraction planes of CeO_2 and YSZ were performed on the Philips Extended X'Pert Material Research Diffractometer (MRD) employing a graded parabolic X-ray mirror and a four-Ge(220)-single-crystals monochromator in the incident beam. The mirror and monochromator produce a parallel beam with an angular divergence less than 0.005° for Cu K_α ($\lambda = 0.1541$ nm). The settings of the generator were 45 kV and 40 mA with a Cu anode.

3. Results and discussion

According to the theory of X-ray rocking curve that was described by Hordon and Averbach, if β_m is the measured FWHM of the rocking curve of a diffraction plane, then

$$\beta_m^2 = \beta_0^2 + \beta_d^2 + \beta_\alpha^2 + \beta_\epsilon^2 + \beta_L^2 + \beta_r^2, \quad (1)$$

where β_0 and β_d are the intrinsic FWHMs for the layer and the analyzing crystals; β_α , β_ϵ , β_L and β_r are the components due to lattice tilting, local strain, crystal size and uniform lattice bending, respectively. The intrinsic β_0 and β_d are usually less than 0.003° [12], thus we can ignore these two parameters here. Then the equation can be re-written as below:

$$\beta_m^2 = K_\alpha + K_\epsilon \tan^2 \theta + K_L \frac{\lambda^2}{\sin^2 2\theta} + \frac{K_r}{\sin^2 \theta}, \quad (2)$$

where θ is the Bragg angle, λ is X-ray wavelength and K 's are constants independent of θ and λ [13,14].

According to the definition, all the coefficients, K_α , K_ϵ , K_L and K_r , are positive constants. In order to find a simple relation between the measured FWHM and each K coefficient, β_m^2 was plotted with various functions of the Bragg angle θ , i.e. β_m^2 versus $\tan^2 \theta$, $1/\sin^2 2\theta$ and $1/\sin^2 \theta$. However, we can only find a linear relation in the plot of β_m^2 versus $1/\sin^2 \theta$, which has a reliable

positive slope (K_r) and an intercept (K_α) with β_m^2 axis as defined before. This suggests that within those four K coefficients, K_ϵ and K_L can be ignored in this film system, and thus we have to set both K_ϵ and K_L to zero to obtain a simple linear relation for the estimation of dislocation density and radius of curvature.

Fig. 1 shows the square of measured FWHM, β_m^2 , of CeO_2 and YSZ rocking curves from various diffraction planes, which exhibits a linear relation with $1/\sin^2 \theta$. The K_α and K_r that are obtained from various slopes and intercepts of different samples can be used to calculate the dislocation density and radius of curvature by Eqs. (3) and (4) as below:

$$K_\alpha = 2\pi \ln 2 \times |\vec{b}|^2 D, \quad (3)$$

$$K_r = \frac{w^2}{r^2}, \quad (4)$$

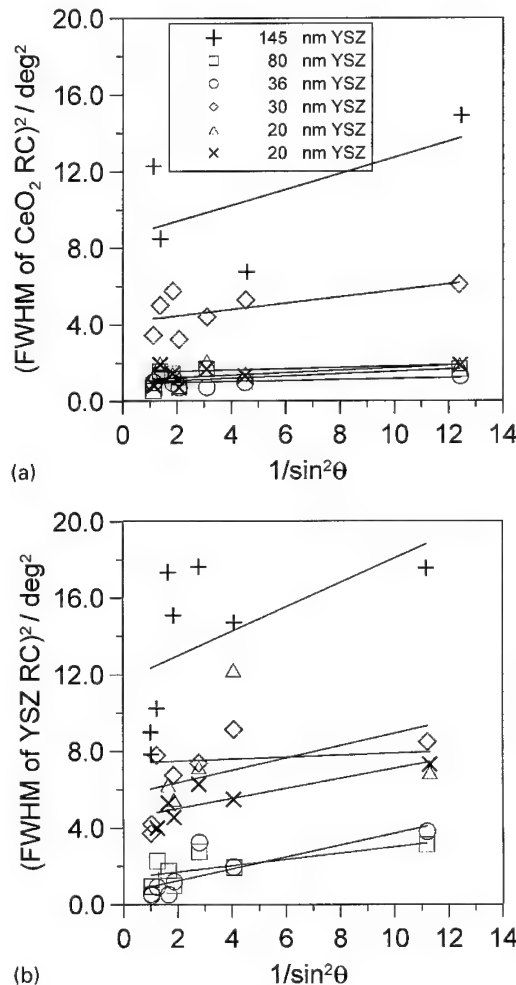

Fig. 1. Squares of measured FWHMs of (a) CeO_2 and (b) YSZ rocking curves versus $1/\sin^2 \theta$.

where b is the burger vector, D is the dislocation density, w is the X-ray beam width and r is the radius of curvature. According to the high-resolution TEM observation, the burger vector of misfit dislocation is $1/2a [1\ 1\ 0]$ in both YSZ and CeO_2 where the values are 0.363 and 0.383 nm for YSZ ($a = 0.514$ nm) and CeO_2 ($a = 0.541$ nm), respectively.

Fig. 2 shows the relationship of dislocation density between YSZ and CeO_2 that is calculated from Fig. 1. The results show that the dislocation density of YSZ (3.3×10^{10} – $6.2 \times 10^{11} \text{ cm}^{-2}$) is a function of that of CeO_2 (4.4×10^{10} – $4.1 \times 10^{11} \text{ cm}^{-2}$). The dislocation density of CeO_2 is always lower than that of YSZ in each sample (all points locate below the broken line). This phenomenon might be caused by the YSZ layer having two interfaces, CeO_2/YSZ and YSZ/Si , containing higher misfit dislocation density. Besides, the dislocation density of YSZ decreases as its thickness increases with a well-fitting function (not shown here), which can be used to estimate the dislocation density of different thicknesses. From this distribution, we can understand the central part of the YSZ layer contains fewer dislocations than its top and bottom interfaces. In our expectation, the dislocation density of CeO_2 should be a constant as its constant thickness (~ 80 nm). However, the dislocation density of CeO_2 changes with that of YSZ indicating that any change in CeO_2 arises from the bottom YSZ layer conditions.

Fig. 3 shows a lattice image of CeO_2/YSZ interface section ($[00\ 1] \times [1\ 1\ 0]$) of 30 nm thick YSZ by high-resolution TEM. After being treated with a fast Fourier transformation, the misfit dislocations around the interface can be seen clearly. The average interval between each misfit dislocation is about 3.9 nm. Here we recall the calculation results from Fig. 2, which is a

Fig. 2. Dislocation density of CeO_2 is a function of that of YSZ.

Fig. 3. Cross-sectional high-resolution TEM lattice image of CeO_2/YSZ interface.

Fig. 4. Radius of curvature of CeO_2 is a function of that of YSZ.

two-dimension dislocation density with a unit cm^{-2} . The one-dimension dislocation density can be estimated by the square root of the previous calculation result, that is, 0.018–0.079 nm^{-1} for YSZ and 0.021–0.064 nm^{-1} for CeO_2 . Thus, the average interval between misfit dislocation is 56–12 nm for YSZ and 48–16 nm for CeO_2 . The much higher interval than the observation of high-resolution TEM comes from the result that high-resolution XRD is an average value in any direction rather than just along the interface.

Fig. 4 shows the relationship of radius of curvature between YSZ and CeO_2 that is calculated from Fig. 1.

The radius of curvature of YSZ (0.07–0.25 m) that is caused by uniform lattice bending is much smaller than that of CeO_2 (0.09–0.36 m). The radius of curvature of bare Si(001) substrate has been measured by high-resolution XRD and shows almost no bending (~ 300 m). Therefore, the relatively huge curvatures of YSZ and CeO_2 were not caused by bent substrate. Here, we consider the thermal expansion coefficients of CeO_2 , YSZ and Si. Since the thermal expansion coefficient of CeO_2 ($13.5 \times 10^{-6} \text{ K}^{-1}$ at 1100 K) is much larger than that of YSZ ($10.9 \times 10^{-6} \text{ K}^{-1}$ at 1100 K) and Si ($4.5 \times 10^{-6} \text{ K}^{-1}$ at 1100 K), the CeO_2 and YSZ layers undergo tensile stress when the specimen is cooled from deposition temperature, 1073 K, and down to room temperature, 298 K. From the calculation of dislocation density as described in Fig. 2, YSZ always has a much higher dislocation density than CeO_2 for various YSZ thicknesses. In other words, the YSZ layers might contain more mosaic domains than CeO_2 because the domain boundary consists of dislocations. As these small mosaic domains are under tensile stress caused by the difference of thermal expansion between each layer, this will lead to a rocking curve broadening effect almost similar to the curvature broadening.

4. Conclusions

In this paper, we have successfully used the X-ray rocking curve theory to clarify the double oxide heteroepitaxial $\text{CeO}_2/\text{YSZ}/\text{Si}(001)$ films. The YSZ has a higher dislocation density and lower radius of curvature than CeO_2 , which is mainly caused by the

larger lattice and thermal mismatches between CeO_2 and YSZ, and YSZ and Si substrate. From the high-resolution TEM observation, the CeO_2/YSZ interface is relaxed by introducing a large amount of misfit dislocations with an average interval ~ 3.9 nm.

Influence of semiconductor film structural imperfection on the physicochemical interaction rate in As_2S_3 –Cu system

M.V. Sopinsky*

Institute of Semiconductor Physics, National Academy of Sciences, 45, Prospect Nauky, 03028 Kyiv, Ukraine

Abstract

Physicochemical interactions in amorphous As_2S_3 –copper thin-film systems were studied by the methods of resistometry, ellipsometry, microscopy and by chemical dissolution. It was shown that the considerable variation of chemical process activity observed in these systems is caused by an essential dependence of the physicochemical interaction rate on chalcogenide film stoichiometry and the imperfection of its structure. Application of our thermochemical model for a probability estimation of quasi-molecular reactions of copper and oxygen with polymerised and non-polymerised fragments in arsenic trisulphide film makes it possible to give a qualitative description of the dark interaction mechanism. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Chalcogenide glassy semiconductors; Physicochemical interactions

1. Introduction

Thin-film systems based on chalcogenide glassy semiconductors (CGS) and some metals (Ag, Cu) [1] have many unique properties. For example, they can be successfully applied in submicron lithography and are very promising in nanolithography as inorganic resists [2,3].

CGS–Me systems, generally, are thermodynamically non-equilibrium ones: there are physicochemical processes which cause their ageing. Besides, the examination of physicochemical interactions (PCI) of CGS and metal films is an important topic of research by itself. We have recently demonstrated that these effects can be applied to the creation of blazed holographic diffraction gratings [4].

2. Experimental

Samples of sandwich-like thin-film CGS–Cu systems were prepared by deposition onto glass substrate

vapours produced by the subsequent thermal vacuum evaporation of the copper load and that of crashed powdered glassy As_2S_3 from tantalum boats at a residual pressure, P , of 5×10^{-3} Pa.

The most universal physical property describing mass transport during solid-state reactions in such systems is the metal layer expenditure, Δh_{Cu} . It was observed by electrical resistance measurements [5].

Multiangle ellipsometrical measurements (LEF-3M ellipsometer, $\lambda = 632.8$ nm) of As_2S_3 –Cu samples and As_2S_3 and Cu control films, were analysed using the Fortran-program which enabled us to distinguish between various ellipsometrical models [6,7].

3. Results and discussion

Thickness changes of the copper film on As_2S_3 –Cu samples prepared in the same vacuum cycle began simultaneously with the start of the chalcogenide film deposition on it and continued after completion of the deposition at the same rate (Fig. 1(2)). During the deposition of As_2S_3 on Cu film covered by the Cu_xS layer, V_c was proportional to the deposition rate, and drops sharply when the deposition is completed

*Fax: +380-44-265-83-42.

E-mail address: sopinsk@class.semicond.kiev.ua (M.V. Sopinsky).

(Fig. 1(3)). As opposed to Cu_xS layers, the Cu_2O ones formed by the exposure of the copper film to free air have barrier properties (Fig. 2).

The As_2S_3 –Cu sample ageing rate depends also on the conditions of the preparation of the As_2S_3 film. During the sample storage in vacuum, the PCI takes place most intensely when the CGS film is obtained by evaporation of primary glassy As_2S_3 . The PCI rate in vacuum slows down by more than one order of magnitude in systems obtained with the evaporation of multiply used As_2S_3 load. The films obtained by evaporating the previously used As_2S_3 shots have a refraction index that is several per cent higher than the films obtained from the fresh load.

The stability of As_2S_3 –Cu systems depends also on the storage conditions: in vacuum or in air. The character of atmospheric influence significantly depends on the conditions of CGS film production.

Fig. 1. Time dependence of the As_2S_3 film thickness being deposited (1) and the thickness change of the copper film being stored in vacuum chamber (2, 3).

Fig. 2. Copper film thickness change depending on the duration of the As_2S_3 –Cu systems storage in vacuum ($h_{\text{As}_2\text{S}_3} = 150$ nm). Intermediate Cu_2O layer. $h_{\text{Cu}_2\text{O}} = 4$ (1) and 7 (2) nm.

In systems with films obtained from fresh shots, the PCI is slower in air than in vacuum (Fig. 3(1) and (2)). On the contrary, in systems in which CGS films are obtained from earlier used material, the PCI rate in air is higher (Fig. 4). In the sample taken from vacuum right after the deposition, the V_e in air is higher than that in vacuum and is practically stationary (Fig. 4(1)). Longer storage of the sample in vacuum (before placing it in air) gradually causes the occurrence of the low V_e initial period (Fig. 4(3)).

The systems under ellipsometrical investigation were well modelled as multilayer structures with sharp layer interfaces. That is, the thickness distribution of the dissolved copper is almost rectangular in shape. It confirms the reactionary nature of the interaction. In

Fig. 3. Change of the Cu film thickness in the As_2S_3 –Cu system being stored in air (1) and in vacuum (2). $h_{\text{As}_2\text{S}_3} = 180$ nm, $h_{\text{Cu}_2\text{O}} = 5.5$ nm.

Fig. 4. Time dependence of copper film thickness change for a As_2S_3 – Cu_2O –Cu system over the vacuum-and air-keeping. The As_2S_3 film has been obtained by the evaporation of load used earlier in four evaporations. (1) Keeping in air, (2, 3) keeping in vacuum (up to the time indicated by \uparrow) and in air (after the time indicated by \uparrow) ($h_{\text{As}_2\text{S}_3} = 106$ nm, $h_{\text{Cu}_2\text{O}} = 5$ nm).

Fig. 5. Thickness change of non-doped (1) and copper-doped (2) parts of CGS film during the storage of the As_2S_3 - Cu_2O - Cu system in air. The CGS film parameters are the same as in Fig. 4.

Fig. 5 the details of ellipsometrical investigations on the acceleration of PCI in air are represented.

The explanation of the observed substantial difference between chemical process rates can be based on heats of formation of copper, and arsenic sulphides and oxides.

For arsenic trisulphide and cupric sulphides the following is true (Table 1):

$$|\Delta H_f(\text{As}_2\text{S}_3)| < |\Delta H_f(\text{Cu}_2\text{S})|, \quad (1)$$

$$|\Delta H_f(\text{As}_2\text{S}_3)| < |\Delta H_f(\text{Cu}_{2-\delta}\text{S})|. \quad (2)$$

From (1) and (2) it follows that if copper and arsenic trisulphide are in contact, fast exothermic exchange reactions should take place, producing the Cu_2S and $\text{Cu}_{2-\delta}\text{S}$ compounds. An interaction rate is determined by the enthalpy and the entropy of the reactions and by the kinetic factors.

It is known [11,12] that the violation of the stoichiometrical composition and structure of As_2S_3 being precipitated due to change of fragmentary composition of vapour phase causes changes of the optical properties of the arsenic trisulphide films. Multiple evaporation of glassy As_2S_3 causes changes in its vapour phase composition—from more volatile sulphur-enriched fractions at the first evaporation of shots to sulphur-deficient fractions when shots are taken through several evaporation cycles. Since (Table 1)

$$\Delta H_f(\text{As}_2\text{S}_5) < |\Delta H_f(\text{As}_2\text{S}_3)| < |\Delta H_f(\text{As}_2\text{S}_2)|, \quad (3)$$

one should expect an intensification of the interaction between the copper and the sulphur-enriched films obtained during the first evaporation of the arsenic trisulphide load. This has been confirmed experimentally.

Table 1

Relative heats of formation (in kcal/mole \times number of chalcogen or oxygen atoms per formula unit) for arsenic, and copper sulphides and arsenic, copper and sulphur oxides

Compounds	$ \Delta H_f $ ([8–10])
As_2S_2	15.95
As_2S_3	13.3
As_2S_5	7.0
$\text{Cu}_2\text{S} \dots \text{Cu}_{1.8}\text{S}$	19.6...17.2
$\text{S}_2\text{O} \dots \text{S}_2\text{O}_7$	−0.098...36.8
Cu_2O , CuO	41.4, 38.7
$\text{As}_2\text{O}_3 \dots \text{As}_2\text{O}_5$	43.9...53.0

The effect of the atmospheric influence can also be explained in a non-contradictory manner in terms of the thermochemical approach. The analysis of data in the table shows that the exothermic effect of the 3-, 4-, 5-valence arsenic atoms reaction with oxygen is greater than the oxygen–copper and oxygen–sulphur reactions. This exothermic effect is also greater than that of the reaction of arsenic or copper atoms with sulphur. This enables us to assume that the overall PCI rate in air increases specifically due to the interaction of atmospheric oxygen with arsenic atoms. The acceleration of the PCI interaction processes should be especially noticeable in samples without excess sulphur, such as thin-film samples without surplus of sulphur, in agreement with the experimental results.

Abstract

Both EPR spectra of Gd impurity and ^{119}Sn Mössbauer spectra in $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ grown from the melt by Bridgman method and doped with Gd impurity during the growth process were investigated. It was ascertained that EPR spectra behavior depended on rare-earth impurity concentration, doping method and matrix composition. It was shown that there were some correlations between Gd EPR spectra behavior and ^{119}Sn Mössbauer spectra parameters in doping crystals under investigation. The results obtained are treated on the basis of the model “Gd impurity–Te-vacancy” complexes, whose creation is caused by the interaction between point defects in the matrix and Gd impurity ions during growth process. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: EPR; Mössbauer effect; Native defects; Gadolinium

1. Introduction

Investigations of rare-earth element (REE) impurities behavior in semiconductors and their influence on physical properties as well as extension of their practical applications are of great scientific interest at the moment [1–4]. Due to the “cleaning effect” caused by REE and their electronic configuration being different from other impurities as well as the presence of unfilled 4f-electron shells, it could be possible to improve operating parameters of doped semiconducting materials and to create semiconductors with new physical properties for fiber-optics communication and spintronics.

This work keeps on methodical investigation of Gd impurity behavior in lead and tin telluride crystals [4–6]. Its main aim is to provide a model of Gd^{3+} charge state creation in materials under the investigations suggested in the preceding work [6] with new arguments. According to this model Gd^{3+} ion exists as a component part of

“Gd impurity–Te-vacancy” complex and arises out of interaction with Te vacancy. This conclusion was drawn during the investigations of $\text{PbTe}:\text{Gd}$ crystal, where Gd was added as a hyperstoichiometric dopant. Present work is an extension of this case, in which Gd was added as a metal component substituting dopant, during the growth from the melt of both $\text{Pb}_{1-x}\text{Gd}_x\text{Te}$ and $\text{Pb}_{1-x-y}\text{Sn}_y\text{Gd}_y\text{Te}$ solid solutions. It was assumed that if Te vacancy really takes a dominant part in Gd^{3+} charge state creation, then it should be indicated in Gd EPR spectra depending on doping method and metal sublattice composition of $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$, because these factors are directly connected with Te vacancies concentration. Obtained investigation results are presented below.

2. Samples and experiments

Single crystals of PbTe and its solid solutions with SnTe , grown from the melt by Bridgman method and doped with Gd, during the growth process, have been

*Corresponding author.

E-mail address: zayachuk@polynet.lviv.ua (D. Zayachuk).

investigated by means of EPR and ^{119}Sn Mössbauer spectroscopy. Gd impurity was added into the crystals as a stoichiometric lead substituting component according to the following chemical formula $\text{Pb}_{1-x-y}\text{Sn}_x\text{Gd}_y\text{Te}$. Gd is a donor impurity in the investigated crystals and its segregation coefficient strongly depends on impurity concentration in the melt [5]. There exists a possibility to create a growth $n \rightarrow p$ transition by taking Gd in a right y amount within every grown crystal and thus obtaining both n - and p -type samples for further investigations. This factor is of great importance due to the main aim of investigation because a type of crystal conductivity in Pb and Sn tellurides is conditioned by the dominant type of point defects in it. If the Te vacancies concentration predominates over the metal vacancies, then the crystal possesses n -type conductivity, otherwise the crystal possesses p -type conductivity [7]. So, initial Gd concentration was taken equal to $y = 0.005$ for all solid solution compositions investigated, $x = 0; 0.05$ and 0.2 .

EPR spectra and ^{119}Sn Mössbauer spectra were studied according to techniques described in Refs. [4,6]. Mössbauer investigations were carried out only at room temperature, and EPR experiments at both room and liquid nitrogen temperatures. Real Gd concentration in crystals was determined by means of electron microprobe analysis with "Camebax" analyzer.

3. Results obtained

Experimental EPR data presented for systems under investigation together with other previously obtained results [6] have demonstrated the following. Main factors which influence the behavior of EPR spectra are impurity concentration, doping method and chemical composition of the matrix around the impurity ion, whereas Pb and Sn are the elements from the same group, and there is a continuous series of their telluride solid solutions crystallizing into NaCl-type cubic lattice. Furthermore, all these factors are interlocked. This means, for example, that the presence of Gd being present in sufficient concentration in the crystal may or maynot be revealed by EPR measurements depends on the composition and conductivity type of $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ matrix whether a Gd may or maynot be revealed by EPR measurements in materials with the same type of conductivity and composition depends on the way in which it was added—as a hyperstoichiometric dopant or as a metal component substituting stoichiometric one.

With respect to the main task of experiments, EPR spectra of n - and p -type samples made from ingot regions situated close to $n \rightarrow p$ transition were of greatest interest. These samples differed slightly from each other in their Gd concentration, but differed fundamentally in type and concentration of dominant vacancies in them,

which define the type of conductivity and free carrier concentration in crystals under investigation. Type conductivity inversion of the ingot was observed at different real Gd concentrations $N_{\text{pn}}(\text{Gd})$ depending on melt composition. $N_{\text{pn}}(\text{Gd})$ was changed from $\sim 1 \times 10^{19} \text{ cm}^{-3}$ for $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ crystal surrounded for $x = 0$ up to $\sim 1 \times 10^{20} \text{ cm}^{-3}$ for nominal composition $x = 0.2$. Main experimental results obtained can be summarized as follows:

- (I) EPR has always been detected in doped n -type crystals for any composition of crystal matrix for x region investigated.
- (II) EPR has been detected or not in doped p -type crystals depends on both crystal composition and doping method.
- (III) EPR has never been detected in doped p -type crystals for nominal composition $x = 0.2$ of $\text{Pb}_{1-x}\text{Sn}_x\text{Gd}_y\text{Te}$ and in p - $\text{PbTe}:\text{Gd}$ doped with Gd as a hyperstoichiometric impurity.
- (IV) Seven fine structure lines corresponding in general terms to Gd^{3+} ion in cubic symmetry local surrounding have been detected only in Sn-free samples of both p - and n - $\text{Pb}_{1-x}\text{Gd}_y\text{Te}$ crystals with Gd concentration less than $1 \times 10^{20} \text{ cm}^{-3}$ in them, Fig. 1.

Fine structure of the EPR spectra was certainly not observed in Sn-containing crystals despite the fact that these samples had perfect crystal structure and were single crystals (minimum amount of Sn was $x \sim 0.02$ in samples made from ingot with nominal composition $x = 0.05$ due to segregation effects). It is for $[001]$ orientation of magnetic field B corresponding to maximum spectrum spread for $\text{Pb}_{1-x}\text{Gd}_y\text{Te}$ that one spectrum line broadened in a greater or lesser degree depending on the real Gd concentration was always registered in n -type $\text{Pb}_{1-x-y}\text{Sn}_x\text{Gd}_y\text{Te}$ crystals. Position of this line was almost the same as for the central fine

Fig. 1. EPR spectra of $\text{Pb}_{1-x}\text{Gd}_y\text{Te}$ crystals at room temperature: (a) p -type conductivity, $N_{\text{Gd}} = 7.3 \times 10^{18} \text{ cm}^{-3}$ and (b) n -type conductivity, $N_{\text{Gd}} = 2.2 \times 10^{19} \text{ cm}^{-3}$.

structure line of the $\text{Pb}_{1-x}\text{Gd}_x\text{Te}$ EPR spectrum. EPR spectra as a one week intensity line were registered in p-type ingot region close to the grown n→p transition for crystals with $x = 0.05$ only at mainly liquid nitrogen temperature, and were not registered at all in crystals with nominal composition $x = 0.2$, despite a rather high Gd concentration— $\sim(7\text{--}8) \times 10^{19} \text{ cm}^{-3}$ —in that ingot region. It should be mentioned here that EPR spectra was registered at both room and liquid nitrogen temperatures in n-PbTe:Gd crystals with Gd concentration that cannot be registered by electron microprobe analysis— $N(\text{Gd}) \leq 10^{18} \text{ cm}^{-3}$.

4. Discussion

We believe that the presented results of the experimental investigations of $\text{Pb}_{1-x-y}\text{Sn}_x\text{Gd}_y\text{Te}$ solid solution EPR spectra give the seal to our model about the origin of the Gd^{3+} charge state in doped lead telluride crystals described above. According to this model, Gd^{3+} ion arises out of Coulomb interaction between Gd^{2+} ion and positive charge point defect (Te vacancy), whereupon Te vacancy captures $5d^1$ electron of Gd^{2+} and makes it a Gd^{3+} .

Due to the constitution diagram specificity [7], tin percentage increase in $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ leads to a tellurium content increase in the crystals grown, and to a corresponding probability decrease of Te vacancy creation as a result of this. Using Gd as a doping impurity during growth from the melt also decreases total Te vacancy concentration in ingots. This was confirmed by recent Mössbauer investigations of SnTe:Gd crystals [4]. However, this tendency not only belongs to SnTe, but also for solid solutions of SnTe basis and even for not rich SnTe ones. It is clearly shown on the Mössbauer spectra of n- and p-type crystals grown from the gadolinium doped melts for $x = 0.07$, Fig. 2.

Line width Γ of Mössbauer spectrum is defined by local surrounding symmetry of Mössbauer ion and it increases when this symmetry decreases. Γ is always smaller in p-type samples for the same composition in crystals under investigation. As was shown in [4], such a behavior of Γ corresponds to Te vacancy concentration, which is much lower in p-type crystals. Electrostatic field of these vacancies deforms the local cubic symmetry of ^{119}Sn surrounding the crystals.

Taking into consideration the facts mentioned just above as well as the fact that homogeneity region in $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ for $x \geq 0.2$ never crosses stoichiometric line and fully corresponds to Te-rich compositions [7], there is every reason to believe that Te vacancy concentration in p-type region of $\text{Pb}_{1-x-y}\text{Sn}_x\text{Gd}_y\text{Te}$ ingot grown from the melt for $x \approx 0.2$ should be very low. According to the model presented this should make Gd^{3+} states

Fig. 2. ^{119}Sn Mössbauer spectra both the n- (a) and p-type conductivity (b) $\text{Pb}_{0.93}\text{Sn}_{0.07}\text{Te}$ crystals doped with gadolinium. Mössbauer spectra parameters: a — $\delta = 3.55 \text{ mm/s}$, $\Gamma = 0.90 \text{ mm/s}$, $S = 0.037$ arb. units; and b — $\delta = 3.55 \text{ mm/s}$, $\Gamma = 0.80 \text{ mm/s}$, $S = 0.038$ arb. units.

creation very unlikely. This is confirmed by the absence of EPR signal in those crystals despite a rather high— $\sim 7 \times 10^{19} \text{ cm}^{-3}$ —Gd concentration in them. In doped n-type crystals, Te vacancy becomes a dominant point defect. That is why p→n transition from p- to n-type region in doped ingot must be accompanied by a strong increase of V_{Te} concentration. Intensive EPR signal being detected in n-region after transition despite very small increase of Gd concentration, indicates that just Te vacancies are the reason for EPR sensitive state of Gd ion— Gd^{3+} state.

Both the appearance of the EPR spectra in p- $\text{Pb}_{1-x-y}\text{Sn}_x\text{Gd}_y\text{Te}$ crystals for $x = 0.05$ and their rather high intensity for $x = 0$ mean that the difference in degree of order between metal sublattice and chalcogen sublattice becomes lower, while x reduces from 0.2 to 0, so V_{Te} concentration becomes sufficient despite V_{Me} domination. It coincides well with the fact that vacancies in points of the SnTe metal sublattice are generated more easily than in PbTe, because relaxation around the free point gives a larger energy effect [8]. Comparing the absence of the EPR spectra in p-PbTe:Gd crystals and their presence in p- $\text{Pb}_{1-y}\text{Gd}_y\text{Te}$, a conclusion can be drawn that Gd decreases average vacancy concentration in IV–VI crystals more effectively, while it is added as a

hyperstoichiometric dopant into the melt rather than as a metal component substituting dopant. Also it is natural that in that case metal components dominate due to growth conditions making it more difficult to obtain p-type crystals with a dominant Te component in them.

Finally, we would like to pay attention to the following. Besides the correlation described above between EPR data for Gd ions and ^{119}Sn Mössbauer spectroscopy data, experimental results correlate in one important aspect as well. V_{Te} Coulomb field deforms not only cubic symmetry of ^{119}Sn ion local surrounding, which is indicated by line width Γ increasing in Mössbauer spectra, but also deforms, cubic symmetry of Gd ion local surrounding, and that deformation is actually observed in EPR spectra. Fine structure lines positioned in the Gd^{3+} EPR spectra of $\text{Pb}_{1-x}\text{Gd}_x\text{Te}$ is never symmetric, and line intensity ratios never match the binomial 16:12:15:7—a theoretical ratio for paramagnetic ion in the crystal field of cubic symmetry [9]. However, these questions are matter of special investigation.

5. Conclusions

The presented results of experimental investigations of the $\text{Pb}_{1-x}\text{Gd}_x\text{Te}$ single crystals give the seal to the

model according to which gadolinium ions interact with native point defects of crystal lattice during the growth process. One of the results of that interaction is Gd^{3+} charge center creation as a component part of the “Gd impurity–Te vacancy” complex.

Quantum chemical modeling of chlorine-doped defects in a-Se

A.S. Zyubin, O.A. Kondakova*, S.A. Dembovsky

Institute of General and Inorganic Chemistry RAS, Leninsky pr. 31, 119991 Moscow, Russia

Abstract

The structure and stability of chlorine-doped defects in amorphous Se were investigated by means of quantum chemical modeling in the frame of cluster approach at B3LYP level. It was found that formation of isolated charged defects (valence alternative pair) is energetically unfavorable. The most stable are terminal positions of Cl atoms at the Se chains (Cl–(Se–)_n). The interaction of Cl-containing fragments of such chains with Se chains or rings so as with hypervalent configurations (HVC) with over-coordinated Se atoms leads to formation of new Cl-doped defects with over-coordinated Se and Cl atoms. Similar configurations are able to activate bonds switching in process of network rearrangement and transformation of HVC to usual network fragments. The destruction of HVC should reduce the concentration of traps for charge carriers. © 2001 Elsevier Science B.V. All rights reserved.

PACS: 31.15.A

Keywords: a-Se; Structure; Defects; Quantum chemical modeling

1. Introduction

In accordance to Refs. [1–3], the introducing of small amount of Cl impurity (~1%) leads to drastic change of viscosity and the electrical characteristics of a-Se, in spite of the preceding proposal about a negligible influence such small additions at the properties of non-crystalline semiconductors. The acute drop of resistance up to 10⁹ Ωcm in a chlorine-doped selenium is accompanied by lowering of conductivity activation energy on 0.26 eV in comparison with non-doped a-Se. The similar results were obtained in the investigations of chlorine-doped liquid selenium [4].

The mechanism of such influence is still unclear. The main previous hypothesis is based on the model of charged centers D⁺, D[−] [5,6]. It is proposed that Cl atoms terminate already existing dangling bonds (D) or instill into Se–Se bonds destroying them with formation of Cl–(Se–)_n chains. In such cases, the Cl atoms are unable to form free charge carriers. In accordance with another variant Cl atom occupies the interstitial position attracting one electron from the lone pair of Se atom and forming C₂⁺ and Cl[−] centers with arising of volume

charge. Such interstitial Cl[−] atoms believed to be the main donor centers [3–5]. At the same time aside from C₂⁺ centers the chlorine atoms can form the other kinds of electron traps in a-Se [7,8]. The halogenated a-Se has a p-type of conductivity the same as the undoped selenium.

The introducing of Cl impurity into a-Se leads to formation of two additional bands (335 and 960 cm^{−1}) in the IR spectrum [9]. The first one is interpreted reliable enough as a vibration of Se–Cl terminal bond. The origin of the second band is still unclear.

The aim of this work is to consider the possible variants of Cl implantation into a-Se network, to investigate the structure and stability of charged and neutral Cl-containing defects, to estimate the participation of such defects in transformation of a-Se network and in destruction of HVC such as VAP-d and C₄⁰ described in the previous papers [10,11].

2. Calculation details

The calculations of the model systems were carried out in the frame of cluster model with (–Se–)_n chains as the main fragments of a-Se network, with termination of the boundary bonds by the H atoms. As a rule the active

*Corresponding author. Fax: +7-095-954-1279.

E-mail address: olgakond@hotmail.ru (O.A. Kondakova).

regions of model clusters were surrounded by two Se–Se links; in this case the influence of boundary atoms onto active region is weak. The geometry optimization was made at B3LYP approach [12] (density functional method). The influence of core electrons was modeled by LANL2 pseudopotential [13] with the appropriate split-valence basis set with the addition of polarizing d-AO. The relative energies of the optimized configurations were refined at the MP2 level (second order of the perturbation theory at the Moller–Plesset scheme). The calculations were made with GAUSSIAN-94 package [14]. The transition states were localized by QST2 method [14].

3. Results

The basic elements of a-Se network are the $(\text{--Se})_n$ chains. The interaction of Cl_2 molecules with such units leads to the more short new chains $\text{Cl}(\text{--Se})_m$ with Cl atoms at the terminal positions. The charge transfer to Cl atom is not very essential $\sim 0.17e$. The appropriate energy lowering calculated at B3LYP level is $\sim 0.82\text{ eV}$. The energies of $(\text{--Se})_n$ and $\text{Cl}(\text{--Se})_m$ chains were taken as zero for determination of relative stabilities of various Cl-containing defects.

The charged defects (valence alternative pair, VAP) were calculated with localization at Cl-containing defects both negative and positive charges. The Cl^+ center is able to form two bonds, and the appropriate configurations 1A and 1B (Fig. 1) were considered with three-coordinated negative center $\text{Se}(3,-)$ (1D, Fig. 1) [11,12] as counterpart (the notation $A(k,-)$ or $A(k,+)$ corresponds to charged defects, k is coordination number of atom A). The relative energies of such pairs are significantly higher than for initial chains (Table 1). The attempts to form interstitial Cl^- center in configuration similar to 1B leads to configuration 1C with single-coordinated Cl and three-coordinated Se atoms, similar to $\text{Se}(3,-)$ center [11,12], but with $\text{Cl}(\text{--Se})_m$ chain instead $(\text{--Se})_n$ one. The relative energy of such defect with positive $\text{Se}(3,+)$ counterpart (1D, Fig. 1) is high as well (Table 1). So, Cl-containing VAPs in Cl-doped a-Se have too high relative energies, similarly to pure a-Se. Additionally, we tried to check the possibility of interstitial location of neutral Cl atom, placing it near the middle of $(\text{--Se})_n$ chain. In this case, the nearest to Cl Se–Se bond was broken with formation of new $\text{Cl}(\text{--Se})_m$ chain and Se chain fragment with dangling bond. The formation of Cl^- center with redistributed positive charge at nearest Se atoms was not found.

The neutral Cl-containing defects is possible to form by interaction of Cl–Se terminal bond from $\text{Cl}(\text{--Se})_m$ chain with fragments of usual Se chain or HVC-defects in a-Se such as VAD-d or C_4^0 (Fig. 2). The rapprochement of Cl–Se bond and polar $>\text{Se}(\text{--Se})_n$ fragment of

Fig. 1. Schematic representation of the charged Cl-containing defects.

VAP-d leads to formation of 3A transition state, passing to 3C structure. The barrier height for such transformation is not high ($\sim 0.5\text{ eV}$ at B3LYP level), and relative energies for the both configurations are lower than Se–Se bond energy (Table 1). The implantation of the Cl–Se fragment into 'weak' bond of C_4^0 HVC produces 3B TS (Fig. 3), which is transformed into the same 3C structure and usual Se chain. In this case, the barrier is slightly higher, nevertheless it is lower than 1 eV (Table 1). The 3C configuration is similar to C_4^0 HVC of a-Se, but with Cl atom instead of $(\text{--Se})_k$ half-chain. It is possible to transform this Cl-containing HVC into new local minimum with just the same relative energy (Fig. 3, 3D), by reducing of approximately linear Cl–Se–Se angle to $\sim 60^\circ$. The barrier value for such transformation is small, ~ 0.3 and $\sim 0.4\text{ eV}$ at B3LYP and MP2 levels. The central fragment of this configuration has bi-pyramidal shape with similar Cl–Se and Se–Se bonds (Fig. 3). The 3D structure is ready to split into $\text{Cl}(\text{--Se})_m$ and usual Se chains by three different ways, passing through the barriers $\sim 0.44\text{ eV}$ (Table 1). This opportunity is able to change the direction of Se–Se chain. The relative energy of the appropriate TS is not very high (Table 1), and it is possible to form the 3D configurations directly from $\text{Cl}(\text{--Se})_m$ and usual Se chains. Such configuration is able to reduce the activation energy of bonds switching and network transformation in Cl-doped a-Se. The bonds switching with participating of

pure Se chains is related with potential barrier ~ 1.7 eV at the B3LYP level.

4. Conclusions

According to the obtained results the most energy favorable positions of chlorine atoms in the a-Se network are at the end of Se chains. In this case, Cl atoms terminate the Se–Se dangling bonds. The charged defects are very unstable and their concentration should be low. The interaction of terminal Cl–Se bonds with Se chains and with hypervalent configurations presented in a-Se creates neutral Cl-containing defects participating in bonds switching and destruction of HVC. Similar mechanisms are able to lower the activation energy of network transformation and to reduce concentration of HVC which are traps of charge carriers in a-Se.

Abstract

The photoluminescence (PL) properties of vacuum-deposited CuGaS₂, produced by the co-evaporation of elemental sources, is reported for the first time. Free excitonic PL is observed up to room temperature. The green PL dominating at ~2.4 eV for slightly Ga-rich material, and at ~2.3 eV for slightly Cu-rich material, involves shallow donor–acceptor pair recombination. It appears that the same shallow donor with binding energy ~53 meV is involved in the recombination process. The dominant acceptor in Cu-rich material is obtained at ~210 meV above the valence band, while a shallower acceptor dominates in Ga-rich material. Possible origins of these defects are proposed. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: CuGaS₂; Vacuum deposition; Photoluminescence

1. Introduction

CuGaS₂ is a member of the I–III–VI₂ chalcopyrite semiconductor family, with a direct band gap energy of 2.53 eV at 0 K [1]. It is epitaxially compatible with III–V substrates such as GaAs and GaP and can be grown at moderate temperatures [2]. To date, n-type material has not been realized. Despite its attractiveness for optoelectronic applications, there is presently only an elementary understanding of the influence of intrinsic defects on the radiative processes in the material. This is true for most of the chalcopyrite semiconductors, a possible exception being CuInSe₂, for which a coherent picture is beginning to emerge [3]. For CuGaS₂ the poor understanding at present arises mainly from a lack of experimental data, and from the fact that the composition of the material investigated is often unknown. Furthermore, the formation energies for intrinsic defects have not been determined. In order to gain more clarity on the defect chemistry in CuGaS₂, it is essential to study the dependence of the optical and electrical properties on stoichiometry. The required control over

this parameter is best obtained during epitaxial growth. In the present work, epitaxial growth was achieved by co-evaporation of elemental sources onto heated GaAs substrates. Preliminary results on the photoluminescence (PL) of slightly Cu-rich and Ga-rich material is discussed. This is the first demonstration of PL from layers produced by this method.

2. Experimental details

Thin films of CuGaS₂ were produced in vacuum (background pressure $\cong 10^{-5}$ Torr) by the co-evaporation of the three elemental sources onto GaAs(100) substrates, heated to 600°C. The Cu, Ga and S sources (99.999% purity or better) were kept at ~1150°C, 850°C and 80°C, respectively. X-ray diffraction on the layers always revealed the diffraction peaks expected for the chalcopyrite phase and indicated that the layers were preferentially orientated either with the *c*-axis or the *a*-axis perpendicular to the substrate. Layer thicknesses varied between 0.4 μm and 0.8 μm. The composition of the layers was determined from energy dispersive X-ray spectroscopy. The surfaces of Ga-rich layers had a slight grainy texture, while layers deposited under Cu-rich

E-mail address: botha@physik.tu-dresden.de (J.R. Botha).

conditions became increasingly covered in crystallites containing only Cu and S in the atomic ratio of approximately 1:1. PL spectra were obtained using an Ar⁺-laser (458 nm) or a Kr⁺-laser (413 nm) for excitation. The luminescence was dispersed by a 1 m monochromator (calibrated with the 632.8 nm line of a HeNe laser) and detected using a GaAs photomultiplier.

3. Results and discussion

In Fig. 1 the 4.2 K PL spectra obtained for layers with different compositions are compared. The S-content varied between 46 and 49 at%. For slightly Cu-rich material, the spectra are dominated by lines between 539.0 nm (2.300 eV) and ~560.0 nm. For slightly Ga-rich material, the dominant line is at 517.0 nm (2.398 eV). Smaller Cu/Ga-ratios ($\ll 1$) lead to a quenching of the near-band edge PL in favor of broad bands involving deeper lying states. For layers #1 to #4, weak luminescence is also observed between 495 and 505 nm. In this paper, the PL measured for layers #1 and #4 (subsequently referred to as Cu-rich and Ga-rich) in the range 490 nm to 560 nm, will be discussed. It will only be mentioned that the PL observed above 600 nm for some layers, appears to be typical for S-poor material: the broad band seen for layer #3 (but almost absent for layer #2) has been suggested by Massé [4] to involve S-vacancies, since it disappeared when chemical vapor transport (CVT) grown single crystals were annealed in a S atmosphere.

Fig. 1. Typical PL spectra measured at 4.2 K for vacuum-deposited CuGaS₂ with different compositions.

The PL measured for slightly Cu- and Ga-rich material in the range 490–505 nm, is compared in Fig. 2. For the Cu-rich layer, five lines are distinguished at ~495.5 nm (2.502 eV), 497.3 nm (2.493 eV), 498.9 nm (2.485 eV), 500.5 nm (2.477 eV) and 503.1 nm (2.464 eV). Also indicated are the reported range for the recombination of free excitons (FX) in single crystals [1,5] and the calculated positions for donor-bound (D^0, X) and acceptor-bound (A^0, X) exciton recombination, using binding energies for effective mass donors and acceptors of 48 meV and 127 meV, respectively. Effective masses for electrons and holes of $0.26m_0$ and $0.69m_0$, respectively [6] and a dielectric constant $\epsilon_0 = 8.6$ [5] were used, while the binding energies of the bound excitons were estimated from Atzmüller et al. [7]. The peaks measured at ~495.5 nm and 497.3 nm are attributed to FX and (D^0, X) recombination, respectively. The donor involved in the latter transition is probably the same defect giving rise to the line at 500.5 nm (i.e. 53 meV below E_g), the position of which correlates very well with the calculated position (499.5 nm; 2.482 eV) for a transition between a neutral effective mass donor and the valence band (D^0, h). The line at 498.9 nm does not involve an effective mass acceptor, but is attributed to an exciton bound to a deeper acceptor, as discussed below. The line at 503.1 nm is of unknown origin.

The PL for Ga-rich material is broader with a maximum at ~496.7 nm (2.496 eV) and a shoulder at ~498.5 nm (2.487 eV). The latter is of extrinsic origin (i.e. involves defects/impurities) and disappeared above 120 K, while the former line persisted up to 290 K. The energy shift measured for the 496.7 nm line relative to its position at 1.9 K is plotted in Fig. 3 (circles) versus temperature, and compared with the reported change of the A-exciton position obtained from photoreflectance measurements on CVT-grown single crystals [2]. From the identical shifts observed, it is concluded that the line is due to FX recombination.

Fig. 2. Comparison of low temperature PL for slightly Cu-rich and Ga-rich material in the excitonic spectral range.

Fig. 3. Temperature dependence for the positions of the PL lines at ~ 496.7 nm in Ga-rich, and at 539.0 nm in Cu-rich material. The dotted lines are guides to the eye.

Fig. 4. Laser power induced shift at 4.2 K for the PL lines at 517.0 nm in Ga-rich and at 539.0 nm in Cu-rich material. The solid lines are least-squares-fits to Eq. (1).

The strong green PL from slightly Cu-rich material (layer #1-Fig. 1) is attributed to donor-acceptor (D^0, A^0) pair transitions, which interact with lattice phonons. Typically, up to four lines are observed. The intensities are Poisson distributed, and the energy spacing is ~ 45 meV, which correlates with the highest energy $\Gamma(\text{LO})$ phonon modes (43.1, 48 and 49.5 meV [8]). The energy shift of the zero phonon line relative to 3.8 K, is also shown in Fig. 3 (squares). Between 60 K and 120 K the line “blue-shifts” by ~ 14 meV. At the same time, a shoulder was seen to develop on its high-energy side (inset Fig. 3) at ~ 534.0 nm (2.322 eV). These results are consistent with the evolution of a free-to-bound type of transition from the pair emission, where the deeper center involved has a binding energy of ~ 210 meV. In the same temperature range, the integrated PL intensity for the series of lines was thermally quenched with an activation energy of 53 ± 9 meV, which is ascribed to the ionization of the shallower center. The participation of a shallow center is also deduced from the dependence of the zero phonon line energy $h\nu_m$ on laser power (P). This is plotted in Fig. 4 (squares). The solid line is a best-fit using the expression [9]:

$$P = D \frac{(h\nu_m - h\nu_{\text{inf}})^3}{h\nu_B + h\nu_{\text{inf}} - 2h\nu_m} \exp\left(-\frac{2(h\nu_B - h\nu_{\text{inf}})}{h\nu_m - h\nu_{\text{inf}}}\right). \quad (1)$$

Here, D is a proportionality constant, $h\nu_{\text{inf}}$ is the peak position for infinite pair separation, and $h\nu_B - h\nu_{\text{inf}}$ yields the binding energy of the shallower species. The fit yields a binding energy for the shallower defect of 32 ± 4 meV (the error excludes the errors in the data). A comparison of this value and the 53 meV thermal activation for the quenching of the PL, with the position of the line at 2.477 eV, strongly suggests

that the shallower level is an effective mass-like donor with binding energy of 53 meV, and that the level at ~ 210 meV from the band edge is due to an acceptor. This acceptor is probably also the center binding the exciton, giving rise to the line at 498.9 nm in Fig. 2.

The green PL at 517.0 nm (phonon replica at 527.0 nm) dominating for slightly Ga-rich material, also appears to be (D^0, A^0) in nature. Between 30 and 80 K this line was quenched with an activation energy of 45 ± 5 meV. The shift of the zero phonon line with laser power (Fig. 4, circles) is again typical for pair emission involving an effective mass-like center. A binding energy for the shallower center of 16 ± 4 meV was extracted from the fit to Eq. (1) (solid line), which will contain a large uncertainty due to the limited range of laser power studied.

In summary, it is tempting to assume from the above, that the same shallow level is involved in the green PL dominating for both Cu- and Ga-rich layers. The most likely candidate is the donor at ~ 53 meV below the conduction band edge, deduced from the PL for the slightly Cu-rich layer. Since both layers are S-deficient, this donor is possibly the S-vacancy. A change in the Cu/Ga-ratio then seems to change the dominant acceptor forming in the material, with the acceptor level in Cu-rich material being ~ 210 meV above the valence band. A possible candidate for this acceptor, is the Cu_{Ga} -antisite. The binding energy of the deeper center involved in the pair luminescence for the Ga-rich layer, has not been determined here. However, the green PL at ~ 2.40 eV is typical for Ga-rich and S-deficient single crystals [10]. Bellabarba et al. [5] deduced from absorption measurements that the dominant acceptor in such material is 89 meV

above the valence band and ascribed it to the Cu-vacancy (V_{Cu}). It should also be noted that Zhang et al. [3] recently calculated that for n-type CuInSe_2 (i.e. Se-poor material), the Cu_{In} -antisite has the lowest formation energy in Cu-rich material, while the V_{Cu} has the lowest formation energy in In-rich material. If the same order holds for the corresponding defects in CuGaS_2 , it would fit in excellently with the above assignments. However, in the absence of calculated defect formation energies for CuGaS_2 , any defect assignment remains speculative.

Abstract

Cu_xS is one of the most prevalent minor phases co-existing in CuInS_2 films. In order to understand its influence on CuInS_2 , we first focus our study on the binary compound Cu_xS . Cu_2S and CuS films were deposited on float glass substrates using a reactive RF sputter process with optimized sputter parameters, such as power, temperature of the substrate, and the gas flow of the H_2S . X-ray diffraction spectra showed that the Cu_2S films have (002) preferential orientation, and both compounds have a hexagonal structure. The surface morphology and the composition of the layers were analyzed by atomic force microscopy and Rutherford back-scattering spectroscopy, respectively. X-ray photoelectron spectroscopy and ultraviolet photoelectron spectroscopy were used to characterize the layer surfaces, as well as the surface composition. Hall-effect measurements were carried out to determine the electrical properties of the films. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

With a direct band gap of 1.55 eV and a high absorption coefficient of more than 10^4 cm^{-1} , CuInS_2 (CIS) has been regarded as a promising absorber for thin film solar cell applications [1]. So far, solar cells based on the CIS have achieved an energy total area conversion efficiency of 11.4% [2]. Cu_xS is one of the most prevalent minor phases co-existing in the CIS films independent from the production techniques and plays an important role both on the structural and electrical properties of the CIS. On the other hand, the Cu_xS ($x = 1\text{--}2$) thin films themselves are of interest due to numerous technological applications such as in applications of solar cells [3], in photothermal conversion of solar energy as solar

absorber coatings [4], and as selective radiation filters in architectural windows [5], as well as in electroconductive coatings deposited on organic polymers [6]. So it is important and interesting to study Cu_xS films from both points of view.

Up to date, several methods have been used to produce CIS and Cu_xS films [1,7]. The sputtering technique has the potential for industrial applications due to its advantages of simple and flexible control of the film stoichiometry over a large scale at relatively low cost. The initial goal of this work is to deposit CIS films by radio frequency (RF) reactive sputtering in one step. Prior to this, Cu_xS films have been prepared by the same process for comparison.

2. Experimental

Cu_xS films were prepared on bare float glass substrates by a reactive sputtering process. High-purity

*Corresponding author. Tel.: +49-641-99-33137; fax: +49-641-99-33119.

E-mail address: yunbin.he@physik.uni-giessen.de (Y.B. He).

(99.999%) argon was used to provide the plasma at a base pressure of 10^{-6} Torr, and H_2S (purity: 98.0%) was injected as reactive gas during the sputtering. A metallic 99.999% Cu circular plate with a diameter of 10.16 cm was used as the sputter target. The RF power was in the range between 50 and 300 W ($0.62\text{--}3.70\text{ W cm}^{-2}$), while the H_2S flow was varied from 2.0 to 10 sccm. The substrate temperature was changed from room temperature to 500°C . Typically the film thickness was in the range between 50 and 600 nm mainly depending on the sputtering power and time.

The structure of the layers was studied by X-ray Diffraction (XRD) using a Siemens D5000 diffractometer with $\text{Cu K}\alpha$ ($\lambda = 1.5418\text{ \AA}$) radiation. The surface morphology of the layers was studied by atomic force microscopy (AFM). Photoemission (XPS, UPS) experiments were performed using a VG ESCA system at a photon energy of 1253.6 eV ($\text{Mg K}\alpha$ radiation). The sample surface was sputtered with 4 kV Ar ions. The electrical properties, such as the carrier concentration, Hall mobility, and specific resistivity of the films were characterized by Hall-effect measurements in the temperature range between 77 and 400 K.

3. Results and discussion

3.1. X-ray diffraction

Fig. 1 shows the XRD spectra of θ – 2θ mode of three samples, and the standard JCPDS patterns of Cu, Cu_2S and CuS for comparison. It is clearly seen that pure Cu co-exists in the film when the H_2S flow is too low (Fig. 1a). The pure Cu_2S films with hexagonal structure can be obtained when the H_2S flow is sufficient, i.e. in the range of 5.0–9.0 sccm. These films have highly (002) preferential orientation (Fig. 1b), since only reflections from the (002), (004), and (006) planes are detected by the XRD. The full-width at half-maximum (FWHM) of the (004) diffraction peak is about 0.24° , which means the crystallinity of the films is very good. In our experiments, the main parameter for controlling the Cu/S ratio of the films is the H_2S flow, as well as the sputter power. By increasing the H_2S flow and decreasing the sputter power at the same time, pure CuS films with hexagonal structure were deposited (see Fig. 1c). These films are randomly distributed polycrystalline films.

3.2. Atomic force microscopy and scanning electron microscopy

The Cu cones segregation on the surface of the samples sputtered with insufficient H_2S flow can be directly observed by scanning electron microscopy

Fig. 1. The XRD spectra of samples sputtered under different conditions. Sample (a) was sputtered at 500°C with a sputter power of 200 W and H_2S flow of 3.5 sccm; sample (b) was sputtered at room temperature with a sputter power of 200 W and H_2S flow of 8.0 sccm; and sample (c) was sputtered at 200°C with a sputter power of 50 W and H_2S flow of 10.05 sccm.

(SEM) as shown in Fig. 2a. This confirms the XRD measurement on the same sample (Fig. 1a). Both pure Cu_2S and CuS films have very good crystallinity, which is not only indicated by the XRD measurements, but also directly supported by the AFM images of the surface of the samples (see Fig. 2b–e). While the Cu_2S film has an average grain size of about 200 nm, the CuS films show relatively smaller grains of around 80 nm, which is mainly due to the relatively lower sputter power. Compared with the CuS films, the Cu_2S films show more uniform and well-grown columnar grains on the surface.

3.3. XPS and UPS characterization

For surface characterization, XPS and UPS studies of Cu_xS samples with varying x values were carried out. The spectra were obtained from films cleaned by a short Ar^+ ion etching prior to the measurement to remove the surface contaminants. Two different samples were chosen for comparison: a CuS film with a Cu/S ratio of 1:1 and another with a Cu/S ratio of 3:2. These stoichiometry values were calculated by quantitative analysis of the XPS-spectra (Fig. 3a and b).

The UPS spectra of these two films are shown in Fig. 3c. The most striking difference is a shift of curve A (stoichiometric CuS) towards lower binding energies.

Fig. 2. The SEM and AFM images of the surface of different samples. (a) The SEM image of Cu cones on the surface of sample (a) of Fig. 1; (b) two-dimensional and (c) three-dimensional AFM images of sample (b) of Fig. 1; (d) two-dimensional and (e) three-dimensional AFM images of sample (c) of Fig. 1.

The valence band maximum reaches the Fermi energy at 0 eV, indicating the metallic properties of the film. Curve B (Cu-rich sample) is clearly recognizable as semiconducting due to its gap of 0.5 eV between the valence band maximum and the Fermi energy. The XPS spectra (Fig. 3a and b) show the same shift switching from the metallic to the semiconducting state.

3.4. Hall-effect measurements

Hall-effect measurements were carried out to study the electrical properties of the Cu₂S and CuS films. The carrier (hole) concentrations, Hall mobilities, and specific resistivities of the Cu₂S films range from

1×10^{18} to $3 \times 10^{19} \text{ cm}^{-3}$, 10 to $4 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, and 0.8 to $0.04 \Omega \text{ cm}$, respectively, within the temperature interval from 90 to 400 K. At room temperature, the values are $1.0 \times 10^{19} \text{ cm}^{-3}$, $6 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, and $0.1 \Omega \text{ cm}$, respectively, which is in agreement with the results of Ref. [8]. In principle, the hole concentration p is dependent on the temperature by

$$p \propto \exp[-\Delta E_A/kT], \quad (1)$$

where ΔE_A is the activation energy of the acceptor, k is the Boltzmann constant, and T is the temperature. A semi-log plot of the hole concentration versus the reciprocal temperature for a typical Cu₂S film is

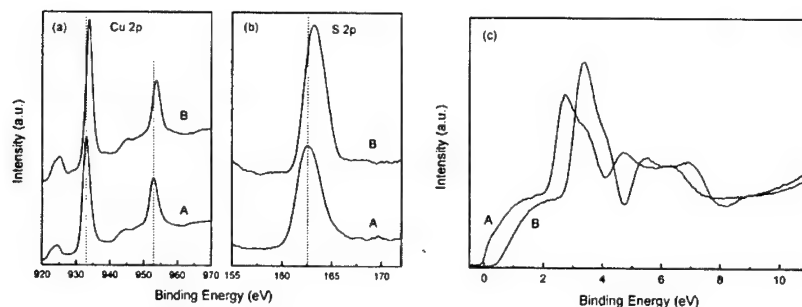

Fig. 3. The XPS spectra of Cu 2p (a) and S 2p (b) peaks, and the UPS spectra (c) of two films: A: CuS and B: Cu₃S₂.

Fig. 4. The temperature dependence of the hole concentration of the Cu₃S films.

Fig. 5. The temperature dependence of the specific resistivity of the CuS films and Cu₃S films.

presented in Fig. 4. Three activation energies can be estimated as 106 ± 5 , 38 ± 2 , and 4 meV, respectively. The first two are in line with the results given by Ref. [8], and may be related to intrinsic acceptors i.e. the Cu vacancies. The small activation energy observed at low temperatures indicates hopping transport.

Compared with Cu₃S, CuS has a much higher carrier concentration (hole) of around 10^{22} cm^{-3} , which results in a remarkably lower resistivity of about $10^{-4} \Omega \text{ cm}$. The resistivity increases with temperature slightly and almost linearly (see Fig. 5), which is the typical characteristic of the metallic phase, in good agreement with the XPS and UPS results. The CuS film has a lower Hall mobility than the Cu₃S in the range of $1\text{--}4 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ mainly due to the higher carrier concentration.

4. Conclusion

Cu₂S and CuS films with good crystallinity have been deposited on bare float glass substrates by RF reactive sputtering. Both films have hexagonal crystal structures at RT as studied by the XRD. Typically Cu₂S films are highly (002) oriented with the FWHM of the (004) peak of about 0.24° . There are Cu precipitate cones coexisting in the Cu₂S films when the H₂S flow during sputtering is not high enough. Two activation energies related to the intrinsic defects in the Cu₂S films have been found by Hall-effect measurements. The CuS is in the metallic phase at RT, and has a relatively high carrier concentration around 10^{22} cm^{-3} , a much lower resistivity of about $10^{-4} \Omega \text{ cm}$, and a slightly lower Hall mobility of about $3 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ compared with the semi-conducting phase Cu₂S.

Abstract

The ternary compound semiconductor CuInS_2 has attracted much attention owing to its potential applications in photovoltaic devices. We deposit CuInS_2 films on float glass substrates by a reactive radio frequency sputter process using a Cu–In inlay target and H_2S gas in one step. The morphology of the films was studied by Atomic Force Microscopy. X-ray Diffraction was used to check the crystal structure of the films. The composition of the layers was determined by Rutherford Back-scattering Spectroscopy and Energy-Dispersive X-ray Analysis. The electrical properties of the layers, i.e. the carrier concentration, Hall mobility, and specific resistivity and their dependencies on temperature were investigated by Hall effect measurements. © 2001 Elsevier Science B.V. Keywords: CuInS_2 ; Thin films; Photovoltaic; Defects

1. Introduction

Recently the ternary compound semiconductor CuInS_2 (CIS) has attracted much attention due to its potential applications in photovoltaic devices. Solar cells based on CIS with a total area efficiency of 11.4% have been demonstrated using a rapid thermal process [1]. Usually, Cu-rich films are grown for efficient solar cells, which leads to the formation of a CuS secondary phase on the film surfaces. This phase is subsequently removed by chemical etching with potassium cyanide (KCN). From In-rich films, on the other hand, in which CuIn_3S_8 or In_2S_3 secondary phases co-exist, it was not possible to produce efficient solar cell devices [2,3].

We try to prepare CIS films by a radio frequency (RF) reactive sputter process, using a Cu–In inlay target with H_2S as reactive gas in one step. The crystallinity of the as-sputtered films is studied by X-ray diffraction (XRD) measurements, which indicate that the films are highly (112) oriented CIS films. The composition characterization of the films by both Rutherford back-scattering

spectroscopy (RBS) and energy-dispersive X-ray analysis (EDX) reveals that the films are extremely Cu-rich, i.e. the Cu to In ratio strongly deviates from 1. To resolve the contradiction between XRD and composition results, only the Cu–S binary compound has been sputtered in the same equipment using a pure Cu target and H_2S gas. XRD shows that the sputtered Cu_xS films are also highly oriented, and their XRD peaks are very close to that of as-sputtered “CIS” films. This indicates that the main phases of our “CIS” films are CuS and Cu_2S , which clarifies the problem mentioned above.

2. Experimental

Cu–In–S films were prepared on bare float glass substrates by a reactive sputter process with a conventional RF (13.56 MHz) sputter setup. High purity (99.999%) argon was used to provide the plasma at a base pressure of 10^{-6} Torr, and H_2S (purity: 98.0%) was introduced as reactive gas during the sputtering. A Cu metal disk inlaid by In with the area ratio Cu/In about 1 and diameter of 10.16 cm was used as sputter target. The RF sputter power was in the range between 100 and 500 W ($1.23\text{--}6.15\text{ W cm}^{-2}$), while the H_2S flow was varied from 3 to 10 sccm. The substrate temperature

E-mail address: yunbin.he@physik.uni-giessen.de (Y.B. He).

was changed from room temperature to 400°C. Typically the as-sputtered film thickness was in the range from 175 to 1000 nm within a sputter time between 5 and 30 min.

The structures of the layers were studied by XRD using a Siemens D5000 diffractometer with Cu K_{α} ($\lambda = 1.5418 \text{ \AA}$) radiation. Atomic force microscopy (AFM) was used to observe the surface morphology of the layers. The composition of the layers was analyzed by EDX (SiLi-detector with an ultrathin window (UTW) installed in a Philips XL20 SEM equipment) and RBS, respectively. The electrical properties of the films in the range between 77 and 400 K were characterized by Hall effect measurements.

3. Results and discussion

Fig. 1 shows the AFM images on the surface of a typical film, which was sputtered for 15 min at 200°C with a sputter power of 300 W and a H_2S flow of 8.0 sccm. The surface is smooth with the root mean square (RMS) roughness of 4.05 nm, which is derived by AFM, consisting of uniformly sized and densely packed grains. The columnar-shaped and well-grown grains are distributed with an obviously preferential orientation as shown in Fig. 1a and b, which is also revealed by XRD measurements (see below).

A typical XRD spectrum of sputtered film is shown in Fig. 2a. There are only three diffraction peaks appearing at 2θ of 27.80°, 54.40°, and 57.40°, which seem to correspond to the (1 1 2), (1 1 6), and (2 2 4) peaks of CIS, respectively, as compared with the standard CIS pattern: Joint Committee on Powder Diffraction Standards (JCPDS) file 27-0159. It seems that the film is a nearly stoichiometric CIS film with a (1 1 2) preferential orientation in accordance with AFM measurements described above. However, the composition analysis as examined by RBS shows a surprising result—the film is extremely Cu-rich, and there is only very little In content in the film with Cu 49%, In 4%, S 47%, respectively (see Fig. 3a). To be sure, EDX measurements (Fig. 3b) have been carried out from the cross section of the same sample. A comparable result with RBS has been obtained: Cu 50%, In 8%, S 42%, respectively, which means that the In content is too low throughout the whole layer, not only in the surface region, but also in the bulk material. Usually, for Cu-rich CIS films deposited by other techniques, there is only In deficiency on the surface due to secondary phases such as CuS and Cu_2S segregations [2]. However, our sputtered films are completely non-stoichiometric CIS with a low In content throughout the whole layer in a way contradicting with the XRD measurements.

In order to clarify the problem, Cu–S binary compound films were sputtered with identical para-

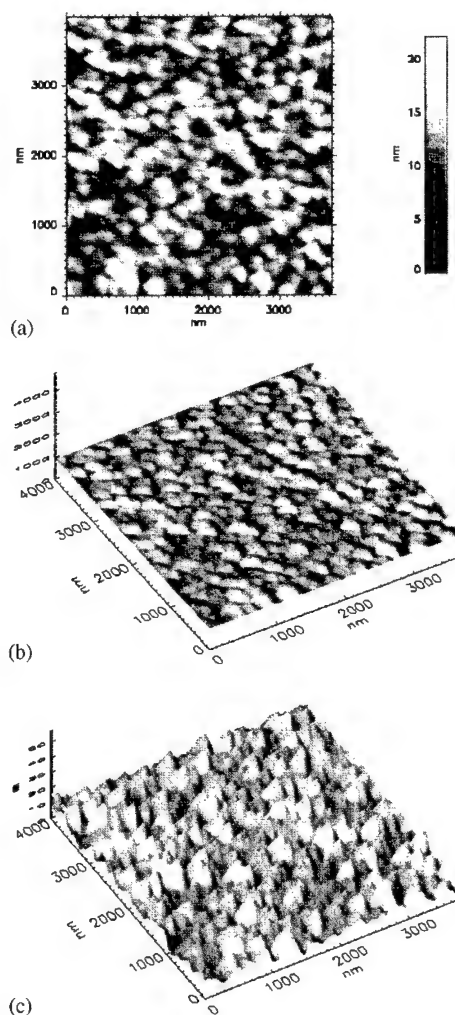

Fig. 1. AFM images on the surface of a typical as-sputtered film. (a) Top view (two-dimensional). (b) Three-dimensional image with the same Z scale as X, Y. (c) Three-dimensional image with the Z scale from 0 to 60 nm.

eters for comparison. As can be seen in Fig. 2b the as-sputtered Cu_2S film is completely oriented with (0 0 2) plane parallel to the substrate, and its (0 0 2), (0 0 4) diffraction peaks overlap exactly with two peaks of “CIS” around 26.45° and 54.40°, which means the formerly identified “CIS” (1 1 6) peak actually originates mainly from Cu_2S (0 0 4). Similarly, comparing the XRD of the “CIS” film with that of CuS, one can clearly see that the formerly identified “CIS” (1 1 2) and (2 2 4) peaks are mainly from CuS (1 0 1) and (2 0 2) peaks, respectively. Now, our puzzle about the conflict between XRD and composition measurements has been clarified. The sputtered “CIS” films consist of three phases: CuS, Cu_2S , and $CuInS_2$, and the In to Cu ratio strongly deviates from 1. Although in Ref. [4] it is reported that

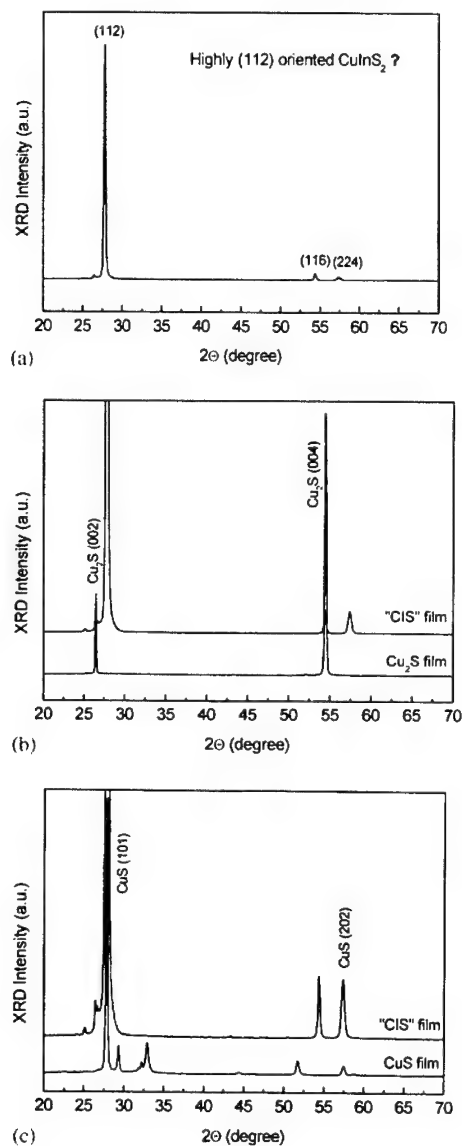

Fig. 2. (a) Typical XRD spectra of an as-sputtered "CIS" film; (b) Comparison of XRD spectra of sputtered a "CIS" film and a Cu_2S film; (c) Comparison of XRD spectra of sputtered a "CIS" film and a CuS film.

stoichiometric CIS films can be produced by a DC reactive sputtering process using a fan-shaped Cu and In metal target with CS_2 introduced as reactive gas, according to our experiments, it is hardly possible to deposit stoichiometric CIS films by a reactive sputtering process using a Cu–In inlay metallic target with a H_2S gas flow. We noticed that there is a black-colored top layer covering the surface of the In inlay after the target has been sputtered for several ten times. We speculate it is an In–S compound due to the reaction of the metallic In with the H_2S gas during sputtering. This top layer on

Fig. 3. Composition characterization of a typical film by (a) RBS and (b) EDX.

the In inlay reduces the sputter rate of In, and results in a considerably lower In/Cu ratio in the sputtered films. So the In/Cu ratio in the sputtered films not only depends on its area ratio in the target, but is also influenced by the H_2S flow amount and period. Therefore, the content of Cu and In in the layers may strongly and in a delicate way deviate from its original ratio in the target. By using a Cu–In alloy target instead of the inlay target the problem described above has been overcome, and nearly stoichiometric CIS films have been deposited by the same sputtering process [5].

Characterization of the electrical properties of the films were done by Hall effect measurements. In general, the carrier concentration, Hall mobility and specific resistivity of the sputtered Cu-rich "CIS" films are in the range between 3.55×10^{17} to $1.58 \times 10^{19} \text{ cm}^{-3}$, 4.15 to $1.15 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, and 4.24 to $0.35 \Omega \text{ cm}$, respectively, for temperatures between 77 and 350 K. Compared with stoichiometric CIS single crystals and thin films, the Cu-rich "CIS" films have hole concentrations 2–3 orders of magnitude higher [6,7]. This is partly due to CuS and Cu_2S phases co-existing in the films. It is known that CuS is metallic at room temperature (RT) with a hole concentration of about 10^{22} cm^{-3} . Cu_2S is a semiconductor but can have also relatively high hole

Fig. 4. The temperature dependence of carrier concentration of a sputtered Cu-rich "CIS" film.

concentrations around 10^{19} cm^{-3} at RT [8,9]. By a linear fit to the carrier concentration dependence on temperature (Fig. 4), two thermal activation energies of 126 ± 4 and $19 \pm 2 \text{ meV}$ can be deduced.

4. Summary and conclusions

Cu rich Cu–In–S films with good crystallinity were deposited on float glass substrates by a RF reactive sputter process using a Cu–In inlay target with H_2S as reactive gas in one step. The In/Cu ratio in the sputtered films is much less than 1 although its ratio is nearly 1 in the target. It not only depends on the different sputter yield of In and Cu, but is also influenced by an additional layer covered on the surface of the In inlay due to the reaction of H_2S and In inlay during sputtering. The sputtered film consists of CuS, Cu_2S , and CuInS_2 phases, which results in a strong deficiency

of In in the layer. It is not always reliable to characterize the composition by XRD only. The combination with other kinds of methods for composition examination is necessary, especially when the film is highly oriented and only very few diffraction peaks show up in the XRD spectrum. The hole concentrations of the as-sputtered Cu-rich "CIS" films range between 3.55×10^{17} and $1.58 \times 10^{19} \text{ cm}^{-3}$, for temperatures between 77 and 350 K. The carrier concentration can be tuned from 10^{19} to 10^{17} cm^{-3} by using a Cu–In alloy target as shown in Ref. [5]. From the sputtering process there is still enough freedom to produce CIS films appropriate for solar cells.

EDMR of MEH-PPV LEDs

G.B. Silva^a, L.F. Santos^b, R.M. Faria^b, C.F.O. Graeff^{a,*}^a *Dep. de Física e Matemática, FFCLRP-USP, Av. Bandeirantes 3900, 14040-901 Ribeirão Preto, Brazil*^b *IFSC-USP, CP 369, 13560-970 São Carlos, Brazil*

Abstract

In this work, electrically detected magnetic resonance (EDMR) at X-band is used to study the electronic properties of poly(2-methoxy-5-(2'-etil-hexiloxy)-1,4-phenylene vinylene) (MEH-PPV) light-emitting diodes (LEDs). The EDMR signal from MEH-PPV LEDs is found to be composed of two lines, a Lorentzian with peak-to-peak linewidth of 5 G, and a Gaussian with peak-to-peak linewidth of 24 G. The g -factor of both the components is about 2.002. The EDMR signal amplitude is typically 10^{-5} , and only observed at forward bias, for $V > 10$ V. The signal is a quenching, and is assigned to the spin-dependent fusion of two like-charged polarons to spinless bipolarons. The Lorentzian component is attributed to positive polarons fusion, and the Gaussian to negative polarons. The EDMR signal is found to depend on the process of carrier injection, polaron mobility, temperature and indirectly on bipolarons. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: MEH-PPV; LED; Magnetic resonance

1. Introduction

One of the most promising polymers is PPV and its derivatives, showing good processibility and efficiency in optoelectronic devices [1]. Among the various techniques of investigation, electron spin resonance (ESR) has been used intensively [2], since it enables one to directly “see” the polaron, a paramagnetic charge carrier species, which plays a major role in the physics of conjugated polymers. On the contrary, electrically detected magnetic resonance (EDMR), which has provided insight into various transport and recombination processes in a wide array of semiconductors, has not been used frequently [3]. In an EDMR experiment, microwave-induced changes in the conductivity are measured as the sample is subjected to a swept DC magnetic field.

2. Experimental details

The poly(2-methoxy-5-(2'-etil-hexiloxy)-1,4-phenylene vinylene) (MEH-PPV) were obtained through standard procedures [4]. The LED was made using ITO-coated glass as the positive electrode. Over the ITO, a film of MEH-PPV was spin coated using chloroform as solvent. Thermally evaporated Al was used as the negative electrode. Typical MEH-PPV film thickness was around 360 nm. EDMR measurements were done using a modified, computer interfaced Varian E-4 X-Band spectrometer in the temperature range of 145–300 K. In order to avoid degradation induced by O₂ or H₂O, the sample was maintained under a nitrogen flux. The spin-dependent changes of conductivity were measured by modulating the static magnetic field (H_0) and using lock-in detection of the resonant current changes.

The results discussed are obtaining from the investigation of about 7 diodes. An intrinsic problem found in the investigation of these devices was the poor reproducibility of the device itself. For example, the active layer thickness varied from sample to sample; these variations were reflected in the device operation characteristics, in special the luminescence efficiency, and the $I \times V$ curves.

E-mail address: cgraeff@dfm.ffclrp.usp.br (C.F.O. Graeff).

The devices investigated were not encapsulated, and even though we have avoided exposing the diode to air and/or light, which are known to be responsible for the device degradation [5], the operation lifetime was hardly longer than 100 h. We have tried to work as close as possible to the room temperature, in an attempt to make sure that the transport/recombination/injection process that we observe are those that are important for the commercial use of these devices.

3. Results and discussion

Fig. 1 shows the typical EDMR spectra from different MEH-PPV light emitting diodes. The signal could only be observed in forward bias. From a phase analysis dependence on modulation frequency, it is found to be a quenching signal, or in other words, the conductivity of the device decreases in resonance. The LEDs spectra in Fig. 1 have different emission efficiencies, decreasing from (a) to (c). Notice, however, that the $I \times V$ characteristics of these samples are quite comparable. For the conditions shown, $V \approx 18$ V and $T \approx 200$ K, the current was around 2×10^{-4} A. In fact, the LED whose spectra are shown in Fig. 1(c) had an electroluminescence that could not be seen by naked eyes. The spectra in general can be simulated by the composition of two lines, a Lorentzian and a Gaussian. The g -factor of both lines varies from sample to sample between 2.001 and 2.003. The origin of the variation in g -factor is not well known; however, the values are closer to those of commonly found for positive or negative polarons in conjugated conductive polymers [3]. The Lorentzian line has a peak-to-peak linewidth of 5.0 ± 0.5 G, while the Gaussian line has $\Delta H_{pp} = 24 \pm 1$ G. Care was taken so that the signals were not saturated. In the worst

situation, saturation started at about 20 mW. As can be seen in Fig. 1, the relative intensities of both Gaussian and Lorentzian lines are dependent on the light emitting efficiency; the bad emitter has the highest Lorentzian/Gaussian line amplitude ratio. In fact, for the sample just mentioned the Gaussian component is hardly observable.

In the samples, where the Gaussian component had a significant amplitude, it was observed that apart from the in-phase signal, there was also a signal in quadrature. By the adequate change in phase settings, in fact, the Gaussian component could be isolated. This phenomenon has been well described by Dersch et al. [6] in a-Si:H. It happens when the EDMR components obtained from process have different response times. Thus, the fact that we do observe such an effect is an indication that the Gaussian and Lorentzian lines come from different spin dependent transport processes in the diode. In some diodes it was possible to observe not just an EDMR signal but also the conventional ESR signal. The ESR lineshape in all cases could be well fitted using the parameters of the Lorentzian line found in the EDMR spectra.

In Fig. 2, the EDMR signal ($\Delta\sigma/\sigma$) is plotted against the bias voltage as filled symbols, for two different samples. In the same plot, the signal-to-noise (S/N) ratio as a function of bias voltage is plotted for one of the samples as open circles. Notice that the two samples present more or less the same behavior. However, the absolute value of the EDMR signal is different by a factor of 2–3. We have observed that for the same diode, normally near the end of its operation lifetime, the EDMR signal could decrease by as much as a factor of 10 in exactly the same experimental conditions. For both diodes, 10 V is just when the diode starts to emit light. As can be seen for $V < 17$ V, the signal increases, remains

Fig. 1. Typical EDMR signal for different MEH-PPV LEDs. From (a) to (c) the light emission efficiency decreases.

Fig. 2. EDMR signal amplitude (filled triangles) and signal-to-noise ratio (open circles) as a function of bias voltage, for different LEDs.

constant up to $V < 27$ V, and then drops. The variations are small, of the order of a factor 10 maximum. This complex behavior is not understood in detail at present. However one important point to note is that for these devices, the luminescence is not homogeneous for the whole sample, it is in fact concentrated in certain 'hot' spots. We are assuming that the initial increase of $\Delta\sigma/\sigma$ is basically derived from an increase in the number or size of the 'hot' spots. As the current injection increases these hot spots stabilize, and so does the EDMR signal amplitude. For very high injection, a significant local temperature increase cannot be ruled out, increases in temperature are followed by a decrease in $\Delta\sigma/\sigma$. Note that the S/N ratio does follow a similar behavior, and gives further support to the simple picture just described. The consequence of having both a decrease in signal amplitude and S/N ratio, turned the detection at lower voltages (or current injection) nearly impossible.

The temperature dependence of the EDMR signal depends on the emitting efficiency of the diode. For diodes that have both Gaussian and Lorentzian lines the temperature dependence for $T < 220$ K is rather weak, with a drop when the T reaches room temperature. The diode with an EDMR signal identified as 'pure' Lorentzian, has no such change in behavior and can be simulated by $\Delta\sigma/\sigma \propto T^{-2.2}$. This temperature behavior is not understood in detail at present.

EDMR has already been used for the characterization of similar diode structures based on PPV, summarized in Ref. [3]. However, quite different results have been found on ITO/PPV/Ca structures. For example, the EDMR signal amplitude was found to be as strong as 10^{-3} , and temperature independent for $20\text{ K} < T < 296\text{ K}$. The origin of such differences between the present and previous studies is not understood.

EDMR only probes paramagnetic states involved in the conduction process. As a consequence bipolarons which have $S = 0$ for example, are not observed directly by EDMR (or ESR). The two components observed by EDMR are assigned to polaron-polaron fusion, which results in a bipolaron [3]. The Lorentzian line is observed in ESR as well as in the EDMR and for ESR assigned to positive polarons. As mentioned earlier, the diodes with the worst light emission efficiency were those whose Lorentzian line amplitude was dominant. One possible explanation for the bad EL efficiency is an unbalanced carrier injection, in our case a poor negative polaron injection. Thus a surplus of positive carriers exists inside the bad emitting diode, which correlates with a higher Lorentzian line amplitude. Thus we attentively assign the Lorentzian line to $p^+ + p^+ \rightarrow bp^{++}$, while the Gaussian line is attributed to $p^+ + p^- \rightarrow bp^{+0}$. The differences in linewidth are probably derived from the differences in mobility. One could expect that the more mobile p^- has a lineshape

that is motionally narrowed. In this simple explanation, the difference in mobility can also explain the quadrature signal. However, at this point more evidence is needed to further attest this proposition. Note that the fact that the amplitude of the EDMR signal varies from sample to sample as well as for the same diode, is an indication that non-spin dependent transport paths are present in this diode. As discussed elsewhere [7], the effect of having non-spin dependent transport paths (bipolarons) parallel to spin dependent ones, is an overall decrease in $\Delta\sigma/\sigma$.

4. Conclusions

EDMR has been used to study the transport/recombination/injection of light emitting diodes based on MEH-PPV. The EDMR signal was found to be composed of two lines a g -factor around 2.002. The first line can be fitted by a Lorentzian with a $\Delta H_{pp} = 5.0 \pm 0.5$ G. The second line is a Gaussian with $\Delta H_{pp} = 24 \pm 1$ G. The relative amplitude of those components was found to be dependent on light emission efficiency of the diode. The Lorentzian is dominant for bad emitters. It is proposed attentively that the Lorentzian line is related to the fusion of positive polarons, which creates a positive bipolaron, while the Gaussian line comes from the same process however for negative polarons. It is found that EDMR in ITO/MEH-PPV/Al LEDs can qualitatively provide information about carrier injection, polaron mobilities as well as indirectly indicate the presence of bipolarons.

Abstract

Polycrystalline thin-films of the multinary chalcopyrite semiconductor $\text{Cu}(\text{In,Ga})\text{Se}_2$ are very well suited for highly efficient thin film solar cells. The material exhibits an astonishingly broad range of compositions in which good electronic properties are maintained. This article analyses some important aspects of the defect physics and defect chemistry of this semiconductor and compares recent models for the surface of polycrystalline $\text{Cu}(\text{In,Ga})\text{Se}_2$ and their consequences for the formation of the $\text{ZnO}/\text{CdS}/\text{Cu}(\text{In,Ga})\text{Se}_2$ heterojunction. © 2001 Elsevier Science B.V. 1. Introduction

The Cu-chalcopyrite CuInSe_2 and its alloys $\text{Cu}(\text{In,Ga})(\text{Se,S})_2$ provide the absorber material for the to date most efficient thin-film solar cells. A high power conversion efficiency of close to 19% obtained with an alloy $\text{Cu}(\text{In,Ga})\text{Se}_2$ (with a $\text{Ga}/(\text{Ga} + \text{In})$ -ratio ≈ 0.2) [1] yet challenges the conventional wafer-based polycrystalline silicon solar cell technology. The usage of the complete $\text{Cu}(\text{In}_{1-x}\text{Ga}_x)(\text{Se}_{1-y}\text{S}_y)_2$ alloy system is interesting when aiming towards high open circuit voltage solar cells as the band gap energy E_g of CuInSe_2 increases upon alloying with Ga and/or S [2]. Besides the technologically advantageous features including the outstanding radiation hardness of CuInSe_2 and its alloys [3,4], the Cu-chalcopyrites attract also considerable scientific interest because of their unusual defect physics: e.g., the ability to form electronically inactive defect complexes [5] explains the large structural tolerance of these materials to anion-cation off-stoichiometry.

High-efficiency $\text{Cu}(\text{In,Ga})\text{Se}_2$ solar cells are produced either by co-evaporation of the elements onto a heated Mo-coated glass substrate or by selenization of the stacked elemental layers. The use of glass substrates restricts the temperature for the film growth to below 600°C , the melting point of glass. The photovoltaically active polycrystalline p-type $\text{Cu}(\text{In,Ga})\text{Se}_2$ absorber has a typical thickness of $1.5\text{--}2\text{ }\mu\text{m}$ and a grain size in the μm range. The device is completed by chemical bath deposition of a 50 nm thin CdS buffer layer and by sputtering of an n-type ZnO front electrode (for recent reviews on device technology and characterization, see [6,7]. It is the relative ease of manufacturing and the large process window for producing efficient absorber layers what makes $\text{Cu}(\text{In,Ga})\text{Se}_2$ a very promising candidate for large-scale production of efficient and cost-effective photovoltaic devices. Prerequisites for an efficient thin-film photovoltaic absorber materials are: (i) The possibility to grow single-phase material of good crystalline quality, i.e., in a multinary compound there should be some tolerance to stoichiometry deviations. (ii) Growth of the material in a substrate configuration implies that during the growth process an ohmic contact with the metal on the glass must be formed which should also have favourable recombination properties for the minority carriers. In addition, this interface plays an

E-mail address: schock@ipe.uni-stuttgart.de (H.W. Schock).

important role as the seed for the growth of the polycrystalline film. (iii) The absorber film should be thick enough to absorb all sunlight with a photon-energy above the semiconductor's band gap and, in same time, the minority carrier diffusion length should be large enough to enable collection of all photogenerated charge carriers. (iv) Intergrain defects should be few and/or electronically inactive, unless the grain size does not exceed the film thickness by at least one order of magnitude (what is not the case in $\text{Cu}(\text{In,Ga})\text{Se}_2$ thin films). (v) The grains should contain a low concentration of electronically active (intra grain) defects. (vi) After growth of the absorber film, the film surface should enable the formation of a heterointerface with a favourable band offset between the absorber and the heterojunction partner in order not to affect the photovoltaic properties.

Twenty years of research were necessary to develop solutions which, after all, almost perfectly meet the requirements (i)–(vi) outlined above. However, most of the achievements accumulated during those years were initiated rather by intuition than by knowledge-based technological design. Only now, we begin to achieve a more detailed understanding of the basic physics working behind the scene. We now recognize that, in many respects, we were just lucky to find the needle, and begin to realize how large the haystack is. Fig. 1 depicts the complete layer sequence of the $\text{ZnO}/\text{CdS}/\text{Cu}(\text{In,Ga})\text{Se}_2/\text{Mo}$ heterostructure. All three interfaces between the four functional layers of the device exhibit interface reactions, e.g. the formation of MoSe_2 at the Mo back contact. Most of the 13 chemical elements tend to interdiffuse between the layers. For example Na from the glass plays an active role during film growth. Nevertheless, it appears that it is just the complexity of the defect physics of $\text{Cu}(\text{In,Ga})\text{Se}_2$ which is the reason for the outstanding performance, stability, and radiation hardness of this material. In the following we tempt to outline some of the physics that allows $\text{Cu}(\text{In,Ga})\text{Se}_2$ to meet the requirements (i)–(vi) and to perform so well as a photovoltaic material.

Fig. 1. Schematic representation of the layers and interfaces in a $\text{ZnO}/\text{CdS}/\text{Cu}(\text{In,Ga})\text{Se}_2$ solar cell.

2. Off-stoichiometry, secondary phases, and intrinsic defects

In contrast, to the binary compounds where small deviations from stoichiometry cause drastic changes of the electronic properties, the ternary compounds, in particular CuInSe_2 , are much more tolerant. Note that the Cu content of device-quality CuInSe_2 or $\text{Cu}(\text{In,Ga})\text{Se}_2$ absorbers varies typically between 22 and 24 at% Cu. Thus, these films are markedly Cu-poor but maintain excellent semiconducting properties. In terms of point defects, a non-stoichiometry of 1% would correspond to a defect concentration of roughly 10^{21} cm^{-3} . This is by about five orders of magnitude more than the acceptable density of recombination centres in a photovoltaic absorber material and still four orders of magnitude higher than the maximum net doping concentration of some 10^{17} cm^{-3} that is useful for the photovoltaic active part of a solar cell. Even if we allow a degree of compensation of 99%, the respective densities of donors and acceptors would be only in the 10^{19} cm^{-3} range. Thus, as illustrated in Fig. 2, the virtual number of defects related to off-stoichiometry has to be brought down to reasonable quantities which are compatible with the good electronic quality that is required to build a photovoltaic device.

There are basically two ways to reconcile stoichiometry deviations with good electronic properties: either the non-stoichiometry is accommodated in a secondary phase that is not harmful to the photovoltaic performance, or the off-stoichiometry related defects are electronically inactive. Most probably CuInSe_2 realizes both possibilities. The two point defects which are related to an overall Cu-poor composition are the Cu-vacancy V_{Cu} (a shallow acceptor) and the In–Cu antisite In_{Cu} (a deep double donor). According to first-principle calculations [5], these two defects form a defect complex ($2V_{\text{Cu}}, \text{In}_{\text{Cu}}$) which is electronically neutral and has no transitions within the energy gap of CuInSe_2 , thus being electronically inactive as could be. Interestingly, ordered

Fig. 2. Virtual number of defects related to off-stoichiometry. This number has to be brought down to reasonable quantities which are compatible with the good electronic quality that is required in a photovoltaic device.

arrays of this complex can be thought as the building stones of a series of Cu–In–Se compounds like CuIn_3Se_5 , CuIn_5Se_8 [8], i.e., the secondary phases that delimit the single-phase region of CuInSe_2 (α -phase) towards the Cu-poor side [9].

The existence range of the α -phase on the quasi-binary tie line Cu_2Se – In_2Se_3 of the phase diagram is from about 24.5–24 at% Cu, thus even not involving the proper stoichiometric composition with 25 at% Cu [9]. The Cu content of device-quality absorbers is between 22 and 24 at% Cu. This lies within the single phase region of the α -phase only at the growth temperature of 500–550°C. But at room temperature, the equilibrium phase diagram [9] predicts a two-phase $\alpha + \beta$ region for Cu contents below 24%. The situation with respect to secondary phase segregations is a bit different in thin films compared to single crystals which are used to determine a phase diagram. First, in these films about 20–30% of the In is replaced by Ga and, second, these films grow on Na-containing glass and, consequently, contain around 0.1 at% Na that diffuses out of the glass during deposition. Both, the incorporation of Ga and Na, inhibit the formation of secondary phases in the bulk of the thin film [10].

However, the surface of these films exhibits the 1-3-5 composition of the $\text{Cu(In,Ga)}_3\text{Se}_5$ defect phase [11], i.e., the surface is always more Cu-poor than the bulk of the material. Most likely, the Cu-poor surface of these thin-films is not the consequence of the segregation of a secondary bulk phase but rather is resulting from the accumulation of Cu-deficiency related defects and defect complexes [10]. The precise properties of this surface defect layer are not yet known. However, it is of some importance (and discussed later in the present paper) that the band gap at the surface of the Cu(In,Ga)Se_2 thin films is somewhat larger than the band gap in the bulk of the material [11].

On the Cu-rich side of the single-phase region of the phase diagram, Cu_2Se segregates as a secondary phase. In thin films Cu_2Se can be easily removed by etching the sample in KCN leaving behind a CuInSe_2 or Cu(In,Ga)Se_2 film with the proper stoichiometry. It is one of the puzzles of that material that films prepared in such a way exhibit good electronic quality (judged, e.g., from photoluminescence experiments [12–14]), whereas solar cells made from material that is grown in such a way are far less efficient than those with a slightly a Cu-deficient absorber.

3. Electronically active defects in Cu(In,Ga)Se_2 thin films

Up to here, we got a rough idea of how the material comes along with non-stoichiometry and meets requirement (i) of our list. In the following, we approach the topic from the experimental point of view, i.e., we

concentrate first on electronically active defects that are found in photovoltaic grade, i.e. slightly In-rich, polycrystalline Cu(In,Ga)Se_2 . The charge density in the space charge region of any photovoltaic device must not exceed a level of 10^{17} – 10^{18} cm^{-3} , because otherwise tunneling enhanced recombination would significantly decrease the open circuit voltage of the solar cell [15]. In fact, in Cu-chalcopyrite semiconductors this limit appears rather to be close to few times 10^{17} cm^{-3} [16]. High-efficiency Cu(In,Ga)Se_2 absorber material has a net charge density of around or few times 10^{16} cm^{-3} [17]. The shallow acceptor level V_{Cu} (around 30 meV above the valence band) is assumed to be the main dopant in this material [5].

The best experimental access to deeper defects in Cu(In,Ga)Se_2 provides admittance spectroscopy (AS) and Deep Level Transient Spectroscopy (DLTS) [18–20]. Fig. 3 displays a defect spectrum as obtained from (AS) by the method of Walter et al. [19] together with the band diagram of a $\text{ZnO/CdS/Cu(In,Ga)Se}_2$ -heterostructure. The spectrum exhibits two distinct peaks N1 and N2, at energies of ~ 100 and ~ 300 meV, respectively. While peak N1 corresponds to donor-like defects at the surface of the Cu(In,Ga)Se_2 absorber [20], peak N2 is an acceptor either in the volume or at the grain boundaries of the Cu(In,Ga)Se_2 absorber [19,20].

The importance of defect N_2 is given by the fact that its concentration is related to the open circuit voltage V_{OC} of the device. Detailed investigations of $\text{Cu(In}_{1-x}\text{Ga}_x\text{)(S}_y\text{Se}_{1-y})_2$ heterojunctions unveil that recombination via defect N_2 determines V_{OC} of solar cells made from absorbers in a composition range covering the $\text{Ga}/(\text{In} + \text{Ga})$ ratio $0 \leq x \leq 1$ [21] as well as the $\text{S}/(\text{S} + \text{Se})$ ratio $0 \leq y \leq 0.4$ [22]. Fig. 4 illustrates the correlation between the maximum defect densities with the open circuit voltage loss $E_g/q - V_{\text{oc}}$ which is a convenient measure to compare V_{oc} of solar cells with different bandgap energies of the absorber. Regardless

Fig. 3. Defect spectrum as obtained from admittance spectroscopy together with the band diagram of a $\text{ZnO/CdS/Cu(In,Ga)Se}_2$ -heterostructure. The spectrum exhibits two distinct peaks N1 and N2, at energies of ~ 100 and ~ 300 meV, respectively.

Fig. 4. Band diagrams of the surface of (a) In rich and (b) Cu rich Cu(In,Ga)Se₂. The surface is either more In or more Cu rich compared to the bulk and thus determines the position of the Fermi level.

of the origin of the defects, a clear correlation of defect densities with the loss in open circuit is found. Differences in the absorber quality resulting from preparation of films under different conditions like lower substrate temperature or different growth methods [21], the degradation of the absorbers by damp heat treatments [23], or the defect generation by irradiation with high-energy particles [3,4] can be subsumed in the same correlation of the defect densities and the open circuit voltage loss.

After all, it appears well established that recombination in all devices that are based on Cu(In,Ga)(Se)₂ alloys is determined by defects in the volume of the absorbers, as long as these absorbers are prepared with a slightly Cu-poor final composition. At the moment it is difficult to judge whether these defects are located in the grain volume or at the grain boundaries of the polycrystalline material. A rough estimate from available solar cell output parameters, however, puts a limit of $S_{\text{gb}} < 10^4$ cm/s to the recombination velocity S_{gb} for minority carriers at the grain boundaries [6,7]. Thus, grain boundaries in Cu(In,Ga)Se₂ exhibit only a weak electronic activity. This is considered to be a result from extrinsic passivation of the grain boundaries by oxygen [24,25]. This passivation is either explicitly performed by post-deposition air annealing or implicitly achieved by Na-catalyzed oxygenation of the grain boundaries during absorber growth [26].

4. Interface properties and surface defect layers

In a well-tailored solar cell the thickness of the absorber layer should not exceed the diffusion length of the minority carriers. Therefore, the recombination properties at both contacts to the active layer, at the charge-separating hetero-contact as well as at the ohmic back contact, should be favourable. Analysis of current

collection by Electron Beam Induced Currents (EBIC) indicate a good collection efficiency for *electrons* which are generated *close to the back contact* [27]. An explanation for these findings is provided by the fact that during absorber deposition a MoSe₂ film forms at the Mo surface [28,29]. MoSe₂ is a layered semiconductor with p-type conduction, a band gap of 1.3 eV and weak van-der-Waals bonding along the *c*-axis. The *c*-axis is found either in parallel or perpendicularly to the interface, depending on the initial growth condition of the film [28]. Therefore, the method of film growth has some impact on adhesion and electronic properties of this interface. Due to the larger band gap of the MoSe₂ compared to that of standard Cu(In,Ga)Se₂ films this semiconductor layer provides a back-surface field for photogenerated electrons and at the same time provides a low resistive contact for the holes.

The electronic properties of the front surface of photovoltaic-grade (Cu-poor) Cu(In,Ga)Se₂ result from the properties of the surface defect layer discussed in Section 2. The detailed band diagram of the heterojunction close to the metallurgical CdS/Cu(In,Ga)Se₂ is still under debate (for discussion, see e.g. [30–32]). In spite of the various models that exist for the surface of Cu-poor Cu(In,Ga)Se₂, two important features have to be considered as a matter of fact. (i) In the completed device the surface of the Cu(In,Ga)Se₂ absorber is inverted. The electronic transition (N1 in Fig. 3) due to interface donors has an activation energy of around 100 meV as measured by AS and DLTS [20]. This activation energy just corresponds to the distance ΔE_F between the conduction band of the Cu(In,Ga)Se₂ absorber and the Fermi energy E_F at the heterointerface. The barrier Φ_b^p that hinders holes from the absorber material to recombine at the heterointerface [16,33] is given by $\Phi_b^p = E_g - \Delta E_F$. Thus, a small ΔE_F is necessary to avoid interface recombination. (ii) A widening of the band gap energy towards the Cu-poor surface [11] further increases Φ_b^p as indicated in Fig. 5. In turn, all

Fig. 5. Correlation of defect densities with the open circuit voltage loss. Regardless of the origin of the defect a clear correlation with the loss in open circuit is found. The different symbols represent different fabrication processes and alloy compositions (open triangles), ageing procedures (circles) and irradiations (solid squares).

devices which are prepared from Cu-chalcopyrite material that has been grown Cu-rich even after removal of the Cu_2Se secondary phase (or CuS in case of Cu-rich grown CuInS_2) are dominated by interface recombination [33,34]. Therefore, we postulate that the properties of the surface defect layers of Cu-poor grown material guarantee the Fermi level pinning close to the conduction band and the band gap widening at the absorber surface as illustrated in Fig. 5. Thus, the advantage of Cu-poor Cu(In,Ga)Se_2 absorber films is essentially given by their favourable surface properties and the ease to form heterojunctions with low losses.

5. Conclusions

The favourable photovoltaic properties of Cu(In,Ga)Se_2 and the wide process tolerance for thin film deposition arise from the ability of the multinary material to form defect complexes which are electrically neutral and fit into the structure of the material as elements of defect phases. These defect phases exhibit a similar structure as compared to the chalcopyrite crystal. The front surface of photovoltaic grade material is characterised by a defect layer with a CuIn_3Se_5 composition. This layer minimises recombination losses at the interface of the photovoltaic heterojunction. As a consequence, the open circuit voltage is determined by the bulk properties of the material, i.e. the defect densities in the bulk of the absorber layer.

Positive and negative magnetoresistance in the system silver–selenium

Gesa Beck, Jürgen Janek*

Physikalisch-Chemisches Institut, Justus-Liebig-Universität Gießen, Heinrich-Buff-Ring 58, D-35392 Gießen, Germany

Abstract

The (transversal) magnetoresistance (MR) effect of bulk $\text{Ag}_{2+\delta}\text{Se}$ ($\delta = 0; 5 \times 10^{-4}; 0.33$) in its low-temperature α -phase has been measured at temperatures $-100^\circ\text{C} < T < 50^\circ\text{C}$ in magnetic fields up to $B = 8$ T. A stoichiometric sample with well-controlled metal excess was prepared by growth from the elements and subsequent electrochemical treatment. The MR effect of this sample is relatively small and positive. Silver-rich material exposes both relatively large positive and negative effects, depending on the metal content. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

In an early work, Junod [1] determined the magnetoresistance effect of stoichiometric Ag_2Se as approximately 1% at 20°C and at a magnetic field of 1 T. Recently, an unusually large positive MR effect was observed by Xu et al. in bulk material of the nonmagnetic silver-rich silver chalcogenides $\text{Ag}_{2+\delta}\text{Se}$ and $\text{Ag}_{2+\delta}\text{Te}$ [2]. Samples with compositions between “ $\text{Ag}_{2.01}$ ” and “ $\text{Ag}_{2.33}\text{Se}$ ” have been studied, and MR effects up to 120% were observed at room temperature and magnetic fields of 5.5 T. The magnetic field dependence shows no evidence of saturation up to a magnetic field of 5.5 T and is linear down to 10 mT.

Ogorelec et al. also studied $\text{Ag}_{2+\delta}\text{Se}$ in order to optimise the MR effect [3] but were not able to reproduce the large MR effect observed originally by Xu et al. They suggest the Hall mobility of the charge carriers to be the important parameter which has to be optimised. Further experimental studies deal with large magnetoresistance in bulk material and thin films of $\text{Ag}_{2+\delta}\text{Te}$ [4–6].

Motivated by these experimental observations, Abrikosov [7,8] advanced a theoretical explanation for this unusual MR effect. His model grounds on the assumption of material being inhomogeneous on an atomic scale, i.e. he assumes the presence of small metal clusters of excess silver. In addition, the model requires a material which can be regarded as a gapless semiconductor with a linear energy spectrum. For such hypothetical material Abrikosov obtains a positive MR effect with linear dependence on the magnetic field. Since the quantum condition in this model persists to very low fields and high temperatures Abrikosov suggests to call this effect *quantum magnetoresistance*.

In the present study, we investigate the MR effect of two heterogeneous samples obtained from the melt and a stoichiometric sample which is much better characterised with respect to its chemical composition. In the following, we firstly describe the sample preparation, report on the MR effect and discuss our results in the context of the concentration of metal in Ag_2Se and available theories on MR effects.

The phase diagram of the system Ag–Se is well studied between 75°C and 190°C [9]. A phase transformation from the high-temperature phase ($\beta\text{-Ag}_{2+\delta}\text{Se}$) to the low-temperature phase ($\alpha\text{-Ag}_{2+\delta}\text{Se}$) occurs at $T = 133^\circ\text{C}$. Due to the significant density changes during

Fig. 1. Schematic phase diagram of the system silver-selenium.

the transformation, dislocations and grain boundaries are created in the α -phase and lead to a material with a high concentration of nonequilibrium defects. Since all practical applications of the MR effect work at room temperature, the α -Ag₂Se phase is of primary interest. This phase exists only in a very small range of homogeneity which becomes even narrower with decreasing temperature, as indicated schematically in Fig. 1.

2. Experimental

For the preparation of heterogeneous silver-rich samples, we melted together silver and selenium in the required mass ratio in evacuated silica ampoules. The ampoules were heated for 24 h at 960 °C in a furnace and then cooled down to room temperature. Rectangular specimens were cut from the resulting material. Parts of this material were polished for SEM figures. Other parts of the product were ground and characterised by powder X-ray-diffraction.

Homogeneous silver selenide was grown in a capillary by one-dimensional growth from the elements at $T = 240$ °C. On one side of the capillary, a rod of silver metal was placed. On the other side, selenium was filled into the capillary and melted. Silver reacted with the selenium and a β -silver selenide crystal grew into the capillary with a growth rate of approximately 10 mm/day. By cooling slowly down to temperatures below 133 °C always the α -phase is produced. At 100 °C the crystal was then equilibrated with bulk silver metal for several weeks. This long equilibration period is necessary since the chemical diffusion coefficient of silver in the α -phase is relatively low compared to the β -phase. Furthermore, dislocations which were created during the phase transformation healed out at least partially. Nevertheless, the product remains polycrystalline with coarse grains and with a silver activity of $a_{\text{Ag}} = 1$ at

100 °C. By coulometric titration—a standard technique in solid state electrochemistry [10]—we finally prepared the exactly stoichiometric product Ag_{2.000000}Se, $\Delta\delta < 10^{-6}$ from this material.

All samples were contacted with platinum wires and the transversal magnetoresistance was measured in fields up to $B = 8$ T using a four probe dc technique.

3. Experimental results

X-ray-diffraction of the silver-rich “Ag_{2.33}Se” proves that the material is primarily orthorhombic α -Ag₂Se [11]. However, silver metal precipitates are also identified by the (hkl) reflection at $2\theta = 38.1^\circ$.

The “Ag_{2.0005}Se” and the “Ag_{2.33}Se” specimens are polycrystalline and contain precipitates of silver metal in the micron scale (see inset in Figs. 3 and 4). The distribution of the precipitates in “Ag_{2.33}Se” appear to be quite regular, exhibiting typical morphologies of eutectic systems produced from the melt. The size of the precipitates depends on the cooling rate. In “Ag_{2.33}Se” large dendrite-like precipitates of silver (with dimensions in the 100 micron scale) are formed in regions with reduced cooling rate. Over large areas, small silver particles of approximately 1 μm diameter form chains with almost regular structure. Frequently, small areas with silver particles being arranged almost lattice-like are found. In “Ag_{2.0005}Se”, we find only few silver precipitates (inset Fig. 3). The smallest silver particles we found here have a diameter of approximately 0.2 μm . Summarizing, all material produced by melting and subsequent solidification is heterogeneous and shows silver precipitates. HSEM studies did not show silver precipitates with diameters less than 0.1 μm .

We obtained different results for the magnetoresistance effect. The MR effect of stoichiometric silver selenide is small and positive. It shows a quadratic field dependence and there is no saturation up to fields of

Fig. 2. MR effect of stoichiometric Ag_{2.000000}Se measured at different temperatures.

Fig. 3. MR effect in Ag–Se samples with the mean composition “Ag_{2.0005}Se” measured at different temperatures. Inset: SEM micrograph taken from this sample.

Fig. 4. MR effect in Ag–Se samples with the mean composition “Ag_{2.33}Se” measured at different temperatures. Inset: SEM micrograph taken from this sample.

$B = 8$ T (Fig. 2). “Ag_{2.0005}Se” shows a negative MR effect at 50 °C. With decreasing temperatures, the MR effect becomes more and more positive (Fig. 3). This positive effect is almost linear in its field dependence. For Ag–Se samples with the mean composition “Ag_{2.33}Se”, we find a positive effect which decreases with increasing temperatures. The field dependence is almost quadratic but is better described by an additional linear term (Fig. 4).

4. Discussion

Our data from the coulometric titration of silver selenide show that α -Ag_{2+ δ} Se with a metal excess δ higher than 2×10^{-4} will necessarily be a two-phase mixture of silver and α -silver selenide at 20 °C [11]. Thus, our samples with $\delta = 5 \times 10^{-4}$ and 0.33 are definitely heterogeneous and contain small silver precipitates. Increasing or decreasing the silver excess (silver activity)

within the phase field of α -silver selenide increases or decreases the concentration of electrons or electron holes, respectively. Measurements of the electronic conduction confirm this [12,13]. For the sake of the argument, we assume that any metal excess directly leads to a corresponding increase of the carrier density, i.e. we assume complete dissociation of the metal dopant, irrespective of whether we consider homogeneous or heterogeneous samples.

The classical theory of ordinary magnetoresistance (OMR) in semiconductors yields a positive and quadratic field dependence [14] of the MR effect $\Delta\rho/\rho$ when the product of the Cyclotron frequency ω_c and the relaxation time τ is small compared with 1 (small magnetic fields B) or for stoichiometric semiconductors, where the concentration of electrons n equal to that of holes p .

$$\frac{\Delta\rho}{\rho} \propto B^2, \quad \omega_c \cdot \tau \ll 1,$$

$$\frac{\Delta\rho}{\rho} \propto \text{const}, \quad \omega_c \cdot \tau \gg 1, \quad n \neq p.$$

For nonstoichiometric samples, the OMR effect always reaches saturation at sufficiently large magnetic fields. In the simple case of a non-degenerate semiconductor with a parabolic band structure and electron relaxation by phonon scattering, we can predict the OMR effect for our samples inserting appropriate mobilities and the density of electrons and holes [11].

For stoichiometric silver selenide and for “Ag_{2.33}Se” we indeed measure a square field dependence. The MR effect of the stoichiometric sample shows ordinary magnetoresistance simply caused by the Lorentz force on the charge carriers in the magnetic field. An increased silver excess should lead to an even smaller positive MR effect. Obviously this is in contradiction to the experimental findings—the MR effect of “Ag_{2.33}Se” is much larger than that of the stoichiometric sample.

In the heterogeneous samples, the chemical potential of silver always equals the standard potential of silver. This might have an effect on the band structure of the system. We also observe silver precipitates (see inset in Fig. 4). Thus, we believe that it is unreasonable to describe the MR effect of this material by a simple OMR model.

The “Ag_{2.0005}Se” sample shows a linear MR effect at a low temperatures and a negative effect at 50 °C. Such change of the MR effect has not been reported yet and requires further investigation.

Both the GMR effect in film structures [15,16] and the CMR effect [17] are negative effects. The GMR effect also exists in granular systems [18]. In all these cases, a necessary condition for the occurrence of negative effects are permanent magnetic structures. Yet there is no

doubt that silver selenide and silver metal are diamagnetic, and thus, both the GMR and CMR effect do not explain the present results on $\text{Ag}^{2+}\delta\text{Se}$.

Other types of negative MR effects have been proposed and measured in disordered systems [19–21]. But normally these MR effects appear only at very low temperatures (of a few Kelvin). In the current state of investigation, we believe that a metal excess is indeed necessary for the occurrence of the observed unusual MR behavior. Currently, we investigate whether precipitates in the nano-scale regime might be the origin of this effect. In this case, the linear contribution could be explained by the quantum magnetoresistance model of Abrikosov [7].

Finally, we assume that the measured effects of “ $\text{Ag}_{2.33}\text{Se}$ ” are a superposition of a saturating negative and a linear positive effect. Further, our own measurements in [11] confirm this.

Abstract

Transmission electron microscopy developed from an imaging tool into a quantitative electron beam characterization tool that locally accesses structure, chemistry, and bonding in materials with sub-Angstrom resolution. Experiments utilize coherently and incoherently scattered electrons. In this contribution, the interface between gallium nitride and sapphire as well as thin silicon gate oxides are studied to understand underlying physical processes and the strength of the different microscopy techniques. An investigation of the GaN/sapphire interface benefits largely from the application of phase contrast microscopy that makes it possible to visualize dislocation core structures and single columns of oxygen and nitrogen at a closest spacing of 85 pm. In contrast, it is adequate to investigate Si/SiO_xN_y/poly-Si interfaces with incoherently scattered electrons and electron spectroscopy because amorphous and poly-crystalline materials are involved. Here, it is demonstrated that the SiO_xN_y/poly-Si interface is rougher than the Si/SiO_x interface, that desirable nitrogen diffusion gradients can be introduced into the gate oxide, and that a nitridation coupled with annealing increases its physical width while reducing the equivalent electrical oxide thickness to values approaching 1.2 nm. Therefore, an amorphous SiN_xO_y gate dielectric seems to be a suitable substitute for traditional gate oxides to further increase device speed by reducing dimensions in Si technology. © 2001 Elsevier Science B.V. 1. Background

Recent progress in high resolution transmission electron microscopy (HRTEM) allows investigating crystalline materials by phase contrast microscopy with a resolution close to the 80 pm information limit of a 300 kV field emission microscope [1–4]. A reconstruction of the electron exit wave from a focal series of lattice images converts the recorded information into interpretable resolution [5,6]. It was reported before that Z-contrast microscopy achieved sub-Angstrom resolution [7].

From a materials point of view, a resolution enhancement in electron microscopy is required to achieve truly mono atomic resolution in most materials systems. A typical point resolution around 0.2 nm does commonly not suffice. Fig. 1 depicts this situation by

plotting the band gap energy of different ceramics and semiconductors versus their inter-atomic spacing. It is seen that the resolution of single atomic columns in ceramic-like materials is barely possible. In practice, their separation often requires a better point resolution because lattice imaging along zone axes of crystals nearly always shortens the inter-atomic spacing by the involved projection into the image plane. For example, the resolution of dumbbell images along the commonly recorded [110] zone axis of silicon, cubic gallium nitride, and diamond require a point resolution of 0.136, 0.113, and 0.089 nm, respectively.

Moreover, band gap energies tend to increase with shorter inter-atomic distances. From the slope of the trend line in Fig. 1 one finds that a reduction by 1 pm typically changes energies by 50 meV. It is for such reasons that electron microscopy strives for the development of equipment that will allow for sub-Angstrom resolution [3,4,7], will pinpoint the position of atomic columns to within 1 pm [12,13], and will enable

Fig. 1. Band gap energy versus inter-atomic distances in selected semiconductors and ceramics. The slope of the trend line relates 1 pm of distance to 50 meV of energy change.

spectroscopic investigations of single atomic columns with an energy resolution of about 50 meV [8–11].

In the present contribution we investigate interfaces with current state-of-the-art equipment. A CM300 FEG/UT HRTEM with an information limit of 80 pm and a Tecnai F20/ST HRTEM/STEM (scanning transmission electron microscope) with a beam diameter of 0.19 nm, 500 meV of energy resolution, and Z-contrast capability are employed. This allows for a comparison of phase with Z-contrast imaging. Gate oxides in silicon and the interface between GaN and sapphire are examined. Both examples are of substantial technological importance [14,15]. Details of sample preparation procedures are published elsewhere [3].

2. Gate oxides

Fig. 2 depicts images of the amorphous SiO₂ gate dielectric of roughly 2 nm thickness that was deposited on silicon and capped with a poly-silicon layer. Gate oxides of this thickness will be relevant for a 0.1 μm technology that must be standard technology in a few years if Moore's law applies. Excellent film uniformity has to be achieved across wafers and TEM is the primary tool to relate the physical gate oxide thickness to process parameters and to calibrate metrology tools.

We depict three types of images in Fig. 2. Fig. 2a is a usual lattice image which is an interferogram of diffracted beams [16]. As a result the image pattern of the silicon and the poly-silicon changes rapidly with the focus setting of the objective lens that also acts as a filter for spatial frequencies. This produces the speckle contrast of the amorphous material. In addition, there is substantial delocalization of information at interfaces that is visible as a periodic contrast variation in the amorphous layer close to the silicon substrate. It results from the utilization of a field emission electron source [16]. Fig. 2b is a reconstructed phase image of the electron exit wave from a focal series of lattice images [3,5,6]. Delocalization effects are removed during the reconstruction process. Poly-crystalline grains are visible even if they are not imaged along low indexed zone axes because of the 80 pm information limit of the instrument. In thin samples (< 10 nm) the image depicts the 1 s state of the electron wave channeling along atomic columns [17] that are entirely resolved. They appear as bright spots in the phase image. The defocus dependence of the pattern is eliminated. Local phase changes can be analyzed quantitatively since they oscillate with sample thickness. Their oscillation periodicity is given by [17]

$$D_{1s} = \alpha[d^2/Z + 0.276B], \quad (1)$$

where α is a constant, d is the distance between successive atoms, Z is the atomic number and B is the

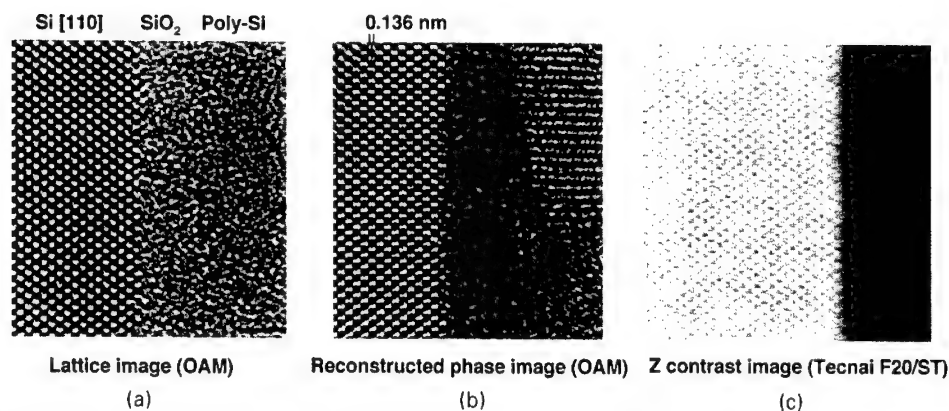

Fig. 2. Gate oxides in silicon. Images were recorded by different techniques. (a) A traditional lattice image recorded with NCEM's One Angstrom Microscope (OAM) that is a specially equipped Philips CM300. (b) Reconstructed electron exit wave from a focus series of twenty lattice images of the OAM. The phase of the electron exit wave is shown. (c) Scanning transmission electron microscopy (STEM) was utilized to produce a Z-contrast image. A Tecnai F20 super twin microscope was used.

Debye Waller factor. Eq. (1) was recently utilized to demonstrate that the phase change at single gold atoms can be detected with a signal to noise ratio of better than 2 [18]. Thus, unlike a lattice image, the phase image of the electron exit wave depicts directly the projection of the layered structure into an image plane. The magnitude of the phase change can be quantified through a simple dependence on sample thickness and chemical composition. However, the speckle contrast of the amorphous SiO₂ remains because the reconstruction process operates over the finite range of spatial frequencies that is determined by the objective lens [5,6]. Finally, Fig. 2c depicts a Z-contrast image. Similarly to the phase images, a Z-contrast image also depicts the 1s state of electrons trapped on atomic columns. However, incoherently scattered electrons are used to build up the picture [19]. Currently, sub-Angstrom resolution is achievable by Z-contrast microscopy at 300 kV [7]. However, the 0.136 nm separation of the dumbbell structure in silicon can already be resolved at 200 kV [20,21]. In comparison with phase contrast images, Z-contrast images lack of speckle contrast in amorphous regions. Its absence eases a quantitative evaluation of intensity profiles to measure the gate oxide thickness and interfacial roughness [22].

Table 1 summarizes results of gate oxide thickness measurements from Z-contrast images and from the phase contrast images. Intensities were evaluated in Z-contrast images and the presence of a pattern from crystalline material was used to locate the position of interfaces in phase contrast images. Two samples were investigated: a control sample (A) and a second sample (B) where nitrogen was diffused into the gate oxide layer. From a comparison of gate oxide thickness in sample A and B one finds that a broadening of the amorphous region occurs as a result of nitrogen incorporation. Moreover, we find that the poly-Si/SiO₂ interface is

rougher by a factor of 2 than the Si/SiO₂ one. Finally, phase contrast images consistently provide a smaller gate oxide thickness than measurements obtained from Z-contrast images. Both procedures reproduce gate oxide thickness data within 0.1–0.2 nm.

We recorded electron energy loss spectra (EELS) by stepping the focused (0.19 nm) electron across the interfaces with 0.1 nm per step. At each step, a full spectrum including the Si L_{2,3}, N K, and O K edges was recorded. Post experiment, we processed the several thousand spectra to produce chemical maps or profiles as shown in Fig. 3. Oxygen, nitrogen and silicon profiles are depicted and the thickness values of the gate oxide as determined from the Z-contrast—and phase contrast images are overlaid. The profiles reveal that O and N gradients are present in the gate oxide. Nitrogen concentrations peak at the poly-Si/SiO_xN_y interface and decrease linearly towards the Si/SiO_x interface. It is not surprising to find that the width determination of the gate dielectric from the Z-contrast images coincides with its chemical width as measured by EELS since the intensities in a Z-contrast image depend on sample thickness and on chemistry.

In summary, we produced a direct comparison between lattice images, electron exit waves, and Z-contrast images of gate oxides. In silicon [110] a resolution of 136 pm suffices to separate individual atomic columns at 300 kV by coherently scattered electrons in combination with exit wave reconstruction and by incoherently scattered electrons. Even the current information limit of leading edge 200 kV equipment allows for a resolution of this dumbbell structure. Both techniques provide pictures of the 1s state of electrons trapped at atomic columns and the signal strength depends on local sample thickness and chemical composition. Differences stem from a larger signal to noise ratio in phase contrast images compared with

Table 1
Quantitative evaluation of gate oxide thickness and interfacial roughness from Z-contrast and phase contrast images^a

^a Sample A: control sample. Sample B: nitrogen containing gate oxide. Roughness measurements were made from Z-contrast images.

Fig. 3. More than 1000 Electron Energy Loss Spectra were recorded with an electron beam focused to 0.19 nm small spot that was repetitively scanned across the gate oxide (Tecnai F20). An automated data analysis produces the depicted profiles of nitrogen, silicon and oxygen in minutes. A 2.07 nm wide dielectric was measured from image patterns in phase contrast images. An analysis of the local intensity of Z-contrast images reveals a 2 nm wide gate oxide.

Z-contrast images. However, in the presence of amorphous material, the limited bandwidth of transmitted spatial frequencies in phase contrast microscopy generates a speckle contrast in amorphous—and partly in poly-crystalline material. Its absence in Z-contrast images eases a quantitative evaluation of interfacial roughness and the dielectric layer width. A nitridation of the gate oxide increases its dielectric constant and the layer width. Both effects are beneficial for devices because they appear electrically “thinner” but are physically thicker. The equivalent electrical thickness approaches 1.2 nm in this case. Therefore, it is feasible to further increase the switching speed of devices while avoiding tunnel currents. A control of nitrogen diffusion gradients is crucial in this process and electron spectroscopy can provide this information on a scale of 0.1–0.2 nm. From a comparison of phase contrast images, Z-contrast images, and electron spectroscopy we find that O and N diffused into the adjacent crystalline materials.

3. Growth of GaN on sapphire

It is evident from Fig. 1 that an investigation of silicon is not extremely demanding in terms of resolution. In case of GaN or sapphire (Al₂O₃), however, the situation changes for two reasons: the inter-atomic distances are smaller and the light elements O and N are involved with low electron scattering power. It is for these reasons that these materials could not be investigated on a truly atomic scale.

Commonly, lattice images of GaN are recorded along a [1 1 2 0] zone axis as shown in Fig. 4a because it is this projection that allows at least for a separation of the Ga atoms. Even more restricting is the presence of a huge defect density at the interface between GaN and sapphire that is generated to partly accommodate 14% of lattice mismatch [23]. Fig. 4b shows the same region in [1 1 0 0] projection. This experiment benefits from two factors: First, we resolved the GaN lattice in [1 1 0 0] projection, which requires 0.15 nm of resolution.

Second, the $[1\bar{1}00]$ projection eliminates the stacking fault contrast that usually obscures lattice images recorded in $[11\bar{2}0]$ projection. Thus, image interpretation is drastically simplified by simply having a choice of recording lattice images along different zone axes and yet resolving a lattice.

From a focal series of lattice images it is then possible to reconstruct the electron exit wave shown in Fig. 5a. Again, the reconstructed phase image is directly interpretable: a bright spot in the exit wave picture marks the position of atomic columns, its intensity depends on chemical composition and the spacing of atoms along the column (Eq. (1)). It is seen that all atom columns at the interface and in the sapphire are resolvable with a smallest projected aluminum–oxygen spacing of 85 pm in the sapphire. Consequently, it is now possible to detect single columns of oxygen atoms at a sub-Angstrom spacing because of the excellent signal to noise ratio of the phase contrast image and the improved resolution.

An additional advantage of phase contrast imaging comes from the precision as to which lattice parameters can be measured [12]. Fig. 5b summarizes lattice parameter measurements in plane of the interface and normal (out of plane) to it. It is seen that the in plane

lattice parameter does not vary more than 1 pm except for a surprisingly 0.8–1 nm narrow interfacial region. Even the out of plane lattice parameter is reduced by only 10 pm which correspond to a displacement of only 4%. One would estimate an out of plane lattice parameter variation of roughly 30% for fully strained pseudomorphic growth with a lattice mismatch of 14%. Closer inspection of the narrow interfacial region reveals the presence of a misfit dislocation network. One of the misfit dislocations is depicted in Fig. 6. It is seen that its core structure is entirely resolved. The dislocation is of edge character and a row of oxygen or nitrogen atoms terminates the inserted extra half plane. It is not possible to discriminate between nitrogen and oxygen atoms because of their similar Z of 7 and 8, respectively. The misfit dislocation spacing along the interface is regular. From Fig. 5a we find that they are standing off the interface by 0.5–1 nm and that six GaN $(11\bar{2}0)$ planes of 0.1595 nm spacing match seven sapphire $(3\bar{3}00)$ planes spaced by 0.1374 nm. Here we used literature values for lattice parameters. Resultantly, one calculates that 0.957 nm in GaN match 0.962 nm in sapphire along the interface which leaves a residual strain of less than 1%. Such values agree reasonably well with the

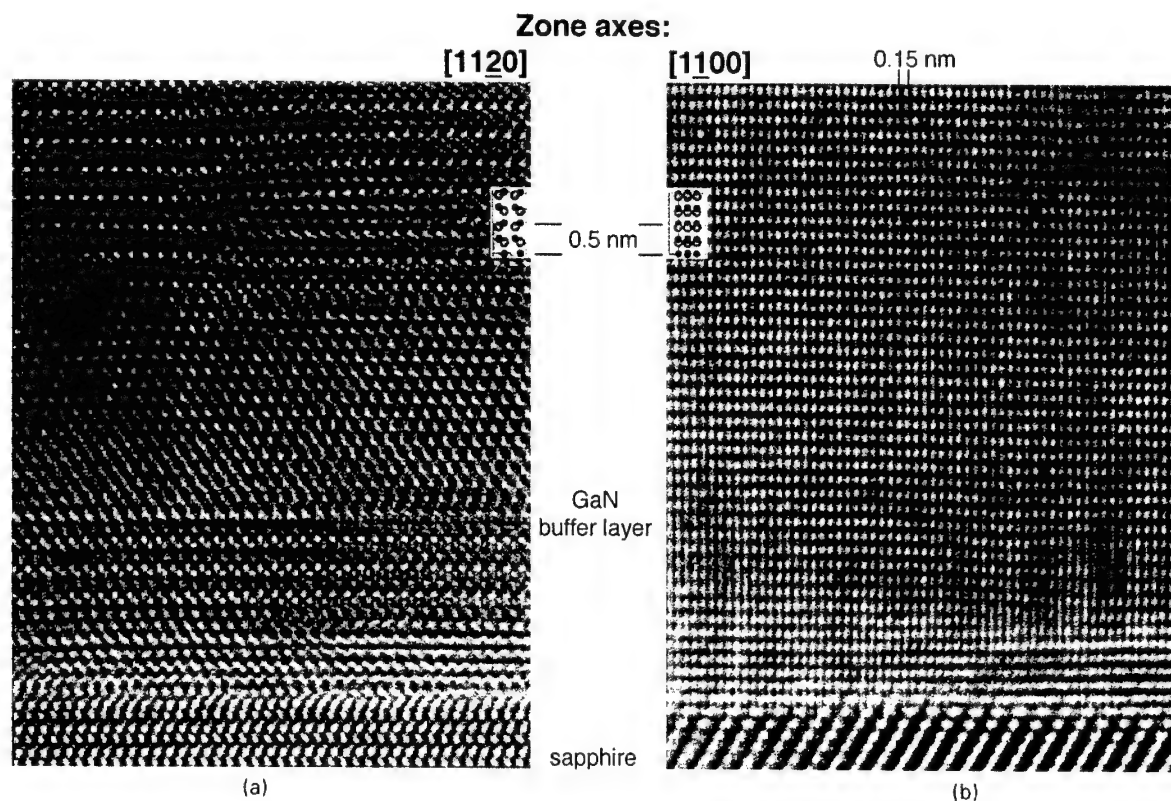

Fig. 4. Lattice images of GaN along two different zone axes a and b . An information limit of 80 pm of the OAM allows for a choice of suitable zone axes. Here, they are chosen such that the contrast of stacking faults is eliminated in b . Insets show the unit cells of hexagonal GaN projected along the two different zones.

Fig. 5. Top (a) Phase of the electron exit wave reconstructed from 20 lattice images. (b) Measurement of lattice parameters across the field of view. Values in plane of the interface and normal to it (out of plane) are averaged in columns across the picture.

Fig. 6. Core structure of an oxygen terminated misfit dislocation at the interface between GaN and sapphire. The model (right) was obtained from pinpointing atomic columns in the phase image.

measured 5% of the out of plane lattice parameter change considering that GaN growth can be largely non-stoichiometric [23].

In summary, we applied phase contrast microscopy to investigate the interface between sapphire and GaN with sub-Angstrom resolution. The investigation benefits from the gained ability to choose from different zone axes that comes with the improvement of resolution and

the large sensitivity of phase contrast microscopy that enables scientists to detect light elements even if they are closely spaced to heavier next neighbors. Dislocation core structures are now resolvable. In this particular case we find that the complicated process to initiate growth of GaN on sapphire [23] is linked to the fabrication of a misfit dislocation network that accommodates most of the initial lattice mismatch of 14%. The dislocated area

is confined to a 0.8–1 nm narrow interfacial region. Residual displacements are about 5% and they vanish over several nanometers as the distance from the interface increases in the thin TEM foils.

4. Conclusions

Investigations of GaN on sapphire and of the silicon gate oxides are performed to analyze two technologically important materials with state-of-the-art transmission electron microscopy. Phase contrast microscopy, Z-contrast microscopy, and electron spectroscopy are employed. In the case of silicon gate oxides a moderate resolution of 136 pm suffices to resolve the structure which is achievable with all techniques these days. The presence of the amorphous gate dielectric, however, favors applications of Z-contrast microscopy because of frequency limitations that come with the application of phase contrast microscopy and produces a speckle contrast in the amorphous layer. It complicates a quantitative image analyses. The application of electron spectroscopy is desirable in any case. Here we demonstrate that industry seeks to increase switching times in Si based devices by increasing the dielectric constant of the gate oxide with the addition of nitrogen. Its diffusion can be controlled such that the N concentration peaks at the poly-Si side but is negligibly small on the SiO₂/Si side of the gate oxide. In addition a nitridation of the gate oxide increases its width which reduces the risk of undesirable tunnel currents as the dimensions of the devices shrink. In case of GaN on Sapphire, only phase contrast microscopy with sub-Angstrom resolution allows to resolve all atomic columns at this interface for the first time. Even dislocation core structures are now accessible. With such tools it is now possible to systematically study the initiation of thin film growth on ceramic materials and semiconductors with short bond length on a truly atomic level. Overall the investigation demonstrates that newly emerging TEM techniques can be chosen such that they provide a best solution for a particular problem in materials sciences.

Abstract

We reported a novel silicon nanostructure, a chain of crystalline-silicon nanospheres: crystalline-silicon nanospheres are covered with and connected by silicon oxide at a nearly equal spacing forming a chain-like nanostructure. We have found that additional metal impurities such as lead can promote a periodic instability in the vapor–liquid–solid growth of silicon nanowires resulting in the chain formation. By controlling the metal impurities, we have successfully grown dense chains and also measured their phonon structures. Through the analysis of Raman spectra, we have found that the phonons were confined in the silicon nanospheres. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Nanostructure; Impurities; Self-organization

1. Introduction

In the self-organized formation of nanostructured materials, impurities and defects which are involved in the growth process often affect yield, morphology and properties of fabricated materials. Sometimes, impurities and defects obstruct and at other times they enhance the self-organized formation. For instance, it is well known that the formation of porous silicon [1], namely anodization of silicon, is dopant sensitive. In the case of carbon nanotube [2], its growth is governed by metal catalysts and also sensitive to the additional impurities such as sulfur. Therefore, the understanding of the role of impurities and defects is indispensable for controlling the self-organized formation. Of course, the role of impurities and defects is closely related to the growth mechanism; therefore, the understanding will also give useful information on the growth mechanism.

Recently, we found a novel silicon nanostructure, a chain of crystalline-silicon nanospheres [3]. The chain of

crystalline-silicon nanospheres is a self-organized semiconductor–insulator nanostructure: crystalline-silicon nanospheres are covered with and connected by amorphous silicon oxide at a nearly equal spacing forming a chain-like structure. The chains are grown via an extension of the well-known vapor–liquid–solid (VLS) mechanism from gold catalysts. We found that the chain growth is strongly affected by additional metal impurities such as lead [4]. In this paper, we discuss the structure, growth mechanism, role of metal impurities in the chain growth, and properties.

2. Growth and structure

Phosphorous-doped silicon (100) was used as a substrate and gold of about 10 nm thick was deposited on each substrate via vacuum evaporation. In order to add metal impurities such as lead to gold catalyst, each sample was sealed in a silica glass ampoule with a small piece of metal in a vacuum of 10^{-5} Torr and heated at a specific temperature for 30 min. Then, only the sample was sealed in a new ampoule in a vacuum of 10^{-5} Torr and heated at 1230°C. Transmission electron microscopy (TEM) observations were performed using a

200 kV-TEM, JEOL JEM-2010. Energy-filtered TEM images were obtained using a Gatan Image Filter with a charge coupled device (CCD) detector equipped in a 300 kV-TEM, JEOL JEM-3000F instrument at Osaka National Research Institute.

By using gold/lead catalysts, numerous chains were grown on the silicon substrate as shown in Fig. 1(a). The chains have a wire-like one-dimensional structure; however, their diameters are periodically modulated. In fact, there is a silicon nanocrystallite in the core of each knot. Some crystalline-silicon nanospheres are defective and have a twin structure as shown in Fig. 1(b). The necks which connect nanospheres and the surface layers of silicon nanospheres are amorphous silicon oxide.

When lead was not added to the gold catalyst, the chain growth became unstable and many silicon nanowires were grown as by-products of the chains. In Fig. 2, we show the yield of the chain growth against the temperature at which lead was added. Clearly, the chain growth is promoted by additional lead.

3. Growth mechanism and role of metal impurities

As shown in Fig. 1(a), there is a gold particle at the end of a chain. This is a strong evidence that the chains are grown via the VLS process. The growth mechanism of the chains of crystalline-silicon nanospheres was speculated by authors as follows: (i) the diameter of a silicon nanowire changes periodically due to a periodic instability in the wetting property of a molten catalyst at the tip of the wire; (ii) the wire was oxidized completely at the necks and incompletely at the knots leaving a silicon nanosphere in the core of each knot.

The periodic instability in the wetting property is explained by the following feedback mechanism [5,6]. If the diameter of a wire changes, then the curvature of the molten catalyst changes. As a consequence, the amount of vapor silicon taken in the catalyst at the vapor–liquid interface changes due to the Gibbs–Thomson effect. If the mole fraction of silicon in the molten catalyst changes, then the roughness of the liquid–solid interface changes due to the effect of the kinetic roughening resulting in the change in the wetting property of the molten catalyst and the diameter of the wire. Taking the above feedback mechanism into account, we performed computer simulations of the chain growth and found that the periodic instability was induced by the feedback mechanism [6] with adequate parameters such as temperature, size of molten catalyst and balance of interface tensions. Considering the fact that the periodic instability was sensitive to the parameters in our simulations, we speculate that the metal impurities such as lead affect the balance of interface tensions and promote the periodic instability. When we added copper

Fig. 2. Yield of the chain growth as a function of the lead-treatment temperature (closed circles). Closed triangles correspond to the yields without lead treatment.

instead of lead, many silicon nanowires were grown instead of the chains. It is likely that copper also changes the balance of interface tensions, but it suppresses the periodic instability.

TEM observations also support our growth model indicating that the surface oxidation plays an essential

Fig. 3. Energy-filtered TEM image of a chain of crystalline-silicon nanospheres showing tails of a silicon nanocrystallite.

role in the chain growth. In Fig. 3, we show an energy-filtered TEM image of chains, where the electrons which lost their energy by exciting silicon bulk plasmon (16–17 eV) were used to form the image [7]. Accordingly, the silicon nanocrystallites in the chain can be seen clearly. As is shown, tails of silicon which extend into the core of wires were observed. This image clearly proves that the silicon nanocrystallites were formed as a consequence of the surface oxidation of diameter-modulated silicon nanowires.

4. Raman scattering measurements

In order to reveal microscopic features of the chains, we performed Raman scattering measurements. The Raman scattering spectra were obtained at room temperature using a Jobin-Yvon T64000 spectrometer with an LN₂-cooled CCD detector. The spectrum resolution was 0.6 cm^{-1} . The 514.5 nm line of an Ar ion laser was used for excitation and the excitation light was focused to a spot of $6\text{ }\mu\text{m}$ in diameter with a power density of about 70 mW/cm^2 . We confirmed that the thermal effect on Raman spectra due to laser heating was negligible. In order to avoid background scattering from a substrate, chains were grown on a molybdenum substrate. A chain sample with silicon nanospheres of $5\pm 1\text{ nm}$ in diameter and oxide layers of $2.7\pm 0.3\text{ nm}$ thickness was examined. In Fig. 4, we show a Raman spectrum of the chain sample with that of bulk crystalline-silicon. The FWHM of the one-phonon Raman line of the chain sample was measured to be 11 cm^{-1} , while that of bulk crystalline-silicon was 3 cm^{-1} including the instrument broadening. In addition, the line shape of the Raman line of the chain sample was asymmetric. These features can be attributed to the effect of phonon confinement in the silicon nanospheres.

Fig. 4. Raman scattering spectra of chains of crystalline-silicon nanospheres and bulk crystalline-silicon.

5. Conclusion

We have grown dense chains of crystalline-silicon nanospheres by controlling metal impurities in the growth process. Growth mechanism of the chains was revealed by computer simulations and TEM observations. By adding lead to gold catalysts, the yield of chain growth was remarkably increased. It appears that lead promotes periodic instability in the wetting property of the molten catalysts at the tips of growing chains. We also performed Raman scattering measurements of the chains and found that phonons were confined in the silicon nanospheres in the chains.

Abstract

The effects of P doping on defects in $\text{Si}_{1-x}\text{Ge}_x$ alloy nanocrystals (nc- $\text{Si}_{1-x}\text{Ge}_x$) embedded in SiO_2 thin films were studied by electron spin resonance (ESR) and photoluminescence (PL) spectroscopy. P doping resulted in a drastic decrease in the ESR signals, which are assigned to the Si and Ge dangling bonds at the interfaces between nc- $\text{Si}_{1-x}\text{Ge}_x$ and matrices (Si and Ge P_b centers). It was found that, with increasing P concentration, the signal from Ge P_b centers is first quenched, and then the quenching of the signal from Si P_b centers starts. The quenching of the ESR signals was accompanied by a drastic enhancement of PL intensity. © 2001 Elsevier Science B.V. All rights reserved.

Si nanocrystals (nc-Si) show efficient luminescence in near-infrared to visible regions due to the quantum confinement effects [1–3]. However, even for nc-Si several nanometers in diameter, the indirect band gap nature of bulk Si crystal is highly preserved [4]. This results in a long luminescence lifetime (small optical transition oscillator strength). This long lifetime is one of the obstacles to realizing Si-based light-emitting devices. $\text{Si}_{1-x}\text{Ge}_x$ alloy formation is expected to offer a way for enhancing the optical transition oscillator strength. In fact, the shortening of the radiative lifetime with increasing Ge concentration has been demonstrated for $\text{Si}_{1-x}\text{Ge}_x$ alloy nanocrystals (nc- $\text{Si}_{1-x}\text{Ge}_x$) in SiO_2 matrices [5,6] and porous $\text{Si}_{1-x}\text{Ge}_x$ [7]. However, the formation of nc- $\text{Si}_{1-x}\text{Ge}_x$ is often accompanied by the degradation of band-edge photoluminescence (PL) efficiency [5].

In our previous work, we studied the electron spin resonance (ESR) and PL properties of nc- $\text{Si}_{1-x}\text{Ge}_x$ in SiO_2 [8]. It was found that the ESR spectrum is a

superposition of signals from Si and Ge dangling bonds at the interfaces between nc- $\text{Si}_{1-x}\text{Ge}_x$ and SiO_2 matrices (Si and Ge P_b centers). As the Ge concentration increased, the signal from the Ge P_b centers increased, while that from the Si P_b centers was nearly independent of Ge concentration. The increase in the number of Ge P_b centers was accompanied by strong quenching of the PL. The observed correlation between the two measurements suggests that the Ge P_b centers act as efficient non-radiative recombination centers for photogenerated carriers, resulting in the quenching of the band-edge PL.

Proper surface passivation is essential in obtaining efficient luminescence. Surface passivation controls the luminescence intensity through the elimination of the P_b centers. The passivation of Si P_b centers by hydrogen and oxygen has been reported to be effective in improving luminescence efficiency [9,10]. Recently, we demonstrated that Si P_b centers can effectively be passivated by P doping [11–13]. It was shown that, as the P concentration increases, the intensity of the band-edge PL increases drastically, while Si P_b centers-related PL decreases. These results suggest that the density of the P_b centers decreases by P doping, leading to the

improvement in the band-edge PL efficiency. For nc-Si_{1-x}Ge_x, the passivation of Ge P_b centers by similar approaches might be possible. In this work, we prepared nc-Si_{1-x}Ge_x as small as 4 nm in diameter embedded in phosphosilicate glass (PSG) thin films with different P concentrations and studied the ESR and PL properties.

P-doped Si_{1-x}Ge_x alloy nanocrystals were prepared by co-sputtering of Si, Ge, SiO₂, and PSG [5,6]. After the deposition, films were annealed in an N₂ gas atmosphere for 30 min at 1100°C to grow nc-Si_{1-x}Ge_x in PSG matrices. P and Ge concentrations were determined by electron probe microanalysis and Raman spectroscopy [5], respectively. P concentration was varied from 0 (without P doping) to about 1.0 mol%. Ge concentration (*x*) was fixed at 0.3. Experimental details are found in our previous papers [5,6,8].

Figs. 1(a) and (b) show PL spectra of nc-Si_{0.9}Ge_{0.1} (sample A) and nc-Si_{0.7}Ge_{0.3} (sample B) with various P concentrations, respectively. PL peaks are observed around 1.4 and 0.9 eV. The 1.4 eV PL peak corresponds to the band-edge PL. The 0.9 eV peak is generally assigned to the recombination of photoexcited carriers via Si P_b centers [11,12,14]. The integrated intensities of the band-edge PL and the 0.9 eV PL are shown in Fig. 2 as a function of P concentration. With increasing P concentration, the intensities of the band-edge PL for both the samples first increase and then decrease. The PL intensity of sample A is improved by a factor of 3, while that of sample B by a factor of 14. The maximum PL intensities are almost the same for both series of samples and are also almost the same as the maximum PL intensity of P-doped pure nc-Si [11,12]. In Fig. 2, for sample A, the intensity of the 0.9 eV PL decreases monotonically, while for sample B that takes a maximum at 0.6 mol%.

Fig. 1. Photoluminescence from nc-Si_{1-x}Ge_x with (a) *x* = 0.1 and (b) *x* = 0.3 dispersed in PSG thin films at 10 K.

Fig. 2. Intensities of the band-edge PL and Si-P_b-center-related PL at 10 K as a function of P concentration. Vertical axis represents the PL intensity with respect to the band-edge PL intensity of nc-Si_{0.9}Ge_{0.1} in SiO₂ (without P doping).

Fig. 3. Integrated ESR spectra of nc-Si_{1-x}Ge_x dispersed in PSG thin films at room temperature.

Figs. 3(a) and (b) show the integrated ESR spectra of samples A and B with various P concentrations, respectively. For the samples without P doping, asymmetric ESR signals are observed; the *g*-value and the line width are 2.0058 and 10.7 G for sample A, and 2.0103 and 36.6 G for sample B. These signals can be assigned to a superposition of signals from Si and Ge P_b centers [8]. As the P concentration increases, the intensity of the ESR signals decreases. Fig. 4 shows the integrated intensities of the ESR signals for Si and Ge P_b centers as a function of P concentration. The intensities are obtained by deconvoluting the ESR spectrum into two Lorentzian functions. In the sample A, intensities of Si and Ge P_b centers decrease at almost the same rate with

Fig. 4. Integrated intensities of ESR signals from Si and Ge P_b centers as a function of P concentration. Vertical axis represents the ESR intensity with respect to the intensity of Ge P_b centers in nc-Si_{0.9}Ge_{0.1} in SiO₂ (without P doping).

increasing P concentration, indicating that the number of Si and Ge P_b centers decreases monotonically by P doping. On the other hand, in the sample B, Si and Ge P_b centers exhibit different P concentration dependence; the intensity of the signal from Ge P_b centers decreases rapidly with increasing P concentration, while that from Si P_b centers is almost constant at low P concentration range and then decreases gradually with further increasing P concentration.

The present P concentration dependences of PL and ESR properties can consistently be explained by the following model. From a point of view of PL properties, nc-Si_{1-x}Ge_x embedded in SiO₂ matrices can be classified into four categories. One is nc-Si without non-radiative recombination centers, which show the band-edge PL around 1.4 eV. The second kind of nanocrystals are those having at least one Si P_b center. These nanocrystals do not show the band-edge PL but show only the 0.9 eV PL at low temperatures. The third and last kind of nanocrystals are those having at least one Ge P_b centers and both the Si and Ge P_b centers, respectively. In these nanocrystals, photoexcited carriers are thought to be preferentially trapped at Ge P_b centers and recombine non-radiatively even at low temperatures [8]. The present samples are the ensemble of these four kinds of nanocrystals. With increasing Ge concentration, the number of nanocrystals not emitting light increases, resulting in the quenching of both the band-edge PL and Si- P_b -center-related PL. This Ge concentration dependence of the PL and ESR intensities can clearly be seen in Figs. 2 and 4.

Fig. 4 demonstrates that not only Si P_b centers but also Ge P_b centers are passivated by P doping. The passivation is considered to be made electrically, i.e., electrons supplied by P doping are trapped at P_b centers and inactivate the centers. The quenching of the ESR signals from Ge P_b centers is much faster than that from

Si P_b centers. This result indicates that, if both Si and Ge P_b centers exist in one nc-Si_{1-x}Ge_x, electrons supplied by P doping are preferentially captured by Ge P_b centers. After completing the passivation of Ge P_b centers, the passivation of Si P_b centers starts.

Preferential passivation of Ge P_b centers increases the number of nanocrystals which do not have electrically active Ge P_b centers. As a result, in nc-Si_{0.7}Ge_{0.3}, the intensities of both the band-edge PL and Si- P_b -center-related PL are enhanced by P doping, i.e., Si P_b centers remain active even if the P concentration is relatively high. On the other hand, in nc-Si_{0.9}Ge_{0.1}, the number of nanocrystals having Ge P_b centers is small. Therefore, the passivation of Si P_b centers starts at low P concentration, resulting in the quenching of Si- P_b -center-related PL at low P concentration region.

At high P concentration, after completing the passivation of both Si and Ge P_b centers, electrically active P atoms supply free electrons in nc-Si_{1-x}Ge_x. Although not shown in this article, in the range where PL intensity decreases, optical absorption due to the intravalley transition of electrons generated by P doping in the conduction band, i.e., free-electron absorption in nc-Si_{1-x}Ge_x is observed. This is the direct evidence that free electrons are generated in nc-Si_{1-x}Ge_x. The generation of free electrons and the resultant three-body Auger recombination of electron-hole pairs is considered to be responsible for the observed PL quenching.

In conclusion, the effects of P doping on defects in nc-Si_{1-x}Ge_x in SiO₂ thin films were studied. It was found that doped P atoms can play some different roles, depending on the condition of surface termination. If P atoms are doped in nc-Si_{1-x}Ge_x with Si and Ge P_b centers, electrons supplied by P doping are preferentially captured by Ge P_b centers and inactivate the centers. After completing the passivation of Ge P_b centers, the passivation of Si P_b centers starts. This results in the improvement in the PL efficiency.

Single impurity centers embedded in self-assembled silicon microcavities

N.T. Bagraev*, A.D. Bouravleuv, L.E. Klyachkin, A.M. Malyarenko

A.F. Ioffe Physico-Technical Institute, Russian Academy of Sciences, 26 Polytechnicheskaya ul, St. Petersburg 194021, Russia

Abstract

We present the findings of high efficient light absorption in self-assembled quantum wells (SQW) embedded in silicon microcavities that exhibit a distributed feedback identified by the FIR transmission spectra. The photo and electroluminescence from SQW is found to be enhanced in the range of the Rabi splitting. The intraband hole transitions are shown to give rise to a fast energy transfer into the d-shell transitions of the center incorporated into the microcavity which is caused by the strong sp-d mixing in the built-in electric field and revealed by the intracenter emission. © 2001 Elsevier Science B.V. 1. Introduction

Dopant diffusion in silicon is known to be amenable to control by means of adjusting the fluxes of self-interstitials and vacancies emerging from the mono-crystalline surface [1]. The diffusion of boron has been found to be enhanced along the $\langle 111 \rangle$ axis in the Si(100) wafer covered by the thin oxide overlayer, whereas the presence of thick oxide overlayer on the Si(100) wafer raises the boron diffusion along the $\langle 100 \rangle$ axis [2]. These indications point out the crystallographic orientation of the excess fluxes of self-interstitials and vacancies that seem to involve dopants in the diffusion process and to be split into space-independent parts generated by the oxidized working side. The goal of the present work, which studied the absorption and emission from self-assembled quantum wells (SQW) inside the ultra-shallow boron diffusion profile, is to exhibit silicon microdefects induced by the excess fluxes of self-interstitials that form the microcavities embedded in SQW.

2. Methods

The short-time boron diffusion was carried out from the gas phase into 350 mm thick n-type monocrystalline Si(100)-wafers with resistivities $20 \Omega \text{ cm}$. The wafers were previously oxidized at 1150°C in dry oxygen containing CCl_4 vapors. Short-time impurity doping was done under fine surface injection of both self-interstitials and vacancies into windows which were cut in the oxide after preparing a mask and performing the subsequent photolithography. Additional replenishment with dry oxygen into the gas phase during the diffusion process provides the generation of excess fluxes of intrinsic point defects from the working side. The variable parameters of the diffusion experiment were the oxide overlayer thickness, the diffusion temperature and the Cl levels in the gas phase during the diffusion process. Diffusion profiles were studied using the four-point probe, SIMS, cyclotron resonance (CR), infrared Fourier spectroscopy and scanning tunneling microscopy (STM) techniques.

3. Results

Using SIMS and four-point probe technique under layer-by-layer etching, the analysis of the structures

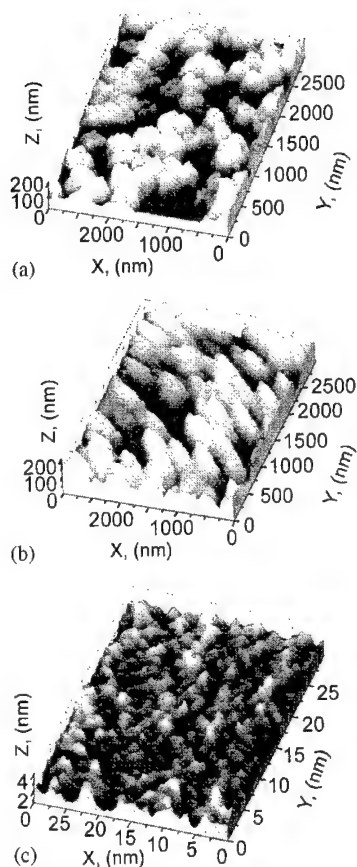

Fig. 1. STM images of the ultra-shallow boron diffusion profiles prepared at diffusion temperature of 800°C (a and b) and 900°C (c) into the Si(100) wafer covered previously by thick (a), thin (b) and medium (c) oxide overlayer. $X \parallel [001]$, $Y \parallel [010]$, $Z \parallel [100]$.

obtained shows that the ultra-shallow boron profiles consist of SQW divided by heavily doped δ -barriers. The SQW characteristics have been identified by the CR angular dependencies and current–voltage (CV) diagrams and brought about the deflection of the bias voltage from the normal to the p^+-n junction plane.

Space-independent excess fluxes of intrinsic defects that cause the formation of SQW appear to be transformed also into microdefects which can be revealed by the STM technique as the deformed potential fluctuations (DPF) near the Si–SiO₂ interface and the surface of the ultra-shallow diffusion profile. The DPF effect induced by the microdefects of the self-interstitials type that are displayed as light poles in Fig. 1 is demonstrated to be brought about by the previous oxidation and to be enhanced by subsequent boron diffusion. The STM technique allowed to define crystallographic orientation of DPF obtained by using

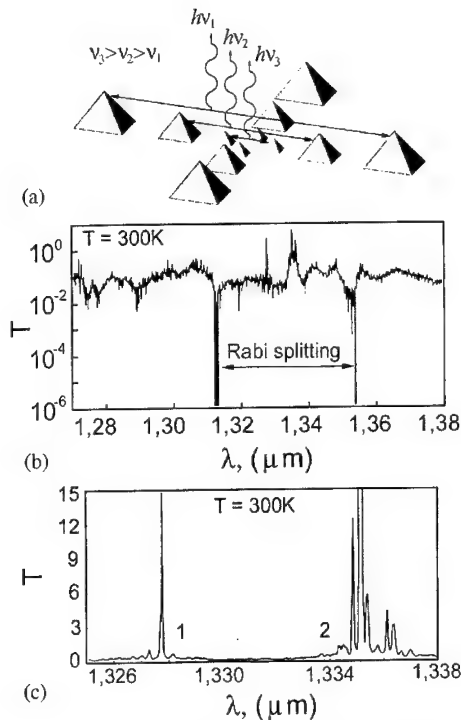

Fig. 2. The model of self-assembled microcavity systems (a) prepared on the Si(100) wafer and revealed by spectral dependence of the light transmission coefficient (b) that demonstrates at $T = 300$ K the enhancement of the photoluminescence (c) from self-assembled quantum well (1) and single residual transition metal center (2).

thick (Fig. 1a) and thin (Fig. 1b) oxide overlayer that corresponds, respectively, to the $\langle 100 \rangle$ and $\langle 111 \rangle$ axis and visualizes practically the orientation of excess fluxes of self-interstitials as a function of the oxide overlayer thickness. The analysis of the STM image of the ultra-shallow boron profile prepared under parity conditions between diffusion mechanisms (Fig. 1c) enables one to hazard a conjecture that the dimension of the microdefect observed is consistent with the parameters expected from the tetrahedral model of the Si₆₀ cluster [3]. Thus, the DPF effect gives rise to the formation of self-assembled quantum antidots with dimensions that are equalized as the diffusion temperature increases. Besides, the interplay between the dimensions of these antidots and their distribution inside the ultra-shallow diffusion profile prepared on the Si(100) wafer is found to be evidence of the fractal mechanism that causes the formation of the microcavities embedded into the SQW system (Fig. 2a).

These silicon microcavities are revealed by the spectral dependencies of the transmission coefficient that exhibits a distributed feedback identified by the Rabi splitting [4]

(Fig. 2b and c). The photoluminescence from the SQW embedded in microcavity is found to be created in spectral range of the Rabi splitting (Fig. 2c). Besides, the strong coupled d-electron states of a residual transition metal center with the s-p electronic states of the host SQW are also revealed by the intracenter emission that seems to exhibit the transitions induced by the Stark effect caused by the built-in electric field of the quantum-size p^+-n junction (Fig. 2c). The quenching and regeneration of the SQW luminescence demonstrated by the angular dependencies of the transmission spectra appears to be defined by the orientation of the self-assembled quantum well along the Si(100) p^+-n junction plane (Fig. 3). The angular dependent positions of the intracenter emission lines that seem to be due to the strong sp-d mixing allow one to propose the excitation of the EPR transitions in the micron range

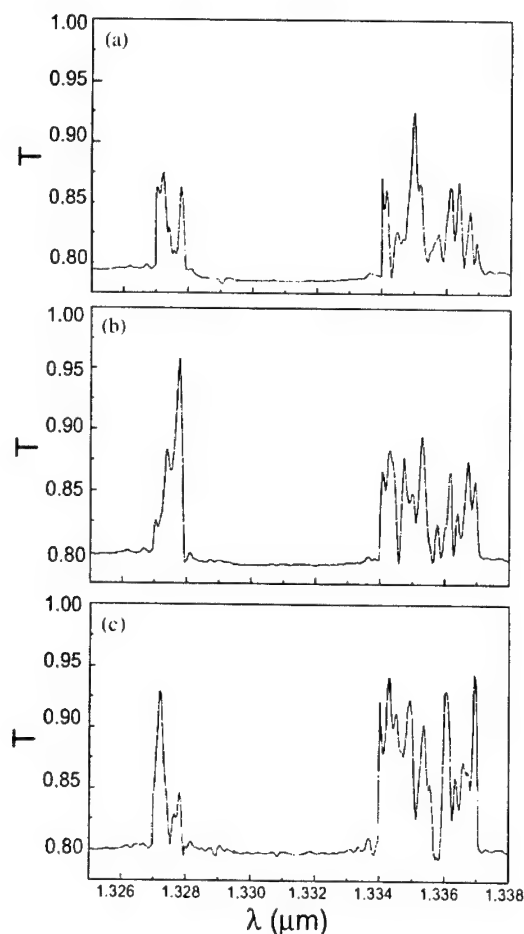

Fig. 3. The transmission spectra measured at different angles between the normal to the Si(100) surface and the light beam, α , that causes the intraband and intracenter emission from the p-type SQW embedded in the silicon microcavity. $T = 300$ K. under strong coupling of the light beam to the microcavity embedded in the SQW series (Fig. 3), the model of which is in progress.

Finally, the resonant tunneling through strongly coupled quantum well series that is accompanied by the cascade emission under injection of both electrons and holes (Fig. 4a) or only holes (Fig. 4b) is able to be a basis of high efficient visible (Fig. 5a) and infrared (Fig. 5b) electroluminescence.

Fig. 5. The electroluminescence spectra caused by the visible (a) and infrared (b) emission from p-type SQW series embedded in the silicon microcavity, $T = 300$ K. (a) The external quantum efficiency of the white light emission (1) is equal to 0.5%, $I_{\text{rev}} = 25$ mA, $U_{\text{rev}} = 40$ V, which is in a good agreement with the spectral eye sensitivity (2). (b) The external quantum efficiency of the infrared light emission is equal to 7%, $I_{\text{rev}} = 30$ mA.

4. Summary

The microdefects that are formed by self-interstitials inside p^+-n junctions in the diffusion process of boron into the Si(100) wafer have been demonstrated to promote the realization of the silicon microcavities embedded in SQW. The luminescence from silicon quantum wells has been found to be enhanced in the range of the Rabi splitting. The intraband hole transitions have been shown to give rise to a fast energy transfer into the d-shell transitions of the center incorporated into the microcavity, which is revealed by the intracenter emission.

Abstract

Photoluminescence spectra and their dependence on the temperature have been used to study the peculiarities of the red photoluminescence in low-dimensional Si structures, such as porous silicon and silicon oxide films with an admixture of silicon. It has been shown that red photoluminescence band of Si wires is complex and can be decomposed into two elementary bands. Practically the same positions of photoluminescence bands are observed in silicon oxide films. Comparative investigation of photoluminescence temperature dependence in Si wires and silicon oxide indicates that oxide defect related mechanisms for photoluminescence bands are involved. The photoluminescence excitation mechanisms in both objects are discussed as well. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

The room temperature visible photoluminescence (PL) of Si wire structures, such as porous silicon (PSi) and silicon nanoparticles in silicon oxide, has attracted much attention due to the high PL efficiency and its potential applications in Si-based optoelectronics. Since the work of Canham in 1990 [1], many studies of PSi have been carried out [2]. The visible PL can be explained either as related to size distribution of quantum confined nanocrystals [1] or/and as a result of the emission of different types of radiative centres on Si-wire surface [3]: polysilan complexes [4], siloxene molecules [5], water molecules with impurities [6], defects in silicon oxide [7] and suboxide [8]. The possibility of the emission of excitons at the Si/SiO₂ interface has been suggested as well [9]. Surprisingly little attention has been paid to the peculiarities of the luminescence spectrum itself, which is of fundamental

importance. Furthermore, it was proposed earlier [1], that only in porous silicon with a high level of porosity (70–80%) one could expect intensive photoluminescence. But there are many examples of high PL intensity in PSi with very low porosity, like 10% [10] or 22% [11]. Thus, the origin of the visible luminescence from PSi still needs to be clarified.

The investigations of photoluminescence of silicon oxide films with an admixture of silicon are not numerous [12–16]. The main aim of such studies was to determine the photoluminescence mechanism of Si-wire structures. As far as we know, the temperature dependence of the photoluminescence in these structures has not been reported so far.

This paper presents a spectral characterization of the PSi photoluminescence emphasizing its dependence on temperature (*T*) and technological conditions. The photoluminescence of silicon oxide films with an admixture of the silicon has also been investigated. In these films, it was possible to change the content of Si in the oxide from suboxide up to dioxide. Models of two luminescence transitions

and corresponding excitation and recombination mechanisms are discussed.

2. Experimental results

The PSi samples were prepared from p-type, B-doped, (100) oriented silicon wafers of $1.0\ \Omega\text{cm}$ resistivity. The porous layers were obtained by electrochemical etching in a solution of $\text{HF}:\text{H}_2\text{O}:\text{C}_2\text{H}_5\text{OH}$ (1:1:2). Groups of samples prepared at an etching duration of $t_a = 10$ min and several values of the etching current densities ($I_a = 5, 10, 15, 20, 50$ and $75\ \text{mA/cm}^2$) were investigated.

The co-sputtered films were prepared by sputtering from two electrodes, one with a silicon target and the other with a quartz target on a long (15 cm) quartz substrate. In this manner, variation of the Si content in the film is obtained. The films were subsequently annealed at 1100°C in an inert atmosphere in order to make them photoluminescent. The continuous change of the Si– SiO_x composition could be observed by the change of the film colour from brown at the Si-rich end to transparency at the Si-poor end. The brown colour indicates the formation of a suboxide, while the transparent end is mostly dioxide.

PL spectra have been measured by excitation of the PSi with an Ar^+ laser tuned at a wavelength of $5145\ \text{\AA}$. The PL signals were dispersed with a Model 1403 Spectrometer. PL was studied in a temperature range of 10–300 K.

2.1. PL spectrum dependences on anodization condition and temperature

Fig. 1 shows PL spectra for PSi samples obtained at different technological conditions. For PSi prepared at low current density ($5\text{--}20\ \text{mA/cm}^2$, Fig. 1a) the PL band, peaked at $h\nu_m = 1.70\text{--}1.73\ \text{eV}$ (for different samples used), with full width at half maximum (FWHM) equal to $300\text{--}320\ \text{meV}$, dominates at 300 K. For all investigated samples this band has essentially a symmetric Gaussian's shape. While for PSi samples prepared at high current densities ($30\text{--}75\ \text{mA/cm}^2$, Fig. 1b) the PL band that dominates at 300 K, is centred at $1.9\text{--}2.1\ \text{eV}$. This high-energy PL band ($h\nu_m = 1.90\text{--}2.10\ \text{eV}$) has a symmetric Gaussian's shape as well, but their FWHMs monotonically increases from 340 up to $390\ \text{meV}$ with increasing PL peak energy. Thus, it is possible in a controlled way to prepare samples with definite PL elementary bands.

The PL spectra variations with temperature for low porosity (10–20%) PSi samples prepared at $I_a = 5\ \text{mA/cm}^2$ are presented in Fig. 1a. At 300 K only the PL band, with a maximum at $1.73\ \text{eV}$ and FWHM of $300\text{--}320\ \text{meV}$, is observed. The spectrum shape, in the T range of $300\text{--}8.5\ \text{K}$, changes with T decrease. This is

Fig. 1. (a) PL spectra of PSi sample prepared at $I_a = 5\ \text{mA/cm}^2$ and $t_a = 10$ min and measured at the T : 300 (1), 250 (2), 150 (3), 50 (4) and $8.5\ \text{K}$ (5). (b) PL spectra of PSi sample prepared at $I_a = 75\ \text{mA/cm}^2$, $t_a = 10$ min and measured at the same temperatures, as for (a).

mainly due to the increase of the high-energy part of the PL band. At the same time, the peak shifts to $1.85\ \text{eV}$ and the FWHM increases up to $450\ \text{meV}$. As can be seen, the low-energy sides of the PL bands at these temperatures change, but not much in comparison with the high-energy sides (Fig. 1a). It is clear that a new PL band appears mainly at the high-energy side of the spectrum when the T decreases (Fig. 1a). Thus, the PL band of PSi at low temperature has a complex nature and can be represented, as the sum of two elementary bands: the original band with a peak at $1.73\ \text{eV}$ and a new one with a peak at $1.95\ \text{eV}$. This new PL band has, in general, a maximum at $1.90\text{--}2.10\ \text{eV}$ (in different samples) and a FWHM, which increases from $340\ \text{meV}$ up to $390\ \text{meV}$ with increase in peak energy. The peak intensity of the first band also risen somewhat with T decreasing (Fig. 2a, curve 1). The second band intensity, on the other hand, monotonically increases noticeable with T decreasing (Fig. 2a, curve 2). The important conclusion to be drawn from the data presented is that the low-energy and high-energy PL bands have different T dependencies (Fig. 2). This indicates the presence of two different radiative mechanisms in this PSi.

In high porosity (70–80%) PSi prepared at high current the PL band, peaked at $1.95\ \text{eV}$, with FWHM of $360\ \text{meV}$ dominates at 300 K. With T decrease in the temperature range of $300\text{--}150\ \text{K}$, the spectrum shape changes, mainly due to the increase of the high-energy part of the PL band as well. The peak maximum shifts to $2.10\ \text{eV}$ and the FWHM increases to $400\ \text{meV}$ (Fig. 1b).

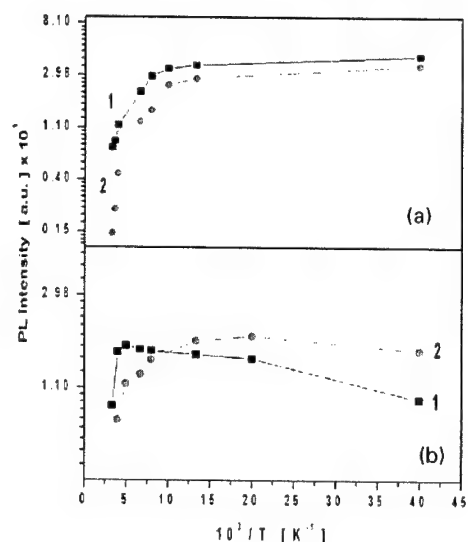

Fig. 2. Variation of PL band intensities with the T increase for PS prepared at $I_a = 5$ (a) and 75 (b) mA/cm^2 and $t_a = 10$ min for PL bands peaked at 1.73 eV (1a), 1.95 (2a), 1.90 eV (1b) and 2.13 eV (2b).

As can be seen, the low-energy sides of the PL bands at these T change only little compared to the high-energy sides (Fig. 1b). There appears also a new PL band when the T decreases (Fig. 1b). The PL band of this PSi at low temperature can be decomposed into two PL bands: the original band at 1.90 eV and a new one at 2.15 eV. The peak intensities of both PL bands increase with T decreasing in the 150 – 300 K range (Figs. 1b and 2b). The intensities of both PL bands decrease with T in the 8.5 – 150 K range (Fig. 2b).

2.2. PL studies of co-sputtered Si-SiO_x films

It was assumed [19–21] that the difference in spectral positions of the PSi luminescent bands might be connected with the different composition of silicon oxide on Si wire surface, where corresponding radiative defects are localized. In this case comparative PL investigation of Si-SiO_x films and PSi can, apparently, confirm such assumption. In Raman scattering spectra of the Si-SiO_x films, the Raman line at 520 cm^{-1} , corresponding to Si-Si vibrations in crystalline Si, has not been registered. This suggests that in these films there are no crystalline Si nanoparticles present. Thus, the different colours of the amorphous oxide films are connected with the change in its composition from suboxide (brown colour) to dioxide (transparent film).

Fig. 3 presents the PL spectra of these films. Two PL bands, peaked at 1.6 – 1.7 eV and at 2.1 – 2.2 eV with an FWHM equal to 320 and 400 meV, respectively, were measured. With increase of the oxygen content in Si-SiO_x film the peak positions of both bands shift towards

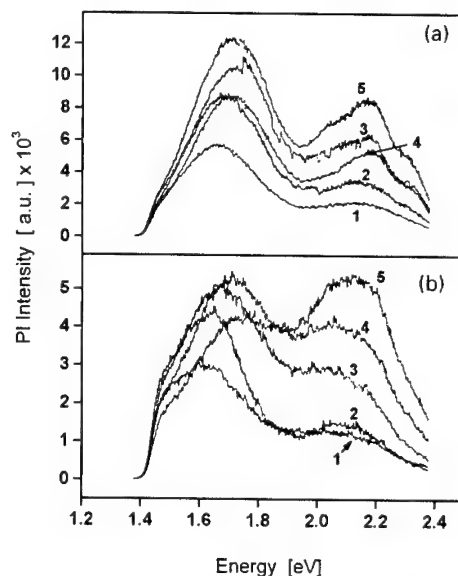

Fig. 3. (a) PL spectra of Si-SiO_x thin films, measured for transparent (dioxide) part at the T : 300 (1), 200 (2), 100 (3), 50 (4) and 10 K (5). (b) PL spectra of Si-SiO_x thin films, measured for brown (suboxide) part at the T : 300 (1), 200 (2), 100 (3), 50 (4) and 10 K (5).

the high-energy side of the spectrum (Fig. 3a). The intensities of PL bands in the dioxide side were highest than in the suboxide side. The FWHMs of the PL bands in the silicon oxide are practically the same as in PSi. The peak positions of both PL bands exhibit a blue shift of 100 meV with decreasing temperature from 300 to 10 K, just the same way as for PSi PL bands. The process of effective thermal quenching with T -increase for PL bands in silicon oxide starts at about 100 – 150 K, similarly as for the PL bands in PSi (Figs. 2 and 4).

It is necessary to emphasize the difference in T -dependences for the PL band at 1.6 – 1.7 eV for Si suboxide and dioxide (Fig. 4b). As one follows from Figs. 3 and 4, the intensity of this PL band in the suboxide decreases when the T decreases from 50 to 10 K. At the same time the intensity of this PL band in silicon dioxide monotonically increases when the T decreases to 10 K.

3. Discussion

The investigation of the PL temperature dependence provides a valuable tool to study the recombination and excitation mechanisms for photo-excited carriers and as a result to study the semiconductor band edges, excitons, impurities and defect level positions. The increase of the PL intensity with T decreasing, usually, reflects an enhancement of exciton recombination or

Fig. 4. Variation of PL band intensities with the T increase for transparent (a) and brown (b) Si-SiO_x thin films for PL bands peaked at 1.73 eV (1a), 1.95 eV (2a), 1.90 eV (1b) and 2.13 eV (2b).

defect related recombination in the T ranges lower than the temperature of a thermal quenching process start. The drop of the PL intensity at low T has been usually attributed to the decrease of phonon participation in the recombination process, due to the decrease of the available number of phonons.

Let us discuss, first of all, the T dependence for the PL bands in silicon oxide. As can be seen from Fig. 4a the intensities of both PL bands monotonically increase with T decreasing. Due to the very high value of the energy gap in silicon dioxide (>8 eV) the two investigated PL bands peaked at 1.6–1.7 and 2.1–2.2 eV should be connected with two different types of defects. Their temperature behaviour is the evidence of the enhancement of defect related PL in the T range below thermal quenching. All PL spectra measurements have been made with excitation by an Ar laser (2.41 eV). Such excitation of the PL band in silicon dioxide films should be connected with interdefect optical transitions. Note that the peak positions of PL bands shift towards the high-energy with the change of the composition of silicon oxide from suboxide to dioxide.

The T dependence of the high energy PL band peaked at 2.1–2.2 eV in silicon suboxide is the same as in silicon dioxide (Fig. 4a and b). The T dependence for the PL band centred at 1.6–1.7 eV, however, is different in the low T -ranges for the suboxide film (Fig. 4). The decrease of the intensity with T decreasing in the 10–50 K range for this PL band indicates a phonon-assisted mechanism of excitation. In the case of silicon suboxide, it could be assumed that the excitation light of Ar laser with an energy of 2.41 eV excites the electrons from the valence

into the conduction band due to phonon assisted optical transition in indirect band gap suboxide material. In the second stage, the photo carriers are trapped by defect-related radiative centre, responsible for the 1.6–1.7 eV PL band. Thus, we can conclude that two types of excitation mechanisms are possible for the 1.6–1.7 eV PL band in silicon oxide: interdefect electronic transition in dioxide and trapping of the free carriers by the radiative centres in suboxide.

The radiative defects in silicon oxide films have been investigated very intensively [17–21]. Based on the joint investigation of PL, absorption, as well as electron paramagnetic resonance spectra, the PL band peaked at 1.9 eV is attributed to non-bridge oxygen hole centre (NBOHC) [17–19]. It was also shown, that this band could shift in the 1.7–2.0 eV spectral range depending on the additional OH group content in the silicon oxide. The latter connects with two, and possibly three different configuration forms for NBOHC centres [19]. It was discovered that 2.41 eV Ar laser directly excites NBOHC defects due to intercentre optical transition [19]. Another type of defect known in silicon oxide is the defect responsible for the 2.4–2.7 eV PL band [20]. The latter defect is attributed to oxygen vacancy in silicon oxide crystal lattice.

In PL spectra of the investigated PSi we observed two PL bands with Gaussian's shape centred at 1.70–1.90 eV and 1.90–2.15 eV. Our previous conclusion [8,20,21] that these elementary PL bands in PSi are connected with the defects in silicon oxide at the Si/SiO_x interface is confirmed independently by PL investigation of the Si-SiO_x films. The spectral positions of the PL bands in Si-SiO_x films are similar to that in PSi, and this is a convincing evidence towards the proposed model (Figs. 1 and 4). Some small difference in the peak position of PSi PL bands can be associated with PSi surface chemistry. Moreover, both PL bands in PSi and in sputtered Si-SiO_x films start their effective thermal quenching process at the same temperature interval (100–150 K).

For PL bands peaked at 1.7–1.9 eV and 1.9–2.15 eV in PSi there may exist two mechanism of PL excitation, like in Si-SiO_x films (Fig. 2a and b). For low porosity PSi the PL intensity monotonically increases with T -decreasing in the 10–50 K range, like in silicon dioxide. The decrease of the PL intensity with T -increasing can correspond to a typical excitonic behaviour, proposed in quantum confined PL model. But the excitonic model cannot explain the drop of the PL intensity, when the T approaches 10 K. Really, for high porosity silicon (70–80%), prepared at high current density with big Si/SiO_x interface area, the PL intensity of both bands decreases with T -decreasing in the 10–50 K range, like in silicon suboxide (Fig. 2b). In this case such behaviour could be attributed to the absorption of excitation light in Si wires followed by radiative recombination of the carriers

via defects at the Si/SiO_x interface [3,21–23]. The excitation transition in indirect band gap material (Si) should be phonon assisted.

Finally, we can conclude that the same types of defect related radiative centres are responsible for PL in the Si–SiO_x films and in PSi. These radiative defects are located at the Si/SiO_x interface or in SiO_x layer on Si wire surface. Two types of PL excitation mechanisms are possible in investigated structures: interdefect and fundamental band-to-band optical transitions. The first mechanism dominates in silicon dioxide layers, while the second one dominates in silicon suboxide and in the Si crystallites of PSi.

The influence of Coulomb effects on the electron emission and capture in InGaAs/GaAs self-assembled quantum dots

M.M. Sobolev*, V.M. Lantratov

A.F. Ioffe Physical Technical Institute, 26 Polytechnicheskaya ul., RAS, 194021 St. Petersburg, Russia

Abstract

The influence of built-in electrostatic potential of interface dipole on barrier energies for the emission and capture of electrons by InGaAs/GaAs quantum dots (QDs) has been found. It was shown that the formation of the interface dipole from carriers localized in QDs and ionized deep level defects depended on isochronous annealing under bias-on-bias-off cooling conditions. The dependence of the height of the capture barrier on the filling pulse duration, related to a manifestation of the Coulomb blockade effects on the capture of electrons into the ground and excited states of the dots, has also been revealed. © 2001 Elsevier Science B.V. Keywords: GaAs; Quantum dot; Defects; Heterostructures; Interaction

1. Introduction

The quantum dots (QDs) fabricated by self-organization during strained layer heteroepitaxy have found a wide application as injection laser [1] and they also promise new applications like the memory devices [2]. However, essential improvement of the performances of the QD lasers as well as design and understanding of an operation of memory devices are not well realized. These may be due to, among other factors, the availability of barrier energies for the emission and capture of carriers by QDs. A measurement technique of the temperature-dependent transient capacitance signal of a p–n diode due to filling and emptying of the deep level trap has been used with considerable success for the determination of barrier energies for the emission and capture of carriers by deep level defects and QD [3–4]. Recently, deep level transient spectroscopy (DLTS) was used to determine the capture barriers for carriers in InAs self-assembled QDs embedded in GaAs [4]. These authors showed the existence of these capture barriers, which in their opinion may be due to the built-in strain in self-organized system giving rise to the appearance of the

apexes in the interface InAs/GaAs. In our previous works [3], we reported on the formation of dipoles due to Coulomb interaction between carriers localized in In(GaAs)/GaAs QDs and ionized deep level defects arranged in the nearest neighborhoods with QDs. It is shown that built-in electrostatic potential due to these dipoles reduced barrier energies for the electron emission from the QDs [3]. The dipole formation depended on the temperature of isochronous annealing and bias-on-bias-off cooling conditions ($U_{ra} < 0$, $U_{ra} = 0$). It is of interest to also study the capture barrier energy dependence on annealing conditions by DLTS method.

2. Results and discussion

The structures under investigation were grown by metal organic chemical vapor deposition (MOCVD). The growth temperature was 480°C. After deposition on n^+ -GaAs substrate of 0.5- μm -thick GaAs buffer undoped layer ($n = 3 \times 10^{15} \text{ cm}^{-3}$), QD layer of InGaAs was deposited. Then growth was interrupted and a thin 50-Å-thick layer of GaAs was deposited over the QD layer, the temperature was raised to 600°C and in situ annealing was performed for 10 min. Thereafter, 0.5- μm -thick n-GaAs undoped layer and the top layer

(M.M. Sobolev).

0.3- μm -thick p-GaAs were grown. DLTS investigations were carried out using a BIO-RAD DL4600 spectrometer. Prior to each DLTS measurement the sample was subjected to isochronous annealing for 1 min at 450 K under one of two conditions: (i) reverse bias $U_{\text{ra}} < 0$, (ii) zero bias $U_{\text{ra}} = 0$. After this a sample was cooled down to 80 K. The thermal activation energy E_{a} associated with the carrier emission from traps and their capture cross section σ_{n} were determined with standard DLTS measurement by changing the rate window from Arrhenius plots. The DLTS spectra measured at various conditions of isochronous annealing ($U_{\text{ra}} = 0$ and $U_{\text{ra}} < 0$) were characterized by the presence of three peaks (Fig. 1). Nothing unusual was observed in the behavior of the ED3 peak ($E_{\text{a}} = 667 \text{ meV}$, $\sigma_{\text{p}} = 7.4 \times 10^{-14} \text{ cm}^2$) that obviously belongs to the well-known defect GaAs: E4 ($V_{\text{As}} - \text{As}_{\text{Ga}}$) [5]. It was arranged in the nearest neighborhoods with QDs. The position of the ED1 (ED1#) and ED2 (ED2#) peaks in the DLTS spectra depended on conditions of isochronous annealing. The ED2 (ED2#) peaks are related, respectively, to the ground electron states of the QDs [4]. The parameters of the states corresponding to ED1 and ED2 peaks determined after previous annealing under $U_{\text{ra}} < 0$ were:

$E_{\text{a}} = 122 \text{ meV}$, $\sigma_{\text{n}} = 2.3 \times 10^{-15} \text{ cm}^2$ and $E_{\text{a}} = 347 \text{ meV}$, $\sigma_{\text{n}} = 4.5 \times 10^{-16} \text{ cm}^2$. The annealing under $U_{\text{ra}} = 0$ resulted in the shift of position of the ED1 and ED2 peaks toward higher temperatures, which we denoted as ED1# and ED2#. The parameters of the states corresponding to these peaks were: $E_{\text{a}} = 156 \text{ meV}$, $\sigma_{\text{p}} = 1.8 \times 10^{-13} \text{ cm}^2$ and $E_{\text{a}} = 369 \text{ meV}$ and $\sigma_{\text{p}} = 7.2 \times 10^{-16} \text{ cm}^2$. We observed large DLTS peak height variations of ED1 (ED1#) and ED2 (ED2#) with change of rate windows that indicates a large temperature dependence of the electron capture cross section and this is related with a filling factor. The procedure of defining the capture parameters (σ and E_{a} are thermal capture and activation energy of the cross section) involves measurements of the variation in the heights of the DLTS signal peak ($S(t_{\text{p}})$) versus the time duration of the filling pulse (t_{p}). [4]: $S(t_{\text{p}}) = S_{\text{sat}}[1 - \exp(-(\sigma v_{\text{th}} n) t_{\text{p}})]$, where S_{sat} is the DLTS peak height when the QDs are filled with carrier, v_{th} is the mean thermal velocity of carrier, n is the free electron carrier. The experimental curves of this dependence for ED2 and ED2# peaks (Fig. 2a and b) showed the presence of two exponential portions: fast ($t_{\text{p}} = (1-5) \mu\text{s}$) and slow ($t_{\text{p}} = (5-100) \mu\text{s}$). A dependence temperature of the σ was defined with variation of the rate window for a fixed pulse duration. The activation energy was determined by the following expression: $\sigma = \sigma_{\text{x}} \exp(E_{\text{a}}/k_{\text{B}}T)$, where σ_{x} is a constant independent of temperature, and k_{B} is the Boltzmann constant. From Arrhenius plot (Fig. 3), we deduced E_{a} and σ_{x} . For fast portions of the curves of $S(t_{\text{p}})/S_{\text{sat}} \propto t_{\text{p}}$, measured after previous annealing of the sample under $U_{\text{ra}} < 0$, they were equal to $E_{\text{a}} = 27 \text{ meV}$, $\sigma_{\text{x}} = 1.7 \times 10^{-16} \text{ cm}^2$, whereas the slow portions were $E_{\text{a}} = 77 \text{ meV}$, $\sigma_{\text{x}} = 4.4 \times 10^{-16} \text{ cm}^2$. The values determined for $U_{\text{ra}} = 0$ were, respectively: $E_{\text{a}}^* = 48 \text{ meV}$, $\sigma_{\text{x}} = 6.7 \times 10^{-16} \text{ cm}^2$ and $E_{\text{a}}^* = 104 \text{ meV}$, $\sigma_{\text{x}} = 2.5 \times 10^{-15} \text{ cm}^2$. The difference in two capture energies determined at annealing under $U_{\text{ra}} = 0$ and $U_{\text{ra}} < 0$ were, respectively, $\Delta E_{\text{a}} = E_{\text{a}}^* - E_{\text{a}} = 21 \text{ meV}$ for the fast portion and $\Delta E_{\text{a}} = E_{\text{a}}^* - E_{\text{a}} = 27 \text{ meV}$ for the slow portion. The difference in the two emission energies determined at annealing under $U_{\text{ra}} = 0$ and $U_{\text{ra}} < 0$ was $\Delta E_{\text{a}} = \text{ED2\#} - \text{ED2} = 22 \text{ meV}$. A close inspection of these data shows that the change of the annealing condition from $U_{\text{ra}} < 0$ to $U_{\text{ra}} = 0$ caused an increase in the thermal emission energy and capture barrier alike on some equal values (21–27 meV) with all t_{p} while the differences in capture barrier with fast and slow electron captures under annealing $U_{\text{ra}} < 0$ to $U_{\text{ra}} = 0$ were close and equal: $\Delta E_{\text{a}} = E_{\text{a}} - E_{\text{a}} = 56 \text{ meV}$ and $\Delta E_{\text{a}}^* = E_{\text{a}}^* - E_{\text{a}}^* = 61 \text{ meV}$. These results show that the mechanism responsible for the observed decrease of the barrier energies for the capture of electrons by QDs under changes of the annealing condition from $U_{\text{ra}} < 0$ to $U_{\text{ra}} = 0$ is common to both portions. Under

Fig. 1. DLTS spectra of the p-n heterostructure with InGaAs/GaAs QDs measurement under reverse bias $U_{\text{r}} = 0.5 \text{ V}$ and filling pulse bias $U_{\text{p}} = 0$ after previous isochronous annealing at $T_{\text{a}} = 450 \text{ K}$ and cooling down to 80 K under: (1) $U_{\text{ra}} = 0$ and (2) $U_{\text{ra}} < 0$.

Fig. 2. Normalized DLTS signal amplitudes as a function of the filling pulse duration under isochronous annealing at (a) $U_{ra} = 0$ and at various temperatures (K): (1) 252.7, (2) 241.6, (3) 238.7, and (4) 222.7; (b) $U_{ra} < 0$ and at various temperatures (K): (1) 256.6, (2) 245.7, (3) 242.0, and (4) 227.0.

annealing at $U_{ra} < 0$, the formation of dipoles from carriers localized in QDs and ionized deep level defects is taking place. The built-in electrostatic potential due to these dipoles reduced barrier energies for the emission and capture of electrons by the QDs. Its value remains equal to $E_{of} \approx 27$ meV at $t_p < 5 \mu\text{s}$. The presence of the capture barrier in this case may be related to Coulomb blockade effect, which arises if a second electron is

Fig. 3. Variation of the capture cross section versus the inverse of the temperature determined at $U_{ra} = 0$ (1,3) and $U_{ra} < 0$ (2,4): (1,2) for filling pulse duration $t_p = (1-5) \mu\text{s}$ and (3,4) for filling pulse duration $t_p > 5 \mu\text{s}$.

added into the ground states of the dots. We evaluated the Coulomb charging energy $E_c = e^2/2C$ (C is the self-capacitance of the QD) which for InGaAs QDs diameter of $d \approx 13$ nm embedded in GaAs is $E_c \approx 27$ meV. At $t_p > 5 \mu\text{s}$, we observed that height barrier energy which does not depend on annealing condition increase twice. This may be linked to the placement of a third electron into the first excited state of the dots which, for surmounting Coulomb blockade of two electrons, has to have charging energy $E_c \approx 54$ meV. Under annealing at $U_{ra} = 0$, the formation of dipoles is not taking place. The magnitude of the band offset is defined by the formation conditions of the heterointerface during structure growth.

The behavior of the ED1 (ED1#) peaks dependence on the annealing condition was similar (Fig. 1) and is also related to the formatting of the electrostatic dipoles. Moreover, for ED1 (ED1#) peaks curves of $(1 - S \times (t_p)/S_{sat}) \propto t_p$ showed the presence of only one exponential portion in the range of $t_p = (1-5) \mu\text{s}$. The activation energy E_a for them is less than for ED2 (ED2#) peaks. These results indicate that ED1 (ED1#) peaks cannot be related to excited states of the dots, they are most likely to result in the emission from the quantum states of the wetting layer.

Thus, we have investigated the processes of the electron emission and capture by the quantum dots in p-n InGaAs/GaAs heterostructures after an isochronous annealing under bias-on-bias-off cooling

conditions and the duration of the filling pulse by the DLTS. These investigations have shown that under annealing at $U_{ra} < 0$ the formation of dipoles from carriers localized in quantum dots and ionized deep level defects occurs. The built-in electrostatic potential due to these dipoles reduced barrier energies for the emission and capture of electrons by the quantum dots while under annealing at $U_{ra} = 0$, there is no formation of dipoles. The amount of the band offset is defined by the formation conditions of the heterointerface during the crystal growth. Dependence of the height of the capture barrier on the duration of the filling pulse has also been found, which is explained in terms of manifestation of the Coulomb blockade effects in the sense of the capture of electrons into the ground and excited states of the dot.

Electronic transport through N quantum dots under DC bias

W.Z. Shangguan*, T.C. Au Yeung, Y.B. Yu

Photonics Lab. 1, School of Electrical and Electronics Engineering, Nanyang Technological University, Singapore 639798

Abstract

This work deals with the electronic transport in a system of an arbitrary number of quantum dots connected in series by tunnel coupling. We calculate the “lesser” and retarded Green’s functions based on the nonequilibrium Green’s function formalism developed by Jauho et al. [Phys. Rev. B 50 (1994) 5528] for a one-dimensional N dot array, where N is an arbitrary positive integer, and we derive an analytical formula for the current under DC bias voltage. The retarded self-energy defined for any individual dot in the array is found to be made up of left and right components and to be of the staircase type, terminating at the two electron reservoirs. For simplicity of numerical computation, we take the 3-dot case for demonstration. The density of states of the 3-dot system is studied by plotting the differential conductance against the Fermi level of the left lead. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Quantum transport; Quantum dot array; Nonequilibrium Green’s function; Equation of motion method

In the last decade, a great deal of work has been done on the transport [1–5] and capacitance spectroscopy [6] of a single quantum dot system to probe its discrete spectrum. It was a significant discovery that the on-site Coulomb interaction leads to important Coulomb-blockade conductance oscillations [7–12] and a Kondo peak in the conductance [13,14].

However, research interest has extended in recent few years to systems of multiple quantum dots [15–18]. For example, electron pumping was studied in a double dot with interdot capacitance [16]; the Kondo effect in a double dot with on-site Coulomb interactions was studied based on the slave-boson mean-field theory [17,18]; and the DC current of a double dot without on-site Coulomb interactions was derived by Kawamura and Aono [19]. In this paper, we study a system of multiple quantum dots connected in series by tunnel coupling. Our formalism is based on the nonequilibrium Green’s function proposed by Jauho et al. [20]. The on-site Coulomb interaction can be ignored when the dot size is relatively large. We calculate the “lesser” and retarded Green’s functions for the N dots connected in

series, where N can be any positive integer, and then derive an analytical formula for the current under a DC bias voltage. For simplicity of numerical computation, we take the 3-dot case for demonstration. We study the density of states of the 3-dot system by plotting the differential conductance against the Fermi level of the left lead.

Consider a system of N quantum dots connected in series by tunnel coupling. The Hamiltonian H is given by

$$H = \sum_{k,\alpha} \varepsilon_{k\alpha} c_{k\alpha}^\dagger c_{k\alpha} + \sum_{i=1}^N \varepsilon_i^0 d_i^\dagger d_i + V_L (c_{kL}^\dagger d_1 + \text{h.c.}) + V_R (c_{kR}^\dagger d_N + \text{h.c.}) + \sum_{i=1}^{N-1} V_{i,i+1} (d_i^\dagger d_{i+1} + \text{h.c.}), \quad (1)$$

where $c_{k\alpha}^\dagger$ ($c_{k\alpha}$) are electron creation (annihilation) operators in reservoir $\alpha = L$ (left), R (right), d_i^\dagger (d_i) are electron creation (annihilation) operators in the i th quantum dot, V_L (V_R) is the tunneling coupling between the 1st (N th) dot and the left- (right-) reservoir, and $V_{i,i+1}$ ($= V_{i+1,i}$) is the tunneling coupling between the i th and $(i+1)$ th dot. The electron spin index is suppressed.

By making use of the formalism of nonequilibrium Green's function [20], the left-current J_L flowing from the left lead into the dot array is given by

$$J_L = \frac{2ie}{h} \int \frac{d\varepsilon}{2\pi} \Gamma_L^L(\varepsilon) \left[G_{11}^<(\varepsilon) + f_L(\varepsilon) \left(G_{11}^r(\varepsilon) - G_{11}^a(\varepsilon) \right) \right], \quad (2)$$

where the factor 2 takes into account the electron spin $\pm \frac{1}{2}$, and $\Gamma_L^L(\varepsilon/h) = 2\pi V_L^2 \rho_L(\varepsilon)$ is the coupling of the 1st dot to the left-reservoir ($\rho_L(\varepsilon)$ is the density of states of electrons in the left reservoir). We have a similar definition for $\Gamma^R(\varepsilon/h)$ for the right reservoir. The "lesser" and retarded Green's functions are defined by

$$G_{ij}^<(t) = i \langle d_j^\dagger(0) d_i(t) \rangle, \quad (3)$$

$$G_{ij}^r(t) = -i \theta(t) \langle \{ d_i(t), d_j^\dagger(0) \} \rangle \quad (i, j = 1, 2, \dots, N). \quad (4)$$

By the method of equations of motion [21] and Keldysh's contour integration [22], we obtain the following equations for the Green's functions:

$$G_{11}^r = g_{11}^r + g_{11}^r \Sigma_1^r G_{11}^r + g_{11}^r V_{12} G_{21}^r + g_{11}^r V_{12} G_{21}^r, \quad (5)$$

$$G_{i1}^r = V_{i-1,i} g_{ii}^r G_{i-1,1}^r + V_{i-1,i} g_{ii}^r G_{i-1,1}^r + V_{i,i+1} g_{ii}^r G_{i+1,1}^r + V_{i,i+1} g_{ii}^r G_{i+1,1}^r \quad (i = 2, 3, \dots, N-1), \quad (6)$$

$$G_{11}^r(\omega) = \frac{1}{\omega - \varepsilon_1^0 - \Sigma_1^r(\omega) - \frac{V_{12}^2}{\omega - \varepsilon_2^0 - \frac{V_{23}^2}{\omega - \varepsilon_3^0 - \frac{V_{34}^2}{\omega - \varepsilon_4^0 - \dots - \frac{V_{N-2,N-1}^2}{\omega - \varepsilon_{N-1}^0 - \frac{V_{N-1,N}^2}{\omega - \varepsilon_N^0 - \Sigma_2^r(\omega)}}}}}} \quad (16)$$

$$G_{N1}^r = g_{N1}^r \Sigma_2^r G_{N1}^r + V_{N-1,N} (g_{N1}^r + g_{N1}^r) G_{N-1,1}^r \quad (7)$$

and

$$G_{11}^< = g_{11}^r \Sigma_1^r G_{11}^< + g_{11}^r \Sigma_1^a G_{11}^< + g_{11}^r \Sigma_1^r G_{11}^a + V_{12} (g_{11}^r + 2g_{11}^r) G_{21}^< - V_{12} g_{11}^r G_{21}^a, \quad (8)$$

$$G_{i1}^< = V_{i-1,i} (g_{ii}^r + 2g_{ii}^r) G_{i-1,1}^< - V_{i-1,i} g_{ii}^r G_{i-1,1}^a + V_{i,i+1} (g_{ii}^r + 2g_{ii}^r) G_{i+1,1}^< - V_{i,i+1} g_{ii}^r G_{i+1,1}^a, \quad (9)$$

$$G_{N1}^< = g_{N1}^r \Sigma_2^r G_{N1}^< + g_{N1}^r \Sigma_2^a G_{N1}^< + g_{N1}^r \Sigma_2^r G_{N1}^a + V_{N-1,N} (g_{N1}^r + 2g_{N1}^r) G_{N-1,1}^< - V_{N-1,N} g_{N1}^r G_{N-1,1}^a \quad (10)$$

where ($i = 2, 3, \dots, N-1$) and the free-particle Green's functions are defined by:

$$g_{ij}^r(t, t') = -i \langle T(d_i(t) d_j^\dagger(t')) \rangle, \quad (11)$$

$$g_{ij}^<(t, t') = i \langle d_j^\dagger(t') d_i(t) \rangle, \quad (12)$$

$$g_{ij}^r(t, t') = -i \theta(t - t') \langle \{ d_i(t), d_j^\dagger(t') \} \rangle, \quad (i, j = 1, 2, \dots, N). \quad (13)$$

Also,

$$\Sigma_1^{r,a,<}(t, t') = V_L^2 \sum_k g_{kL}^{r,a,<}(t, t'), \quad (14)$$

$$\Sigma_2^{r,a,<}(t, t') = V_R^2 \sum_k g_{kR}^{r,a,<}(t, t') \quad (15)$$

are self-energies associated with the tunneling between the left-reservoir and the 1st dot, and that between the right reservoir and the N th dot, respectively. The Green's function $g_{kL}^{r,a,<}(t, t')$ and $g_{kR}^{r,a,<}(t, t')$ correspond to free electrons in the left and right reservoir, respectively.

Solving the Eqs. (5)–(7) for $G_{11}^r(\omega)$, we obtain

The result presented by the above equation has an obvious physical interpretation. The retarded self-energy of the first quantum dot in the one-dimensional dot array is composed of two parts: the "left retarded self-energy" $\bar{\Sigma}_{11}^r(\omega)$ which is simply $\Sigma_1^r(\omega)$ defined in Eq. (14) and can be re-written as $\bar{\Sigma}_{11}^r(\omega) = \sum_k V_L^2 / (g_{kL}^r)^{-1}$, and the "right retarded self-energy" which is of form $\bar{\Sigma}_{11}^r = 1 / [(g_{22}^r)^{-1} - \bar{\Sigma}_{22}^r]$, where $(g_{22}^r)^{-1}$ and $\bar{\Sigma}_{22}^r$ are the unperturbed Green's function and the "right retarded self-energy" of dot 2, respectively. As the second dot is connected to the third dot to its right, the "right retarded self-energy" of dot 2 is modified by $\bar{\Sigma}_{22}^r = 1 / [(g_{33}^r)^{-1} - \bar{\Sigma}_{33}^r]$ (here $\bar{\Sigma}_{33}^r$ is the right retarded self-energy of dot 3) instead of $1 / [(g_{33}^r)^{-1}]$, ..., ending up

with the right electron reservoir at $\Sigma_2^r(\omega) = \sum_k V_{Rk}^2 / (g_{kR}^r)^{-1}$. This structure of the retarded Green's function is applicable to all quantum dots in the dot array.

Similarly, solving the Eqs. (8)–(10) for $G_{11}^r(\omega)$, we obtain

$$G_{11}^r(\omega) = \Sigma_1^r(\omega) |G_{11}^r(\omega)|^2 + V_{12}^2 V_{23}^2 \cdots V_{N-1,N}^2 |G_{11}^r(\omega)|^2 \times |G_{22}^r(\omega)|^2 \cdots |G_{NN}^r(\omega)|^2 \Sigma_2^r(\omega), \quad (17)$$

where the Green's functions $G_{ii}^r(\omega)$ are defined by

$$G_{ii}^r(\omega) = \frac{1}{\omega - \varepsilon_i^0 - V_{i,i+1}^2 G_{i+1,i+1}^r(\omega)}, \quad (i = 2, 3, \dots, N-1), \quad (18)$$

$$G_{NN}^r(\omega) = \frac{1}{\omega - \varepsilon_N^0 - \Sigma_2^r(\omega)}. \quad (19)$$

Finally, we arrive at the following current formula by substituting Eqs. (16) and (17) into (2)

$$J_L = \frac{2e}{h} \int d\varepsilon (f_L(\varepsilon) - f_R(\varepsilon)) T(\varepsilon) \quad (20)$$

where $f_\alpha(\varepsilon)$ is the Fermi function in lead α , and $T(\varepsilon)$ which has the physical interpretation of transmission probability, reads

$$T(\varepsilon) = \Gamma^L \left(\frac{\varepsilon}{h} \right) \Gamma^R \left(\frac{\varepsilon}{h} \right) \cdot V_{12}^2 V_{23}^2 \cdots V_{N-1,N}^2 \left| G_{NN}^r \left(\frac{\varepsilon}{h} \right) \right|^2 \times \left| G_{N-1,N-1}^r \left(\frac{\varepsilon}{h} \right) \right|^2 \cdots \left| G_{22}^r \left(\frac{\varepsilon}{h} \right) \right|^2 \left| G_{11}^r \left(\frac{\varepsilon}{h} \right) \right|^2. \quad (21)$$

We remark that when $N = 1$, our formula of J_L in Eq. (20) is identical to that by Jauho et al. for a single quantum dot with proportionate coupling to leads under a time-independent bias [12]. When $N = 2$ (i.e., a double dot), we reproduce the results derived by Kawamura and Aono [11] for a double dot under DC voltage.

Formula (20) is of the Landauer-Büttiker type, as expected. But the transmission probability $T(\varepsilon)$ is tedious to calculate for a large number of dots (i.e., large N). In principle when $i > 2$ the Green's functions $G_{ii}^r(\omega)$ are obtained by recursion using Eqs. (18) and (19). We will consider the wide-band limit in which $\Sigma_{1,2}^r(\omega) = -(i/2)\Gamma^{L,R}$ where the couplings Γ^L and Γ^R are constants. Since $T(\varepsilon)$ reflects the density of states for the system of N dots, we can use the plot of differential conductance to probe the density of states. To demonstrate the analytical results obtained here we take the case of 3 dots for numerical computation of the differential conductance. We assume that the left and right couplings are identical ($\Gamma^L = \Gamma^R = \Gamma$). All the energies are expressed in units of Γ . We set $\varepsilon_1^0 = \varepsilon_2^0 = \varepsilon_3^0 = \varepsilon_0 = -10$, $1/kT = 100$, and $V_{12} = V_{23} = V = 0.1, 2.0, 5.0$. The right Fermi level μ_R is set to zero.

Fig. 1. The plot of differential conductance against the left Fermi level μ_L , with $1/kT = 100$, $V = 0.1$ and $\varepsilon_0 = -10$. All energies are expressed in units of Γ .

Fig. 2. The plot of differential conductance against the left Fermi level μ_L , with $1/kT = 100$, $V = 2$ and $\varepsilon_0 = -10$. All energies are expressed in units of Γ .

In Figs. 1–3, we plot the differential conductance against the left Fermi level μ_L . When $V = 0.1$ (Fig. 1), there is only one peak at $\mu_L = -10$ in the density of states. We expect this because small V_c means most electrons supplied by the left reservoir to dot 1 turn back before they go forward to the other 2 dots. Thus the electrons see only a single quantum dot in this case. The energy level that they belong to is simply $\varepsilon_1^0 = -10$. Clearly, the single peak in the density of states is due to the coupling of the dot system to the electron reservoirs. We consider $V = 2$ in Fig. 2. There is also one single peak in the density of states. We conclude that V_c should be set at larger values in order to display multiple peaks in the density of states.

In Fig. 3, we set $V = 5$ and there are 3 peaks in the plot of the differential conductance. For large V the electrons oscillate frequently among the 3 dots before

Fig. 3. The plot of differential conductance against the left Fermi level μ_L , with $1/kT = 100$, $V = 5$ and $\epsilon_0 = -10$. All energies are expressed in units of Γ .

they tunnel into the reservoirs. The energy levels of the electrons should be identical to those of an isolated three dot. That is, there should be 3 peaks in the density of states. The couplings Γ^L and Γ^R broaden the 3 peaks.

We then conclude that these are three energy levels in a three dot system for sufficiently large tunneling coupling V . In principle, our current formula (20) can handle any number of dots. We expect that there are N peaks in the density of states for a N dot system.

In summary, by making use of the equation of motion method and Keldysh Green's function technique, we have developed a calculation method for the one-dimensional quantum dot array with arbitrary dots. The retarded Green's function of every dot in the array is found to have a staircase structure, ending at two

electron reservoirs. A general formula for calculating the conductance of the dot array is derived, and the case of a 3 dots is numerically studied.

Abstract

Photoluminescence (PL) properties of SiO_2 films containing Si nanocrystals (nc-Si) and Tm^{3+} were studied. The average size of nc-Si was changed over wide range in order to tune the exciton energy of nc-Si to the energy separations between the discrete electronic states of Tm^{3+} . At room temperature, the samples exhibited broad PL peaks located at an energy region between 1.35 and 1.6 eV corresponding to the recombination of the excitons in nc-Si, and sharp peaks at 1.57 and 0.69 eV corresponding to the intra-4f shell transition of Tm^{3+} . The intensity of the Tm^{3+} related PL showed a strong dependence on the size of nc-Si. This result implies that only nc-Si which are smaller than a threshold size can efficiently excite Tm^{3+} . At low temperatures, the spectral shape of nc-Si PL was strongly modified by doping Tm. From the analysis of the modified spectral shape, the spectroscopic evidence of the resonant energy transfer from nc-Si to Tm^{3+} was obtained. © 2001 Elsevier Science B.V. All rights reserved.

Tm-doped glasses have been investigated as materials for near-infrared light sources and amplifiers. The laser action has been realized at around 0.85 eV (1.46 μm) and 0.69–0.62 eV (1.8–2.0 μm). These lasers and amplifiers have been demonstrated by a Tm-doped fiber [1,2]. However, enough gain has not yet been achieved for practical use. To realize the lasers and amplifiers, it is necessary to excite Tm^{3+} more efficiently. Recently, Si nanocrystals (nc-Si) have been attracting a lot of interest, because Si nanocrystals act as an efficient sensitizer for several rare-earth ions and are believed to yield efficient excitation of Tm^{3+} .

In our previous work, we demonstrated that the photoluminescence (PL) intensity of the intra-4f shell transition of Er^{3+} and Yb^{3+} became stronger by more than 2 orders magnitude by doping nc-Si [3–5]. The excitation of Er^{3+} (Yb^{3+}) is made by transferring the recombination energy of photo-generated excitons in nc-Si. In Er/nc-Si systems, the excitation mechanism of

Er^{3+} has been studied in detail [3,4,6,7] and the direct spectroscopic evidence of the energy transfer has been obtained. Furthermore, energy transfer rates are experimentally determined as a function of nc-Si size. It has been demonstrated that the smaller the size of nc-Si, the larger the energy transfer rate [8]. In contrast to the Er/nc-Si systems, in systems containing other rare-earth ions, detailed mechanism of the interaction with nc-Si has not been well understood, although the enhancement of the intra-4f shell PL is demonstrated.

Tm^{3+} have discrete and complex electronic states. The first ($^3\text{H}_4$), second ($^3\text{H}_5$), third ($^3\text{F}_4$) excited states exist around 0.7, 1.0, 1.6 eV from the ground state ($^3\text{H}_6$), respectively. Furthermore, the band gap of nc-Si continuously changes from bulk band gap to higher energies on decreasing the size of nc-Si [9]. This change in the band gap is due to the zero-dimensional quantum size effects. Therefore, the interactions between the intra-4f shell electrons in Tm^{3+} and nc-Si should depend on the size of nc-Si. For this reason, it is essential to investigate PL in a wide spectral range and to widely change the size of nc-Si. However, the size dependence in

a wide spectral range has not yet been investigated. Although strong interactions between nc-Si and Tm^{3+} have been demonstrated, the spectroscopic evidence of the energy transfer from nc-Si to Tm^{3+} has not been obtained.

In this work, we studied PL properties of SiO_2 thin films containing nc-Si and Tm^{3+} in the wide spectral range from 0.45 to 1.90 eV. We will show a correlation between the intensities of the nc-Si related peak and Tm^{3+} related peaks as a function of the size of nc-Si and temperature. The mechanisms of the interaction between nc-Si and Tm^{3+} are discussed.

SiO_2 films containing nc-Si and Tm were prepared by a method similar to that used to prepare films containing nc-Si and Er [3,4]. Small pieces of Si chips and Tm oxide pellets were placed on a SiO_2 sputtering target and they were simultaneously sputtered in Ar gas atmosphere. After the deposition, in order to grow nc-Si, samples were annealed in N_2 gas for 30 min at temperatures higher than 1100°C. In this work, the average size of nc-Si (d_{Si}) was changed from 2.7 to 3.5 nm and Tm concentration was fixed at 1.41 at%. PL spectra were measured using a single grating monochromator. In the spectral range between 0.45 and 0.80 eV, liquid nitrogen cooled InSb photodiode (Hamamatsu) was used as a detector, and in the spectral range between 0.80 and 1.90 eV, liquid nitrogen cooled Ge detector (North Coast) was used. The excitation source was 514.5 nm line of an Ar-ion laser. For all the spectra, the spectral response of the detection system was corrected by the reference spectrum of a standard tungsten lamp.

Fig. 1 shows the PL spectra at room temperature for the samples containing nc-Si with different size. Tm concentration is fixed at 1.41 at%. The energy position of the first ($^3\text{H}_4$), second ($^3\text{H}_5$), and third ($^3\text{F}_4$) excited states measured from the ground state ($^3\text{H}_6$) are shown on the top of the figure. We can see two peaks. The high-energy broad peak is due to the recombination of excitons confined in nc-Si (nc-Si PL) [3,4,9]. The low-energy one is due to the $^3\text{H}_4$ to $^3\text{H}_6$ transition of Tm^{3+} (Tm^{3+} PL) [1,2]. The spectra are normalized at the maximum intensity of nc-Si PL. As the size of nc-Si decreases from 3.5 to 2.7 nm, the peak energy of nc-Si PL is shifted toward higher energy. For the sample with the average nc-Si size of 2.7 and 3.1 nm, a weak peak can be observed at 1.58 eV. This peak corresponds to the $^3\text{F}_4$ to $^3\text{H}_6$ transition of Tm^{3+} .

Fig. 2 shows the intensity ratio of Tm^{3+} (0.68 eV peak) and nc-Si PL peaks ($I_{\text{Tm}}/I_{\text{Si}}$) as a function of the peak energy of nc-Si PL. The inset shows the energy diagram of the intra-4f shell of Tm^{3+} . The energy position of the third ($^3\text{F}_4$) excited state measured from the ground state ($^3\text{H}_6$) is shown in the figure. $I_{\text{Tm}}/I_{\text{Si}}$ depends strongly on the peak energy of nc-Si PL. On increasing the peak energy of nc-Si PL, the intensity of Tm^{3+} PL peak increases. In particular, the intensity

Fig. 1. PL spectra at room temperature as a function of the size of nc-Si in diameter. Tm concentration was fixed at 1.41 at%. The energy position of the first ($^3\text{H}_4$), second ($^3\text{H}_5$), and third ($^3\text{F}_4$) excited states measured from the ground state ($^3\text{H}_6$) are shown.

Fig. 2. Intensity ratio of the Tm related and nc-Si related peaks ($I_{\text{Tm}}/I_{\text{Si}}$) as a function of the peak energy of nc-Si PL. The line is drawn to guide the eye.

increase drastically as the nc-Si PL peak approaches 1.6 eV. It should be noted that the intensity of Tm^{3+} for the sample of size 2.7 nm is more than 10 times stronger than that of the sample of size 3.1 nm before normalization of the spectra of Fig. 1.

When nc-Si peak energy is relatively low, i.e., the size of nc-Si is relatively large, the intensity of Tm^{3+} peak is very weak. In this case, the first and the second excited states can be excited. However, the energy transfer efficiency is considered to be low, because the energy mismatches between the recombination energy of the excitons and the first (second) excited state is relatively large. At first approximation, the energy transfer efficiency depends on the energy mismatches. With increasing nc-Si peak energy, the number of the nc-Si with the recombination energy larger than the energy separation between the ground state and the third excited state increases. Therefore, not only the first and the second excited states but also the third excited state can be excited. The steep incline in Fig. 2 suggests that the excitons in nc-Si with the recombination energy of around 1.6 eV mainly interact with the intra-4f shell of Tm^{3+} . Since the energy mismatch of the recombination energy of exciton and the third excited state becomes smaller with increasing nc-Si PL peak energy, the energy transfer efficiency become higher.

Fig. 3 shows PL spectra of the sample with 2.7 nm diameter at various temperatures. The intensity of the spectra above 0.8 eV are expanded by a factor of 10. On decreasing the temperature, the spectral shape changes gradually. First, below 150 K, a new broad peak appears at around 1.0 eV. This peak is considered to be due to the recombination of excitons trapped at P_b centers at the interfaces between nc-Si and SiO_2 matrices [10]. Secondly, a very weak peak appears at around 0.84 eV as indicated by arrows. Thirdly, the 1.58 eV peak becomes more pronounced. The 0.84 and 1.57 eV peaks correspond to the intra-4f shell transitions of Tm^{3+} ($^3\text{F}_4$ to $^3\text{H}_4$, $^3\text{F}_4$ to $^3\text{H}_6$). Fourthly, the 0.69 eV peak is slightly shifted toward lower energy (0.69–0.67 eV) and becomes sharper. Finally, the spectral shape of nc-Si PL is strongly modified. At room temperature, the spectral shape is Gaussian-like. At around 100 K, the lower-energy side of the spectrum is strongly suppressed. At 5 K, both sides of the 1.57 eV peak are suppressed. It should be noted here that without Tm-doping, the spectra shape is almost independent of the temperature.

The energy range of the modification is close to the energy separation between third excited state ($^3\text{F}_4$) and the ground state ($^3\text{H}_6$). The excitation energy of nc-Si is transferred to Tm^{3+} before the radiative recombination of excitons occurs in nc-Si. To our knowledge, this is the first direct evidence of the energy transfer from nc-Si to Tm^{3+} . If the energy transfer is made resonantly (without emitting phonons) or by emitting phonons, the suppression should appear only at the high-energy side of the

Fig. 3. PL spectra of the sample with Tm concentration = 1.41 at% at various temperatures. The intensities of the spectra above 0.8 eV are expanded by a factor of 10.

1.57 eV peak. However, the spectra are strongly suppressed not only at the high-energy side of the 1.57 eV peak of Tm^{3+} but also at the lower-energy side. This result can be explained by taking the indirect band-gap nature into consideration. As reported previously, the indirect-gap nature of bulk Si crystal is preserved in nc-Si even if the size is a few nanometers in diameter, i.e., radiative recombination of excitons in nc-Si requires the emission of momentum conserving phonons at Δ minima [11]. Since the TO phonon energy at Δ minima is about 57 meV, nc-Si whose exciton recombination energy exactly coincides with the energy of the third excited state of Tm^{3+} (1.57 eV) shows PL at around 1.57 eV–57 meV, if resonant energy transfer does not occur. If the resonant energy transfer occurs, the recombination energy of excitons is preferentially transferred to Tm^{3+} , resulting in the decrease of the intensity of PL at the lower-energy side. Therefore, the appearance of the spectral suppression at the low-energy side of the 1.57 eV peak is the spectroscopic evidence of the resonant energy transfer from nc-Si to Tm^{3+} .

In conclusion, we studied PL properties of SiO_2 films containing nc-Si and Tm^{3+} as a function of the size of nc-Si. The 1.57, 0.84 and 0.69 eV peaks which corre-

spond to the intra-4f shell transition of Tm^{3+} were observed. The intensity of Tm^{3+} PL at 0.69 eV depended strongly on the size of nc-Si. As the PL energy of nc-Si approached the energy difference between the third excited state and the ground state of Tm^{3+} (1.58 eV), the intensity of Tm^{3+} PL increased drastically. This result indicates that nc-Si interacts mainly with the third excited state of Tm^{3+} , and the exciton energy of nc-Si should be larger than this energy to efficiently excite Tm^{3+} . We also showed that PL spectra were strongly modified at low temperature. From the observed PL dip structures, we demonstrated that the suppression at the lower-energy side of the 1.57 eV peak is spectroscopic evidence of the resonant excitation of the third excited state of Tm^{3+} .

Formation energy of vacancy in silicon determined by a new quenching method

N. Fukata^{a,*}, A. Kasuya^b, M. Suezawa^a

^b Center for Interdisciplinary Research, Tohoku University, Sendai 980-8578, Japan

Abstract

By applying a new quenching method, we determined the formation energy of vacancies (V) in high-purity silicon. Specimens were sealed in quartz capsules together with H₂ gas and heated at high temperatures for 1 h followed by quenching in water. By this method, V are quenched in the form of complexes with hydrogen and the formation energy of V can be determined from the quenching temperature dependence of the intensity of the optical absorption peak due to the complexes. The formation energy of V in high-purity silicon was determined to be about 4.0 eV. This value is in good agreement with results of recent theoretical calculations. © 2001 Elsevier Science B.V. Keywords: Vacancies; Hydrogen; Optical absorption; Silicon

1. Introduction

It is increasingly important to clarify the properties of vacancies (V) existing at high temperatures in silicon. Secondary defects [1] such as voids and swirls which are formed during crystal growth by agglomerations of V are known to have harmful effects on device performance. To understand the agglomeration process and to prevent it, it is necessary to know the properties of V. From a basic-research point of view, determination of the V formation energy has been a critical issue since the 1960s. Theoretical estimation has been performed every time a new calculation technique has been developed [2]. Until now, two kinds of in situ methods, i.e., positron lifetime measurement and measurements of length and lattice parameter, have been applied to the study of point defects in silicon at high temperature. The results obtained by the former method, however, have been contradictory [3–5]. On the other hand, in the latter measurements [6], V formation energy in silicon was not

determined since the temperature dependence of the net concentration of native defects (V–I) was not simple. Consequently, the V formation energy in silicon has not been established experimentally.

To study point defects in thermal equilibrium in silicon, we applied a quenching method instead of the above-mentioned in situ methods. The quenching method itself is very useful and successful in the case of metals. It is, however, difficult to apply it to silicon since the migration energy of V in silicon is very small (<0.45 eV) [7,8] and V easily rises to the specimen surface or forms complexes. To quench isolated V, the quenching speed should be much faster than 10⁵ K/s, which is too high to prevent specimen breakage. To overcome this difficulty, we applied a new quenching method. In this method, quenching is performed in H₂ gas and therefore V are quenched as H–V complexes which are detected by optical absorption due to the localized vibrational mode of H included in the complexes [9–11].

In this paper, we report a new approach for determination of the V formation energy in high-purity silicon. The value determined by applying the new quenching method is in good agreement with the results of recent theoretical estimations.

2. Experimental

A high-purity silicon (n-type, $[P] = 4 \times 10^{12} \text{ cm}^{-3}$) crystal was used for this study. The specimens were sealed in quartz capsules together with H_2 gas and heated at 1200–1390°C for 1 h, followed by quenching in water. Optical absorption measurements were performed at 4.6 K by a Fourier transform infrared spectrometer with a resolution of 0.25 cm^{-1} . The specimen thickness was about 12.5 mm. Isochronal annealing was carried out for 30 min at various temperatures in the range of 100–650°C.

3. Results and discussion

Representative optical absorption peaks observed after quenching are shown in Fig. 1. When specimens were quenched from 1300°C, optical absorption peaks due to H_2 [12] and H_2^+ [13] were observed at about 3618.6 (abbreviated 3619 hereafter) cm^{-1} and 1838.7 & 2062.1 cm^{-1} , respectively. When quenched from 1390°C, five peaks were observed at about 2131.5 (2132), 2191.8 (2192), 2202.7 (2203), 2220.8 (2221) and 2222.9 (2223) cm^{-1} , in addition to the above-mentioned peaks. The peak intensity due to H_2^+ absorption was much smaller than that due to H_2 absorption. The 2223 cm^{-1} peak has been assigned to the Si-H stretching mode of V saturated with four H atoms (VH_4) [14–16]. From this, it is definitely confirmed that V are quenched in the form of H–V complexes. In our experimental conditions, almost all V are quenched in the form of H–V complexes before the pair annihilation of V and self-interstitials (I) due to the following reasons: (1) the concentration of H ($\sim 10^{16} \text{ cm}^{-3}$) is much higher than

Fig. 1. (a,b) Optical absorption peaks observed in high-purity silicon heated at 1300°C and 1390°C for 1 h in an H_2 gas followed by quenching in water. The resolution was 0.25 cm^{-1} .

Fig. 2. The isochronal annealing temperature dependence of the integrated intensities of the 2192, 2203, 2223, and 3619 cm^{-1} peaks. The specimen was quenched from 1390°C.

those ($\sim 10^{14} \text{ cm}^{-3}$) of V and I, (2) the reaction between H and V is very fast and (3) the thermal stability of the complexes is also high.

Fig. 2 shows the isochronal annealing behaviors of various peaks. The 2223 cm^{-1} peak intensity increases with the decrease of the 2192, 2203, and 3619 cm^{-1} peak intensities at above 350°C. This shows that the 2192 and 2203 cm^{-1} complexes (termed the wavenumber complexes which are responsible for the optical absorption at the wavenumber) are transformed to the 2223 cm^{-1} complex by the reaction with H_2 . Incidentally, at temperatures between 100°C and 350°C, the 2192 and 2203 cm^{-1} peak intensities increase and the 3619 cm^{-1} peak intensity decreases. These results suggest the existence of “hidden” V–H complexes which could not be detected and furthermore suggest that these hidden complexes are transformed to the 2192 and 2203 cm^{-1} peaks. Based on the annealing behaviors of the 2192 and 2203 cm^{-1} peaks, our previous result regarding the quenching temperature dependence [10] and the result of Qi et al. [17], we have assigned the 2192 and 2203 cm^{-1} peaks to a VH_3 complex with different vibrational modes [11]. As for these peaks, another model has been proposed [18], namely, a V_2H_6 complex. This was proposed in a study of H-implantation. Contrary to H-implantation, local concentrations of V in quenched specimens seem to be very low. Hence, the probability of V_2H_6 complex formation is very small.

We interpret the annealing temperature dependence of the 2192, 2203, 3619, and 2223 cm^{-1} peaks by the following explanation assuming the hidden complexes to be VH and/or VH_2 . Indeed, we have been able to observe an optical absorption peak due to one of the hidden complexes, the VH_2 complex, in quenched silicon doped with carbon and H, where V concentration was higher than that in high-purity silicon [10]. The increase of the intensities of the 2192 and 2203 cm^{-1} peaks at temperatures between 100°C and 350°C is due to the formation of the VH_3 complex by reactions between a VH complex and an H_2 or a VH_2 complex and an H

Fig. 3. The quenching temperature dependence of the 2223 cm^{-1} peak observed in specimens heated at 1300°C and 1360°C for 1 h in an H_2 gas followed by quenching in water and subsequent annealing at 450°C for 0.5 h in argon gas.

Fig. 4. The quenching temperature dependence of the integrated intensities of the 2223 cm^{-1} peak.

which is dissociated from an H_2 and an H_2^* . The decrease of the 2192 and 2203 cm^{-1} peaks intensities and the increase of the 2223 cm^{-1} peak intensity above 350°C are due to the formation of the VH_4 complex by a reaction between the VH_3 complex and an H_2 or the VH_3 complex and an H. In case of the former reaction, the diffusing H_2 divides into two H atoms when it reacts with the VH_3 complex and one H atom is released after the formation of the VH_4 complex, in the same way as the passivation of B by H_2 ($\text{B} + \text{H}_2 \rightarrow \text{BH} + \text{H}$). The released H atom again reacts with another VH_3 complex (the latter reaction). As already described, the 2221 cm^{-1} peak was also observed. The annealing behavior of this peak shows that the 2221 cm^{-1} complex is also transformed into the VH_4 complex. As for the 2132 cm^{-1} peak, there have been two reports that this peak is due to a defect including interstitial oxygen [17,19]. This peak disappeared after annealing at 450°C .

As shown in Fig. 2, almost all H–V complexes are transformed into only one complex, the VH_4 complex, by annealing at 450°C . Hence, it is considered that the V concentration is proportional to the peak intensity of the VH_4 complex. From this, it is possible to determine the

V formation energy of silicon without determining the V concentrations. Based on this, we annealed specimens quenched from various temperatures at 450°C and then determined the relative concentrations of V from the 2223 cm^{-1} peak intensities. As shown in Fig. 3, the 2223 cm^{-1} peak is sufficiently strong to determine the relative concentrations of the VH_4 complex and, consequently, the formation energy of V. From the Arrhenius plot of Fig. 4, the formation energy of V is determined to be about 4.0 eV . This value is in good agreement with recent theoretical estimations ($3\text{--}4.5\text{ eV}$) [2], confirming the usefulness of our new quenching method.

4. Conclusions

The formation energy of V in high-purity silicon was determined to be about 4.0 eV with our new quenching method. This value is in good agreement with recent theoretical values. This method opens up a new way to determine the formation energy of V in various silicon crystals. Application of this method to Czochralski-grown silicon is highly expected to clarify the void formation mechanism and to lead to new ways of reducing the void density.

Abstract

A new method for calculating the parameters of resonant states as well as the probability of resonant scattering, capture and emission is developed. It is based on the configuration interaction method, which has been first introduced by Fano in the problem of autoionization of He. The method has been applied to resonant states induced by (i) defects in the barrier of GaAs/GaAlAs quantum well structure and (ii) acceptors in Ge under external stress. © 2001 Elsevier Science B.V. Keywords: Resonant states; Quantum well heterostructures; Defects in barriers; Strained germanium

0. Introduction

Resonant states have been studied very well in atomic physics. Semiconductors are other systems where resonant states play a significant role in physical processes. Such states appear, for example, in zero-gap semiconductors doped by shallow acceptors. The system of a special interest is uniaxially strained germanium where the generation of THz radiation has been achieved [1,2].

Here, we suggest a new method for calculating the parameters of resonant states and the probability of resonant scattering, capture and emission of carriers. The approach is based on the configuration interaction method, which was first introduced by Fano [3] in the problem of autoionization of He. The main idea is to choose two different Hamiltonians for the initial approximation: one for continuum states and the other for localized states. Then, wave functions are con-

structed in terms of scattering theory following to Dirac [4]. In a result, the energy shift and the width of resonant level as well as amplitude of resonant elastic scattering and capture probability by resonant states is calculated. The method is applied to resonant states induced (i) by impurities in the barrier of quantum wells and (ii) by shallow acceptors in Ge under stress.

1. Resonant states induced by localized states in barriers of QW

We will demonstrate the general idea by applying it to a system consisting of a quantum well (QW) and one impurity in the barrier. The full Hamiltonian is given by

$$\hat{H} = -\frac{\hbar^2}{2m}\Delta + V(z) + V_d(\mathbf{r} - \mathbf{r}_0), \quad (1.1)$$

where $V(z)$ is the QW potential and V_d is the defect potential (see Fig. 1).

As an initial approximation for the wave function of the localized state induced by the impurity we use the solution of the equation

$$\left[-\frac{\hbar^2}{2m}\Delta + V_d(\mathbf{r} - \mathbf{r}_0) \right] \varphi(\mathbf{r} - \mathbf{r}_0) = E_0 \varphi(\mathbf{r} - \mathbf{r}_0). \quad (1.2)$$

*Corresponding author. Tel.: +7-812-247-9974; fax: +7-812-247-1017.

E-mail address: irina.yassievich@pop.ioffe.rssi.ru (I.N. Yassievich).

Fig. 1. A schematic of quantum well with introduced impurity level; E_0 is the binding energy of an impurity in the first approximation. E_1 is the space quantization energy.

The initial wave functions of continuum states $\psi_{\mathbf{k}}(\mathbf{r})$ satisfy the following equation:

$$\left[-\frac{\hbar^2}{2m}\Delta + V(z)\right]\psi_{\mathbf{k}}(\mathbf{r}) = E_{\mathbf{k}}\psi_{\mathbf{k}}(\mathbf{r}). \quad (1.3)$$

We are considering QW with one energy level only, so that

$$E_{\mathbf{k}} = -\Delta V + E_1 + \varepsilon_{\mathbf{k}}, \quad (1.4)$$

where ΔV is band offset at the QW boundary (see Fig. 1), E_1 is the space quantization level and $\varepsilon_{\mathbf{k}} = \hbar^2 k^2/2m$ is the kinetic energy of 2D motion. So we can write for $\psi_{\mathbf{k}}(\mathbf{r})$

$$\psi_{\mathbf{k}}(\mathbf{r}) = \frac{1}{\sqrt{S}}\phi(z)\exp(i\mathbf{k}\rho), \quad (1.5)$$

where S is a normalizing square.

Now we consider the problem of scattering of the in-plane moving carrier by the impurity in the barrier. Following Dirac [4], we construct the wave function in terms of a scattering theory in the following form:

$$\Psi_{\mathbf{k}}(\mathbf{r}) = \psi_{\mathbf{k}}(\mathbf{r}) + a_{\mathbf{k}}\phi(\mathbf{r} - \mathbf{r}_0)$$

$$+ \sum_{\mathbf{k}'} \frac{t_{\mathbf{k}\mathbf{k}'}}{\varepsilon_{\mathbf{k}} - \varepsilon_{\mathbf{k}'} + i\gamma} \psi_{\mathbf{k}'}(\mathbf{r}), \quad \gamma \rightarrow +0. \quad (1.6)$$

As long as the presence of one impurity does not perturb the continuum spectrum significantly, $\Psi_{\mathbf{k}}(\mathbf{r})$ corresponds to the energy $E_{\mathbf{k}}$. Solving the Schrodinger equation with the full Hamiltonian (1.1) for $\Psi_{\mathbf{k}}(\mathbf{r})$, we get

$$a_{\mathbf{k}} = \frac{1}{\sqrt{S}} \frac{V_{\mathbf{k}}}{E_{\mathbf{k}} - (E_0 + \Delta E) + i\Gamma/2}, \quad (1.7)$$

$$t_{\mathbf{k}\mathbf{k}'} = \frac{1}{S} \frac{V_{\mathbf{k}} Z_{\mathbf{k}'}^*}{E_{\mathbf{k}} - (E_0 + \Delta E) + i\Gamma/2}, \quad (1.8)$$

The energy shift ΔE and the width $\Gamma/2$ of the resonant level are given by

$$\Delta E = \delta - \frac{1}{(2\pi)^2} \int d^2 k' Z_{\mathbf{k}'}^* W_{\mathbf{k}'} + \frac{1}{(2\pi)^2} P \int d^2 k' \frac{Z_{\mathbf{k}'}^* V_{\mathbf{k}'}}{E_{\mathbf{k}} - E_{\mathbf{k}'}} \quad (1.9)$$

$$\frac{\Gamma}{2} = \frac{1}{4\pi} \int d^2 k' Z_{\mathbf{k}'}^* V_{\mathbf{k}'} \delta(E_{\mathbf{k}} - E_{\mathbf{k}'}) \quad (1.10)$$

Here the matrix elements

$$V_{\mathbf{k}} = \sqrt{S} \langle \phi | V_d | \psi_{\mathbf{k}} \rangle, \quad W_{\mathbf{k}} = \sqrt{S} \langle \phi | \psi_{\mathbf{k}} \rangle,$$

$$\delta = \langle \phi | V(z) | \phi \rangle, \quad Z_{\mathbf{k}} = \sqrt{S} \langle \phi | V(z) | \psi_{\mathbf{k}} \rangle,$$

$$V_{\mathbf{k}\mathbf{k}'} = S \langle \psi_{\mathbf{k}} | V_d | \psi_{\mathbf{k}'} \rangle. \quad (1.11)$$

are introduced. In solution (1.9–1.10) we have taken into account resonant scattering only, neglecting the impurity potential scattering.

The probability of resonant elastic scattering $W_{\mathbf{k}\mathbf{k}'}$ of 2D carriers and the capture probability $W_{\mathbf{k}r}$ are given by

$$W_{\mathbf{k}\mathbf{k}'} = \frac{2\pi}{\hbar} |t_{\mathbf{k}\mathbf{k}'}|^2 \delta(\varepsilon_{\mathbf{k}} - \varepsilon_{\mathbf{k}'}) = \frac{2\pi}{\hbar} \frac{1}{S^2} \frac{|V_{\mathbf{k}}|^2 |Z_{\mathbf{k}'}|^2}{(E_{\mathbf{k}} - E_0 - \Delta E)^2 + \Gamma^2/4} \delta(\varepsilon_{\mathbf{k}} - \varepsilon_{\mathbf{k}'}), \quad (1.12)$$

$$W_{\mathbf{k}r} = |a_{\mathbf{k}}|^2 = \frac{1}{S} \frac{|V_{\mathbf{k}}|^2}{(E_{\mathbf{k}} - E_0 - \Delta E)^2 + \Gamma^2/4}, \quad (1.13)$$

respectively. Both probabilities contain the same resonant denominator.

The resonant scattering should be introduced into the kinetic equation when one solves the problem of the 2D carriers distribution function under an electric field applied in the plane of the quantum well. This scattering affects significantly the distribution function $f_{\mathbf{k}}$ of hot carriers [5]. The population f_r of impurities in the barrier is connected with the distribution function $f_{\mathbf{k}}$ by relation [6]

$$f_r = \sum_{\mathbf{k}} W_{\mathbf{k}r} f_{\mathbf{k}}. \quad (1.14)$$

The position of resonance E_r can be found from the condition $E_r = E_0 + \Delta E(E_{\mathbf{k}} = E_r)$, where ΔE is determined by Eq. (1.9). The resonant width Γ is defined by Eq. (1.10) at $E_{\mathbf{k}} = E_r$.

We will apply the above-described approach to calculate the energy level position and the width of resonant states induced by deep donor centers which appear in the barrier region of $\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}/\text{GaAs}/\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}$ heterostructure doped with Si. These centers were extensively studied experimentally [7] because they heavily affect a performance of heterostructure based electronic and optoelectronic devices.

In doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$ with Al content x larger than 0.27, more than a half of Si donor centers produce deep levels with binding energy $E_c \sim 155$ meV measured from the bottom of the Γ -valley [7]. The results of calculations of E_r and Γ as a function of the distance between defect and QW boundary are presented in Fig. 2 for different QW widths. We have used the band offset $\Delta V = 232$ meV, and effective masses 0.067 and 0.092 in QW and barrier regions, respectively.

2. Resonant acceptor states in uniaxially strained germanium

Germanium has a fourfold degenerate top of the valence band. When strained, it is split into two doubly degenerate states. The ground state of an acceptor shows the same behavior under uniaxial stress. At some critical value of the stress—when the splitting is larger than the acceptor binding energy—one of the split levels is shifted into the continuous spectrum of the other

valence subband and becomes resonant. An effective optical transitions between resonant and localized states of the same impurities can take place. If the electric field is strong enough, an electric impurity breakdown occurs and practically all localized impurity states become depopulated. Now, the capture and emission processes lead to an effective population of resonant states. This may cause an intracenter population inversion that is the basis for THz generation [1,2].

Resonant acceptor states were considered in [6] by using the Dirac approach. It requires choosing an initial approximation Hamiltonian which should give localized states overlapping with the continuous spectrum. The approach in [6] applies for large stresses and for small quasimomenta but it fails for the region of the continuous spectrum where resonant states are present.

Using our new approach, we consider the ground resonant state induced by shallow acceptors in uniaxially strained p-Ge. As the initial approximation for localized states we choose the eigenfunctions of diagonal part of the Luttinger Hamiltonian with Coulomb

Fig. 2. The resonant position (a) and the resonant width (b) normalized by the energies of the first space quantization level as a function of the distance d between impurity and QW for the case of deep donor in $\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}/\text{GaAs}/\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}$ heterostructure. (1) $L = 5$ nm, $E_{QW} = 157.7$ meV; (2) $L = 7.5$ nm, $E_{QW} = 185.6$ meV; (3) $L = 10$ nm, $E_{QW} = 201.8$ meV; (4) $L = 12.5$ nm, $E_{QW} = 208.8$ meV.

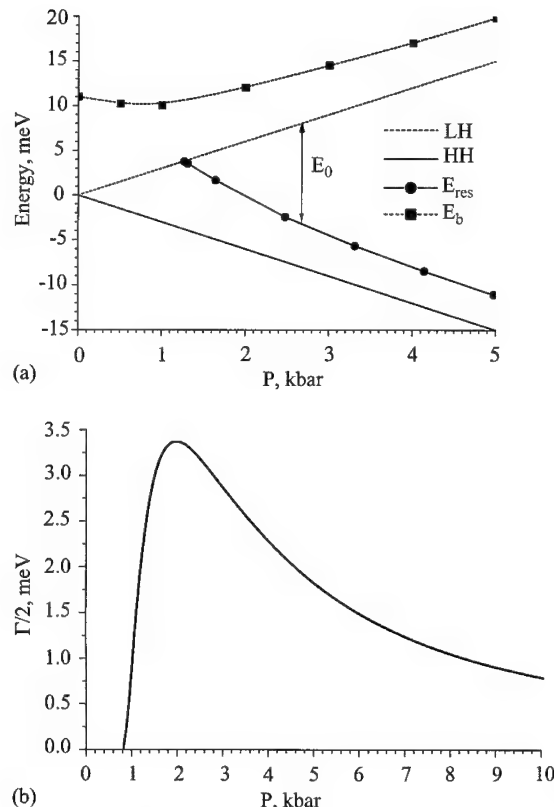

Fig. 3. The position (a) and width (b) of resonant state as a function of uniaxial stress applied to Ge in [001] direction. E_{res} is resonance position and E_b is ground localized state.

potential taken into account. For continuum states we use wave functions $\psi_{\mathbf{k}}^{\pm 1/2}(\mathbf{r})$ of free holes in cylindrical approximation for the Luttinger Hamiltonian. Following the procedure from the first section we are looking for wave functions in the form:

$$\begin{aligned} \Psi_{\mathbf{k}}^{\pm 1/2} = & \psi_{\mathbf{k}}^{\pm 1/2} + a_{\mathbf{k}}^{\pm 1/2, -3/2} \varphi^{-3/2}(\mathbf{r}) \\ & + a_{\mathbf{k}}^{\pm 1/2, -3/2} \varphi^{-3/2}(\mathbf{r}) + \sum_{\mathbf{k}'} \frac{t_{\mathbf{k}\mathbf{k}'}^{\pm 1/2, -1/2}}{\varepsilon_{\mathbf{k}} - \varepsilon_{\mathbf{k}'} + i\eta} \psi_{\mathbf{k}'}^{\pm 1/2}(\mathbf{r}) \\ & + \sum_{\mathbf{k}'} \frac{t_{\mathbf{k}\mathbf{k}'}^{\pm 1/2, -1/2}}{\varepsilon_{\mathbf{k}} - \varepsilon_{\mathbf{k}'} + i\eta} \psi_{\mathbf{k}'}^{\mp 1/2}(\mathbf{r}) \end{aligned} \quad (1.15)$$

The capture probability of holes with momentum projection $+1/2$, $W_{\mathbf{k}\mathbf{r}}$ and the probability of elastic resonant scattering $W_{\mathbf{k}\mathbf{k}'}$ are defined now by

$$W_{\mathbf{k}\mathbf{r}} = \left| a_{\mathbf{k}}^{-1/2, -3/2} \right|^2 + \left| a_{\mathbf{k}}^{+1/2, -3/2} \right|^2, \quad (1.16)$$

$$W_{\mathbf{k}\mathbf{k}'} = \frac{2\pi}{\hbar} \left(\left| t_{\mathbf{k}\mathbf{k}'}^{+1/2, -1/2} \right|^2 + \left| t_{\mathbf{k}\mathbf{k}'}^{-1/2, -1/2} \right|^2 \right) \delta(\varepsilon_{\mathbf{k}} - \varepsilon_{\mathbf{k}'}). \quad (1.17)$$

The expressions for the case of momentum projection $-1/2$ are similar.

The results of calculations of the resonant level shift and level width as function of stress applied along $[001]$ direction are given in Fig. 3.

3. Conclusion

The approach for calculation of resonant state energy and lifetime as well as probabilities of resonant capture

and elastic scattering are suggested and applied to resonant states induced by deep donors in the barrier of $\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}/\text{GaAs}/\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}$ QW heterostructure as well as by shallow acceptors in Ge under stress.

Abstract

During crystal growing, many dislocations are created in the multicrystalline silicon (mc-Si) material. Presence of these dislocations significantly changes the electrical properties of mc-Si wafer. We report here on photoluminescence (PL) and electron beam induced current (EBIC) mapping of recombination centers in low recombination regions limiting a performance of the mc-Si solar cells. By comparing PL mapping with the distribution of dislocations, we present experimental evidence that the 0.8 eV band corresponds to electrically active dislocation networks. At low temperature, a characteristic quartet of the dislocation D-lines was observed. One of these dislocation lines (D1) can be tracked as temperature increased and linked to the “defect” band. We also found using temperature dependent EBIC correlated with PL mapping that intense defect band luminescence originates from dislocation with low level of impurity contamination. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Dislocations; Photoluminescence; Lifetime; EBIC

1. Introduction

Vigorous growth in the photovoltaic market over the past decade has been predominantly driven by advances in crystalline silicon technology. Multicrystalline silicon (mc-Si), which can be produced by ribbon or block-casting techniques, can meet both a low-cost production and a high efficiency requirement for solar cells. Since mc-Si wafers are inhomogeneous, this motivated development of mapping techniques to track recombination activity of defects across entire wafer and solar cell. We report here on photoluminescence (PL) and electron beam induced current (EBIC) mapping of recombination centers in high recombination regions of mc-Si wafers. These regions limit solar cell performance, and their monitoring, characterization, and reduction is a primary goal in the search for approaches to achieve high cell conversion efficiencies. We present experimen-

tal evidence that high recombination regions are characterized by an intense “defect” PL band, associated with contaminated dislocations, which are electrically active at room temperature.

2. Samples and methods

Materials used in this study were boron doped mc-Si wafers grown by Edge-defined Film-fed Growth (EFG) technique. The photoluminescence mapping and PL spectra were analyzed using SPEX-500 M grating spectrometer coupled to a liquid nitrogen cooled Ge detector. The PL signal was processed using a conventional lock-in technique. The PL spectra were corrected to the spectral response of the optical setup. A 800 nm AlGaAs laser diode operating in a pulse mode with a peak power up to 140 mW was used. Photoluminescence mapping at room temperature was performed by placing a mc-Si wafer on a computer controlled *X-Z* moving stage. Spatial resolution in PL maps was limited by the diameter of the laser spot, which was approximately

0.5 mm. Temperature study was carried out between 4.2 and 300 K in the variable temperature liquid helium cryostat.

3. Experimental results

Inhomogeneity in electronic properties of mc-Si wafers gives rise to distinct high and low lifetime regions. In the regions with low recombination activity and high value of the lifetime, the PL spectrum at room temperature consists of the band-to-band line with maximum at 1.09 eV. This line is caused by the phonon-assisted recombination of bound and non-bound free electrons and free holes [1]. On the contrary, regions with enhanced recombination activity and reduced minority carrier lifetime exhibit also an intensive “defect” PL band with the maximum at about 0.8 eV (Fig. 1, spectrum 1). The defect band maximum varies between 0.76 and 0.8 eV from point to point on the same wafer. Recombination properties of the 0.8 eV band were described previously [2].

The intensity of the defect band is highly inhomogeneous across the wafer. In Fig. 2, we present room temperature PL maps of band-to-band intensity (a) and defect band intensity (b). The dark areas on PL maps correspond to the low PL intensity while the light areas represent the high PL intensity. We observe a distinctive reverse correlation of two maps, i.e. regions with high

band-to-band PL show negligible defect luminescence, and opposite, strong defect band is observed in regions with reduced band-to-band peak.

We reported previously [2,3] that the topography of band-to-band PL distribution correlates with distribution of minority carrier lifetime across the wafer. Fig. 3(b) shows both band-to-band PL and diffusion length line scans. We statistically proved using mapping technique that the band-to-band PL positively correlates with minority carrier lifetime.

To assess a possible origin of the defect band luminescence, we performed measurements of PL spectra at low temperature. Three PL spectra at different temperatures measured at the same spot on an EFG wafer are compared in Fig. 1. At room temperature, the defect band is centered at 0.77 eV. As temperature is lowered, the defect peak shifts to higher energy corresponding to the temperature dependence of Si band gap. At 77 K, rich spectral features are now observed at energies below 1.05 eV. Two bands appear at 0.95 and 1.00 eV. At lower energies, the PL spectrum shows the defect maximum at 0.80 eV with a barely resolved additional band as a shoulder. This band was identified with defect maximum at room temperature. At 4.2 K (Fig. 1, spectrum 3), the band-to-band emission is replaced with exciton lines dominated by the TO-phonon replica of the boron bound exciton at 1.093 eV. Along with the increasing intensity between 77 and 4.2 K, the PL bands below 1.05 eV are now much narrower (~ 10 meV) and exhibit additional sub-bands. The only exception is the 0.8 eV band, which retains a large half-width of ~ 60 meV down to 4.2 K.

We performed a numerical deconvolution of the 77 K PL spectrum in the range of 0.72–1.05 eV, and found that the entire spectrum can be satisfactory fit by four Gaussian peaks, D1'–D4' [2]. A set of four similar PL lines, known as D1–D4, with very close energies to those seen here, was previously observed and studied in detail in plastically deformed Cz and float-zone Si single crystals [4]. These bands are attributed to dislocations. The range of dislocation density, measured in low lifetime regions of our mc-Si wafers, ($1\text{--}8 \times 10^6 \text{ cm}^{-2}$) is in the lower end of the range of dislocation densities reported for the plastically deformed Si exhibiting the dislocation D-lines.

To check further an assumption on dislocation origin of the defect band, we compared the band-to-band and defect band PL distributions in EFG wafer with recombination activity distribution measured on the same wafer by EBIC (Fig. 2). It should be pointed that PL mapping and EBIC mapping have different spatial resolutions. The black areas on EBIC maps are related to the region with high recombination activity of dislocations. In this correlation EBIC/PL study, it became clear that the regions of low band-to-band and high defect PL are caused by dislocations.

Fig. 1. PL spectra of an EFG wafer at different temperatures. The spectrum at 77 K is deconvoluted numerically to resolve four individual D1'–D4' Gaussian peaks.

Fig. 2. Room temperature band-to-band (a), defect band (b) PL maps (on the left) and high resolution EBIC maps at room temperature and 80 K (on the right) in EFG wafer.

Fig. 3. Line scans of the defect concentration [1] expressed as the ratio of defect PL to band-to-band PL (1) and dislocation density (2) in an as-grown EFG wafer. A vertical arrow indicates the region with a high dislocation density and low defect concentration.

We conclude that the defect PL is associated with dislocations with moderate degree of impurity contamination. In fact, recombination activity of dislocations strongly depends on both the metal impurity contam-

ination and temperature. According to the model proposed in Ref. [5], a moderate contamination level is exhibited as reduction of EBIC contrast at high temperature compared to 77 K EBIC contrast. This is exactly a case of 0.8 eV PL band defects, as illustrated in Fig. 2. If the contamination level is too low ("clear" dislocation) or too high (dislocation decorated by metal silicate precipitates) the defect PL band luminescence is vanished. However, a relatively low contamination level of dislocations, in the order of 10 impurity atoms per micron of the dislocation length produces distinguishable defect band luminescence.

This study demonstrates a utility of the spectroscopic PL mapping to monitor electrically active dislocations at various contamination levels of precipitated defects.

Resonance ultrasonic diagnostics of defects in full-size silicon wafers

A. Belyaev, S. Ostapenko*

Center for Microelectronics Research, University of South Florida, 4202 E Fowler Avenue, Tampa, FL 33620, USA

Abstract

A resonance acoustic effect was observed recently in full-size 200 mm Cz-Si wafers and applied to characterize as-grown and process-induced defects. Ultrasonic vibrations can be excited into wafers using an external ultrasonic transducer and their amplitude is recorded using a scanning air-coupled acoustic probe operated in a non-contact mode. By sweeping driving frequency, f , of the transducer, we observed an amplification of a specific acoustic mode referred to as 'whistle'. In this paper, we performed theoretical modeling of the whistle which allowed in attributing this mode to resonant flexural vibrations in a thin circular plate. We calculated normal frequencies of the flexural vibrations of a circular plate of radius ρ in the case of the free edge. The model gives an excellent fit to experimental data with regard to whistle spatial distribution. The results of calculation allow the evaluation of resonance acoustic effect in wafers of different geometries employed in the industry. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

The elastic stress in Cz-Si wafers and thin films can be caused by point defects and their complexes. For instance, thermal oxide on Cz-Si creates a residual stress of a few hundreds of MPa in the films due to a difference in thermal expansion of the substrate and oxide, which can be detrimental for gate-oxide integrity and reliability of CMOS devices. Residual elastic stress can also be harmful to silicon substrates, especially, with scaling of wafer diameter up to 300 mm. On the other hand, the stress can be a driving force to various types of defect reactions, such as precipitation of residual impurities deteriorating the electronic quality of material. Therefore, a problem of non-contact and non-destructive monitoring of residual stress/strain in as-grown, oxidized and epitaxial (Cz-Si) wafers is a current issue for microelectronics. Resonance acoustic diagnostics

was developed and employed recently to characterize internal stress in full-size 200 mm Cz-Si wafers [1]. We report here the theoretical analysis of the resonance acoustic effect and compare calculation results with experimental data.

2. Experiment

Ultrasonic vibrations were generated into single-side polished Cz-Si wafers of 200 mm diameter using circular resonance piezoelectric transducer pressed by vacuum against the backside of the wafer [1]. These vibrations are propagated in the wafer beyond the transducer and form standing waves at specific frequencies. The amplitude of the standing wave is measured using an air-coupled acoustic probe. Fig. 1 demonstrates a frequency curve of the acoustic oscillations of Cz-Si wafer measured at probe location of 1 mm above the wafer front surface. By tuning driving frequency, f , of the transducer, we observed amplification of a specific acoustic mode referred to as 'whistle'. By changing the ac driving voltage we

Fig. 1. Frequency scans of the transducer (a) and the whistle mode (b). The later is recorded with lock-in tuned to the half of driving frequency.

Fig. 2. Amplitude dependence of the whistle mode versus the voltage applied to transducer.

measured an amplitude scan of the acoustic signal. The amplitude scan shows a clear threshold as illustrated in Fig. 2, which is dependent on wafer history [2]. The characteristics of the whistle allow the attribution of this mode to resonance flexural vibrations in a thin circular plate.

3. Modeling

We consider flexural vibrations in a thin circular plate with thickness h and radius ρ ($h \ll \rho$), which is a good model of a full-size 200 mm Cz-Si wafer. The equation for flexural vibrations can be represented as follows:

$$(\nabla^2 \nabla^2 - \beta^4)u = 0, \quad (1)$$

where ∇^2 is the Laplace operator applied to u , and $\beta^4 = \omega^2 \rho^4 h \xi / D$ is a dimensionless variable which depends on vibration frequency (ω), thickness and diameter of the wafer and flexural rigidity $D = Eh^2/12(1 - \nu^2)$, where E and ν , here, are Young's modulus and Poisson coefficient, respectively, and ξ is a density of material [3]. For flexural vibrations, we look for the solutions of the Eq. (1) in the form

$$U(\rho, \varphi) = u(\rho)e^{in\varphi}, \quad (2)$$

where u is a normal displacement of a plate from equilibrium and ρ and φ are radial and polar coordinates with respect to the wafer center. Using the method of the separation of variables, one can obtain the general solution of Eq. (1) in the form

$$u(\rho, \varphi) = [aJ_n(\beta\rho) + bI_n(\beta\rho)] \begin{cases} \sin n\varphi \\ \cos n\varphi \end{cases}, \quad (3)$$

where J_n are Bessel functions and I_n are modified Bessel functions of the order n , respectively. Zero value of elastic stress components at the wafer edge ($\rho = 1$) leads to the free-edge boundary conditions

$$\begin{aligned} \left[\frac{2(\lambda + \mu)}{\lambda + 2\mu} \frac{\partial}{\partial \rho} \nabla^2 u + \frac{\partial^3 u}{\partial \rho \partial \varphi^2} - \frac{\partial^2 u}{\partial \varphi^2} \right] \bigg|_{\rho=1} &= 0, \\ \left(\frac{\lambda}{\lambda + 2\mu} \nabla^2 u + \frac{\partial^2 u}{\partial \rho^2} \right) \bigg|_{\rho=1} &= 0, \end{aligned} \quad (4)$$

where λ and μ are Lamé's constants. All the above, allow the calculation of the deformation pattern of thin silicon plate, which performs flexural vibrations. Figs. 3a and b show a correlation between experimental and calculated maps of the acoustic energy, which is proportional to the square of the acoustic displacement.

In the experiment with (100) oriented 200 mm Cz-Si wafers we observe high order flexural vibrations with $n = 20$ (Fig. 3a). This number is a consequence of four-fold symmetry of the (100) crystal plane, which permits $n = 4m$ ($m = 1, 2, 3, \dots$) values of the index n . Note that ρ is multiplied by a scale factor of 100, in order to raise it over to the experimental wafer's size. There is a clear similarity between the experimental and theoretical maps, especially at wafer periphery. One should mention that the additional maxima in the internal part of the experimental acoustic map are probably caused by a superposition of the major Bessel function of $n = 20$ with lower order solutions of Eq. (1), such as $n = 12, 16$, etc. satisfying $n = 4m$ criterion. What is more important is that, according to our calculations, the lower order solutions shift the maximum of the radial distribution toward the wafer center, as illustrated by arrows in Fig. 4a.

Fig. 3. (a)—acoustical map of the 'whistle' measured on 200 mm Cz-Si wafer at $\omega = 12.7$ kHz, $V = 2.8$ Vpp. (b)—theoretical map of the high-order flexural vibrations of thin elastic plate with $n = 20$.

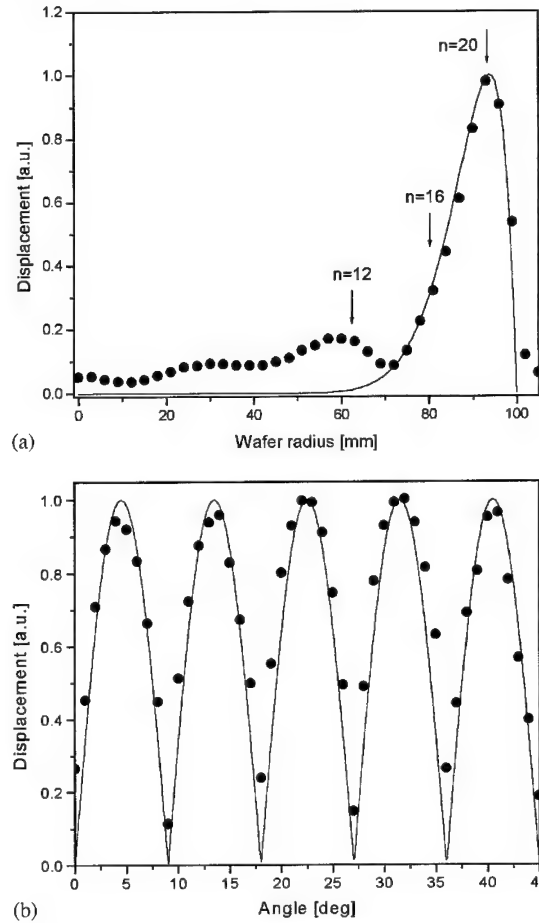

Fig. 4. Experimental distribution of the acoustic power (points) and theoretical fit (solid line) for (a) radial and (b) angular dependencies. Arrows on the radial scan indicate the positions of resonance flexural modes of different orders.

By separating variables in Eq. (1), we fit experimental data for radial and angular part individually. An illustrative example is presented in Figs. 4a and b. The angular curve fits the data with $\sin^2 \varphi$ function. The radial curve shows a very good fit for the main maximum located at the wafer periphery. We notice that the experimental radial distribution of the flexural vibrations (Fig. 4a), shows additional lower index Bessel modes ($n = 12$) as we discussed earlier. Substituting (3) into (4) one can obtain the system of linear equations for coefficients a and b .

$$\begin{pmatrix} -\beta^3 J'_n(\beta) + (1-\nu)n^2[J_n(\beta) - \beta J'_n(\beta)] & \beta^3 I'_n(\beta) + (1-\nu)n^2[I_n(\beta) - \beta I'_n(\beta)] \\ -\beta^2 J_n(\beta) + (1-\nu)[n^2 J_n(\beta) - \beta J'_n(\beta)] & \beta^2 I_n(\beta) + (1-\nu)[n^2 I_n(\beta) - \beta I'_n(\beta)] \end{pmatrix} \times \begin{pmatrix} a \\ b \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \quad (5)$$

The frequency equation can be expressed by the condition that the determinant of the system

vanishes. The normal (resonance) frequencies of flexural vibrations can be calculated using the equation [3]

$$\omega_{nm} = \frac{\beta_{nm}^2 h}{\rho^2} \sqrt{\frac{\mu}{6(1-\nu)\xi}}. \quad (6)$$

Fig. 5 illustrates the three sets of normal frequencies versus an order of Bessel's function for wafer diameters 150, 200, and 300 mm, which are mainly used in microelectronics. The dashed line indicates the resonant frequency observed in our experiment

with 200 mm Cz-Si wafers. It shows that in the case of 200 mm diameter, one should expect flexural

Fig. 5. Normal frequencies of the high-order flexural vibrations in silicon wafers of three diameters. The bars represent the effect on the frequencies the anisotropy of elastic modulus in silicon in $\langle 100 \rangle$, $\langle 111 \rangle$ and $\langle 110 \rangle$.

vibrations at the wafer periphery with $n = 20$. The bars at each Bessel mode n represent anisotropy of the elastic modulus in Si single crystals along $\langle 100 \rangle$, $\langle 110 \rangle$ and $\langle 111 \rangle$ crystallographic directions. The results of this modeling allow the prediction of a resonance acoustic effect in wafers of different geometry, crystallography, and other chemical origin employed by the electronic industry (GaAs, InP).

Abstract

The successful results of multifractal analysis application to a quantitative description of mosaic structure peculiarities, which are typical for GaN epitaxial layer with hexagonal modification grown on (0001) sapphire substrates, have been obtained. A linear dependence of mobility on the multifractal parameters of surface topology of the mosaic structure (the self-organization degree and the disruption of the local symmetry) has been observed in GaN layers. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Multifractal analysis; Mosaic structure; GaN

1. Introduction

A mosaic structure is typical for GaN epitaxial layers of the hexagonal modification. However, the data on the influence of mosaic structure peculiarities on electric characteristics of the layers and device structures are insufficient. In most publications, the peculiarities are analysed at a local level (from transmission microscopy), at an integral level (from X-ray diffraction), or at a qualitative level using atomic-force microscopy (AFM). The results obtained by these techniques are unlikely to reveal important peculiarities of the mosaic structure completely. Perhaps, due to this fact, a correlation between structural properties and electrical characteristics of III-nitrides was not established.

It has been well known that self-organization of the non-equilibrium defect system in the form of a mosaic structure occupies the highest stage of the rank scale for defect classification in solids. Similar objects, in particular, with the mosaic structure, have been studied well

in metallurgy. It was demonstrated that investigations of the surface topology of the objects with the complicated structure followed by the multifractal analysis (MFA) treatment allow the properties of the complex objects to be characterized quantitatively as a whole [1–4]. These properties are the disruption of both general and local symmetry, and the self-organization degree [1,2].

From these facts, the following aims have been formulated in the present paper: (1) To clarify a role of the mosaic structure in forming the characteristics of both the GaN layers and of the devices based on these layers; and (2) along with conventional experimental techniques, to apply the MFA and to clarify the correlation of the multifractal characteristics with electrical properties of the GaN layers, in particular, with the mobility of charge carriers.

2. Experiment

GaN epitaxial layers of the hexagonal modification with a specular surface, which were grown by metal-organic chemical vapour deposition on (0001) sapphire substrates at a pressure of 200 mbar, were investigated.

Renyi dimension (D_q)	1.62	1.49	1.55	1.63	1.64	1.57

The 3–4 μm thick layers were of n-type conductivity with a carrier concentration of $(1\text{--}2) \times 10^{17} \text{ cm}^{-3}$ [5].

Six groups of layers were chosen with different mobilities and with different volume structure properties obtained from the X-ray diffraction [6]. All layers except Group II had the dislocation density of about 10^{10} cm^{-2} . It was one order of magnitude less in II Group layers. The characteristics of these groups are presented in Table 1.

The AFM data allowed both the roughness and the average lateral size of surface domains to be estimated. The AFM data were treated using the MFA. It can ascribe to the structure the quantitative parameters, characterizing the structure as a whole, in addition to the conventional methods of description. In particular, an original technique has been developed by a number of researchers, which involves multifractal parameterization of plane structures on the basis of a new informational-theoretical interpretation of multifractal formalism [1,4] and which allows the degree of order index (the disruption of the local symmetry) of the structures, and the Renyi dimension (the degree of self-organization) to be introduced and to be computed.

Contrary to the conventional fractal analysis, which uses only one level of self-similarity and only one distribution function of a digit ensemble density for the entire system, MFA uses several levels of self-similarity and several distribution functions for large boxes of the system. It allows the distribution functions to be compared both between them and with the whole system. The procedure allows the degree of disruption to be determined quantitatively for local and general symmetry as well as the order degree of a complex system as a whole. Therefore, a more detailed information on the complex system peculiarities can be obtained using MFA.

The procedure of image processing consists of several stages: From the AFM data, the approximated images of the surface are patterned.

Then the binary matrix is obtained assigning “0” and “1” to light and dark points, respectively. In our case, the matrix dimensions are 280×280 units. After that, the matrix is divided into larger boxes consisting of $l_k \times l_k$ elementary units. In our case the maximum l_k is 100. For every rougher partition a characteristic measure P_i was calculated ($P_i = M_i / \sum_i M_i$, where M_i is the sum of the units in the i th larger box, $\sum_i M_i$ is the overall sum of units over the whole rougher partition, and $i = 1, 2, \dots, N$, where $N = (280/l_k)^2$, i.e. the square of the integer part). The conventional multifractal characteristics were calculated in each digitized image using such a collection of either rougher partitions, i.e. the so-called $f(x)$ spectra and the Renyi dimensions $D_q = \tau(q)/(q-1)$ were calculated [2]. D_q carries the information on the thermodynamic conditions of the structure formation. Moreover, it is indicative of both the growth condition non-equilibrium degree and the system self-organization level. It should be noticed that D_q is usable as a means of identification of material structures, which are poorly or not recognized by traditional methods. The dependence of the generalized correlation function $x(q)$ on the size l_k of larger boxes: $x(q) = \sum_i (P_i)^q \propto (l_k)^{-\tau(q)}$, were calculated by a double logarithmic least squares approximation.

Such a technique enables a quantitative evaluation of the uniformity (by the quantity denoted as f_q) and degree of the order index (by the quantity denoted as $\Delta_q = D_1 - D_q$) of the structures investigated. The larger the Δ_q , the more ordered is the structure. The computations are performed using the MFRDrom program developed by Vstovsky [3]. In our case, the maximum value of q was 100 and a number of the canonical multifractal spectra was 38.

3. Results and discussion

The results of our previous AFM and EFM investigations on the structural and electrical properties of GaN

epitaxial layers showed that a random charge distribution was associated with the mosaic structure [7]. The distribution decreased mobility and resulted in unconventional carrier transfer mechanism similar to that observed in low-dimensional structures. The introduction of silicon with the concentration less than 10^{18} cm^{-3} eliminated the charge influence. The greatest impact was observed for the II Group layers (see Table 1). The charge transfer was determined by a classic mechanism [7] in these structures.

Two groups of layers could be separated. Group I and Group II are characterized by strong and weak effects of the mosaic structure on the charge transfer, respectively. The Schottky barriers were formed on the surface of both groups of the layers in one process. For this purpose, the Ni/Au contact of 2 mm diameter was deposited in high vacuum. Ti/Al layers were used as the ohmic contact. As the result, the Schottky barrier height was lower than 0.4 V for Group I, while the leakage current of Group I (Fig. 1, curve 1) was several orders of magnitude higher than that of Group II. The Schottky barrier height of Group II was 0.7–0.8 V, which was closer to the work function difference.

The photoconductivity investigations demonstrated that the persistent photoconductivity was lacking in Group II, while it was high in Group I not only at low temperatures, but at room temperature as well [8].

These results demonstrated at a qualitative level that the mosaic structure peculiarities played an important role in the electrical properties of the layer and device parameters. In this connection, a quantitative characterization of the mosaic structure is required to investigate the influence of its peculiarities on the electrical properties of the layers.

However, the traditional characterization techniques do not allow the peculiarities of the mosaic structure to

Fig. 1. Current–voltage characteristics of the Schottky barrier photodetectors based on GaN at reverse bias for (1) well and (2) poorly organized mosaic structure.

Fig. 2. Correlation between the Renyi dimensions (or the self-organization degree) and the mobility for the GaN epitaxial layers.

Fig. 3. Correlation of the degree of order index Δ_{100} and mobility μ at room temperature for GaN epitaxial layers.

be described in detail. For instance, the average domain size along with the basic axes is evaluated with X-ray diffraction analysis. Diagnostics of GaN surface topology using AFM gives only qualitative characteristics of the mosaic structure.

Only in Groups I and II with a high difference both in mobility and in average domain size of the mosaic structure, the correlation with the surface structure peculiarities was observed. In Groups III–VI, no direct association of the surface peculiarities with the electrical and volume structure properties was found.

In this connection, an effort was made to describe the mosaic structure peculiarities applying MFA of the AFM data for all non layers. A direct correlation between mobility and multifractal parameters was established (Figs. 2 and 3). The layers of Groups II, III, and VI possessed similar concentrations of carriers and silicon, but differed both in self-organization degree and in the disruption degree of local symmetry for the mosaic structure. From a temperature dependence of the mobility in these layers, it followed that scattering on

Fig. 4. Temperature dependence of mobility for Si-doped GaN layers with different Δ_{100} : (1) Group VI; (2) Group III; and (3) Group II.

charge centres made a different contribution at low temperatures (Fig. 4). The linear dependence of μ versus D_{100} and Δ_{100} is reasonable, because the carrier transport mechanism is unconventional (for most of the layers, the temperature dependence of conductivity corresponds to materials with localized charge defects or to low-dimensional structures) [7]. The mechanism depends on the probability of the current channel formation. Therefore, the layers with a higher self-organization level of the mosaic structure (i.e. with a small value of D_{100}) have higher mobility.

4. Conclusion

The important role of the mosaic structure peculiarities on the electrical properties of the layers and the device parameters was demonstrated.

New quantitative data: the self-organization degree (D_{100}) and the disruption of local symmetry (Δ_{100}) of mosaic structure have been obtained for GaN epitaxial layers of the hexagonal modification using the MFA of the surface structure.

The direct correlation between mobility of carriers in GaN epitaxial layers and D_{100} and Δ_{100} parameters of the mosaic structure is observed.

The MFA is a new approach to improve the properties of III-nitride layers.

The strain field around a single point defect in semiconductors spatially resolved by electric field modulation scanning tunneling spectro-microscopy

Akira Hida*, Yutaka Mera, Koji Maeda

Department of Applied Physics, School of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113-8656, Japan

Abstract

We have developed a novel instrumentation that allows us to image with a nano-scale resolution the strain field localized around single point defects in semiconducting crystals. The instrument that coupled the electric field modulation spectroscopy with the scanning tunneling microscopy was applied to point defects in low-temperature-grown GaAs (LT-GaAs) epi-films. The strain field image constructed by the present method exhibited features consistent with other experimental results. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Strain field; Energy gap; GaAs; Scanning tunneling microscopy

The strain field around a defect not only generally determines the elastic interaction between the defect and other defects/impurities but also can affect the electronic properties of the crystal. Particularly in semiconductors, the defect strain field modifies the local electronic band structure inducing significant effects on physical properties such as transport and confinement of carriers. Also, since the knowledge of the strain field provides insights to the atomic structure of the defect, the study of the strain field around defects is of fundamental importance in the research of defects.

So far, the most conventional techniques that allow us to investigate the strain fields around defects are those based on diffraction of quantum beams such as X-rays and electrons. If we want to *image* the strain field in real space, the transmission electron microscopy (TEM) has the highest spatial resolution. However, the TEM is not capable of imaging the strain field around point defects since the strain field damps quickly within a short distance from the defects. Hence, the development of new methodologies has been desired.

In semiconducting crystals, the elastic strain causes a change in the electronic band structures. The electric

field modulation spectroscopy (EFMS) is a variation of the modulation spectroscopy (see, for example, Ref. [1]) the power of which has been demonstrated in accurate measurements of electronic band structures in semiconductors. The principle of EFMS is based on the fact that the application of an electric field to a solid induces an oscillatory change in the optical absorption coefficient depending on the photon energy (the Frantz–Keldysh effect [2]), as illustrated in Fig. 1(a). The EFMS is superior to other techniques in that it can yield spectra with sharp fine structures, even in measurements at room temperature, each representing singularities in optical transitions such as the absorption edge (schematically illustrated in Fig. 1(b)). The high energy resolution of EFMS is thus advantageous for detecting small changes in the electronic band structures caused by the strain fields due to the point defects. The signal detected in the conventional EFMS is usually a change in the reflectivity of a monochromatized probe light illuminated on a surface of a macroscopic sample whose optical absorption coefficient is modulated by an electric field applied to the sample by some means. Although, the lateral spatial resolution may be achieved by reducing the beam size of the probe light [3], it cannot exceed the diffraction limit and also is practically limited by the signal-to-noise (S/N) ratio inherent in the

Fig. 1. (a) An oscillatory change in the optical absorption coefficient α depending on the electric field E applied to the crystal (Frantz-Keldysh effect). (b) A schematic energy-derivative spectrum obtained by electric field modulation spectroscopy. The bandgap energy is indicated by E_g . (c) The tunneling current in STM changes with the surface photo-voltage that is modulated by a chopped light with a magnitude responding to the modulated optical absorption coefficient of the material.

detection of the small change in the reflecting light intensity.

Recently, we have developed a new instrumentation that couples scanning tunneling microscopy (STM) [4] with the EFMS (STM-EFMS) that allows us to image the electronic band structures with a nanometer-scale resolution [5,6]. In the present study, we applied the STM-EFMS to low-temperature-grown GaAs (LT-GaAs) epi-films for imaging the local strain field around single point defects in the crystal.

Since the details of the STM-EFMS have been given in a previous paper [5], we only describe the brief outline. When a semiconducting sample is illuminated with a light whose energy exceeds the bandgap of the crystal, a surface photo-voltage (SPV) is induced if the surface band is bent to some extent [9,10] (see Fig. 1(c)). In an STM, the surface band bending may be induced locally by the bias voltage applied between the sample and the tip (tip-induced band bending) [7,8]. The magnitude of the SPV, that induces a change in the tunneling current, is determined by the number of photo-carriers generated by the light illumination or by the optical absorption coefficient of the sample in the photon energy range above the bandgap (superband-gap). Using another superbandgap light that is chopped, we can modulate the SPV and hence the electric field at the surface. Thus, instead of the light reflectivity in the conventional EFMS [2], we could measure the amplitude of the modulated-tunneling current as the EFMS signal. The use of the STM tunneling current, together with the localized tip-induced band bending, renders the extremely high spatial resolution.

The experimental setup is illustrated in Fig. 2. A sample placed on an ultrahigh vacuum (UHV) STM stage (UNISOKU, a custom model) was illuminated with two different light sources: One was a chopped laser light for electric field modulation and another was a

Fig. 2. A schematic diagram of the experimental setup. The sample placed on a UHV-STM stage is illuminated with two different light sources: One is a chopped laser beam ($h\nu = 1.52\text{ eV}$) for electric field modulation and another is a continuous light from a monochromator for spectroscopic measurements. The modulated signal of the tunneling current is detected by a lock-in amplifier tuned at the chopping frequency to obtain an energy-derivative EFMS spectrum at a specific position of the sample and an EFMS image at the bandgap energy reflecting the spatial variation of the bandgap energy in the sample.

continuous light from a monochromator for spectroscopic measurements. The chopping frequency was chosen to be higher than 1 kHz so that the current modulation was not damped by the STM current feedback control. The amplitude of the tunneling current (ΔI signal) was detected by a lock-in amplifier tuned at the chopping frequency as a function of the tip position \vec{r} , the photon energy $h\nu$ of the continuous light and the sample bias voltage V_s . EFMS spectra at given tip positions \vec{r}_0 were obtained by measuring the $\Delta I(\vec{r}_0, h\nu, V_s)$ signal with a fixed bias V_s as a function of the photon energy $h\nu$. Two-dimensional maps of ΔI signal (EFMS images) were acquired by scanning the tip

Fig. 3. (a) An occupied state and (b) an unoccupied state STM images of a typical point defect, assigned to an isolated As antisite defect, in an LT-GaAs epi-film. The images were taken at $V_s = -2.1$ V and $V_s = +2.3$ V, respectively. (c) An original EFMS image and (d) the strain field image obtained for the same defect after the corrections described in the text. The dark contrast around the defect in the strain field image represents a compressive strain. The strain field is triangular in shape, consistent with the T_d symmetry of the isolated antisite As.

at a given photon energy and a given bias voltage. Since the ΔI signal changes abruptly across the bandgap energy, if we fix $h\nu$ at a value close to the bandgap of the sample, the positional variation of the bandgap energy can be approximately visualized by the EFMS image. STM images in the constant-current mode were also recorded to compare the EFMS images with the topographic features.

The sample we used was an undoped LT-GaAs film of 200 nm thickness grown at 250°C on a Si-doped n-type GaAs (001) substrate ($n \sim 10^{18} \text{ cm}^{-3}$) in a VG-SEMI-CON VG80H molecular beam epitaxy (MBE) system. X-ray diffraction measurements indicated that the LT-GaAs epi-layer expanded normal to the surface by 0.20%. The cross-sectional (110) surfaces of the epi-film prepared by cleaving in the UHV-STM chamber (the base pressure $< 2 \times 10^{-8}$ Pa) were examined with Pt-Ir tips at room temperature. Normally, the samples were biased at +2.3 V with respect to the tip in order to induce an upward band bending in the GaAs (110) cleavage surface that is otherwise free of band bending

due to the absence of surface states and therefore no SPV is expected to arise [11]. The mean demand tunneling current (I_t) was set at 100 pA.

Fig. 3(a) shows an STM image of a typical point defect in LT-GaAs epi-layers observed at a negative sample bias ($V_s = -2.1$ V). The characteristic contrast is in agreement with that reported previously [12] as an isolated arsenic antisite defect (As_{Ga}) embedded in a few layers of GaAs (110) surface. Figs. 3(b) and (c) show an STM image of the same defect as recorded above with a positive sample bias ($V_s = +2.3$ V) and an EFMS image simultaneously acquired at $h\nu = 1.40$ eV which corresponds to the mean bandgap energy of the LT-GaAs epi-film at room temperature. In the EFMS image, the defect is surrounded by a dark contrast, whereas no such contrast is seen in the normal STM image, which indicates that the dark contrast is not of topographic origin.

Precisely speaking, the current modulation may be caused by mechanisms other than that considered above. This is demonstrated by Fig. 4 that shows a set

of EFMS spectra obtained at the same position of a sample with different sample biases. While the characteristic EFMS spectrum is observed at a sample bias of $V_s = +3.0$ V, no spectral features are seen at $V_s = +1.8$ V. The substantial reduction of the spectral variation in the ΔI signal at the lower bias voltage can be understood if one considers that decreasing the bias voltage reduces the surface band bending and hence the magnitude of the SPV necessary for electric field modulation. We should note, however, that even if the spectroscopic signal dwindles at $V_s = +1.8$ V, some magnitude of the modulated signal still remains, giving the constant background level denoted with G in Fig. 4. Generally, the chopped laser illumination could induce the thermal expansion of the STM tip that also would cause a modulation in the tunneling current. Although the modulation of the tip-sample distance due to the thermal expansion of the tip could be reduced by increasing the chopping frequency, it could not be removed completely at 1 kHz. Therefore, the residual background level obtained at $V_s = +1.8$ V is

$$\frac{\Delta I(\vec{r}, h\nu = 1.42 \text{ eV}, V_s = +2.5 \text{ V}) - \Delta I(\vec{r}, h\nu = 1.55 \text{ eV}, V_s = +1.8 \text{ V})}{\Delta I(\vec{r}, h\nu = 1.55 \text{ eV}, V_s = +2.5 \text{ V}) - \Delta I(\vec{r}, h\nu = 1.55 \text{ eV}, V_s = +1.8 \text{ V})}$$

considered to originate in the thermal expansion effect. Another factor that should influence the ΔI signal is the magnitude of the SPV itself that may vary spatially as reported by Hamers et al. [8,9]. The spectroscopic component of the ΔI signal in our work should be proportional to the magnitude of the SPV caused by the laser light chopped for electric field modulation. The magnitude of the SPV can be evaluated by the difference between the background

Fig. 4. A set of EFMS spectra obtained at the same position of a GaAs sample with different sample biases. The characteristic EFMS spectrum is observed at a sample bias of $V_s = +3.0$ V, whereas no spectral features are obtained at $V_s = +1.8$ V. The background level denoted by G is considered to be due to the illumination-induced thermal expansion of the tip. The difference between the background and the baseline of the EFMS spectrum is considered to represent the SPV due to the laser light chopped for electric field modulation.

level (G) and the baseline level (B in Fig. 4) of the spectrum.

Therefore, in order to obtain the image that represents with fidelity the spatial variation of the bandgap energy and hence the strain field, we have to remove the contributions of the above origins from the EFMS image. The correction procedures to remove the thermal expansion effect and the possible variation of SPV are as follows: After measuring the EFMS image or the spatial variation of $\Delta I(\vec{r}, h\nu = 1.42 \text{ eV}, V_s = +2.3 \text{ V})$, we measure the spatial variations of the intensity of $\Delta I(\vec{r}, h\nu = 1.55 \text{ eV}, V_s = +2.3 \text{ V})$ and $\Delta I(\vec{r}, h\nu = 1.55 \text{ eV}, V_s = +1.8 \text{ V})$ in the same area. Since the photon energy of $h\nu = 1.55 \text{ eV}$ is remote from the bandgap energy, $\Delta I(\vec{r}, h\nu = 1.55 \text{ eV}, V_s = +2.3 \text{ V})$ and $\Delta I(\vec{r}, h\nu = 1.55 \text{ eV}, V_s = +1.8 \text{ V})$ represent the spatial variations of the baseline level and of the background level, respectively. As the spatial variation of SPV is given by $\Delta I(\vec{r}, h\nu = 1.55 \text{ eV}, V_s = +2.3 \text{ V}) - \Delta I(\vec{r}, h\nu = 1.55 \text{ eV}, V_s = +1.8 \text{ V})$, the spatial map of the energy gap or the strain field that we want is obtained by calculating

Fig. 3(d) shows the strain field image obtained following the above procedures. The contrasts in the image should represent the variation of the bandgap energy. The dark contrasts indicate that the bandgap energy is larger than the surrounding, which means that the crystal near the defect is compressed elastically. This fact is quite consistent with the macroscopic expansive strain in the epi-films detected by the X-ray diffraction measurements. The dark contrast due to the strain field has a triangular shape with the mirror symmetry axis along the $[011]$ direction, consistent with the symmetry of the defect contrast shown in the STM image (Fig. 3(a)). The mirror symmetry is also consistent with the T_d symmetry of the isolated As_{Ga} that is usually assumed.

Thermo-mechanical stability of wide-bandgap semiconductors: high temperature hardness of SiC, AlN, GaN, ZnO and ZnSe

I. Yonenaga*

Institute for Materials Research, Tohoku University, Katahira 2-1-1, Aoba-ku, Sendai 980-8577, Japan

Abstract

The hardness of single crystals α -SiC, AlN, GaN, ZnO and ZnSe at elevated temperatures was measured by the Vickers indentation method in the temperature range 20–1400°C. The hardness of SiC, AlN, GaN, ZnO and ZnSe is about 25, 18, 11, 5 and 1 GPa, respectively, at room temperature. SiC, AlN and GaN show a decrease in hardness, originating in the beginning of macroscopic dislocation motion and plastic deformation, only at temperature 1200°C. A high thermo-mechanical stability for SiC, GaN and AlN is deduced. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Wide bandgap semiconductors; Hardness; Thermo-mechanical stability

1. Introduction

Silicon carbide (SiC), aluminum nitride (AlN), gallium nitride (GaN), zinc oxide (ZnO) and zinc selenide (ZnSe) appear promising as wide-bandgap semiconductors for application as high power/high-frequency devices, blue- and ultraviolet light-emitting-devices/photo detectors and chemically stable substrates for epitaxial growth of various materials. Additionally, these materials are supposed to be thermo-mechanically stable and available at elevated temperatures except ZnSe. However, up to now, extremely little is known about the mechanical properties of these materials on microhardness only at room temperature. Information on the mechanical strength of materials at elevated temperatures is essential as a basis in order to control the dislocation generation and plastic deformation during crystal growth and device processing, and in utilizing the potential optical and electronic properties of the materials. The difficulty of the preparation of bulk crystals, especially GaN and AlN, is a limiting factor in obtaining this information. Recently thick films of GaN and AlN have been successfully grown by using a

hydride vapor phase epitaxy (HVPE) technique [1,2]. These crystals can be regarded as bulk materials. The author's group has reported the hardness, which is a material parameter indicating resistance to plastic deformation, in the bulk single crystals GaN and AlN at elevated temperatures [3–5].

This paper reports the hardness of the wide-bandgap semiconductors SiC, GaN, AlN, ZnO and ZnSe at elevated temperatures in comparison with those of other materials Si, GaAs, GaP and α -sapphire.

2. Experiments

The hardness of single crystals α -SiC, GaN, AlN, ZnO and ZnSe of 0.5 mm thickness at elevated temperatures was measured by the Vickers indentation method in the temperature range 20–1400°C. Here, GaN and AlN single crystals were prepared from high-quality thick film grown on substrates by the HVPE technique, the details of which were described elsewhere [1,2].

Hardness measurements on the crystals were carried out by the conventional Vickers indentation method using a pyramidal diamond indenter. The applied indentation load P was 0.5–5 N. The dwell time was 30 s for every temperature tested in the range from room temperature (RT) to 1400°C.

E-mail address: yonenaga@imr.edu (I. Yonenaga).

3. Results and discussion

At room temperature, the indentations formed on the basal plane surfaces of the GaN and AlN crystals sometimes exhibited fracture characteristics for brittle materials with radial cracks propagating from the impression corners under an applied load of more than 2 N.

Hardness H_V was estimated from the load P and diagonal lengths $2a$, measured by optical microscopy, of the impression using the following relation:

$$H_V = P/(2a^2). \quad (1)$$

The fracture toughness K_{IC} was also determined from the radial crack length c :

$$K_{IC} = \xi(E/H_V)^{1/2}(P/c^3)^{1/2}, \quad (2)$$

where E is Young's modulus and ξ is a calibration constant ($=0.016$) for brittle materials.

The hardness is almost comparable for the (0001)/(111) and (0001)/(111) polar surfaces of the crystals with the hcp-/cubic-based structure at all temperatures investigated. At RT, the hardness of GaN is 10.8 GPa, about twice and ten times the value of GaAs and ZnSe, respectively, which is similar to 12 and 12.3 GPa given by Drory et al. [6] and Hong et al. [7], respectively. The hardness of AlN at RT is 17.7 GPa. The fracture toughness of GaN is measured to be $1.1 \text{ MPa m}^{1/2}$ using Eq. (2) with $E = 295 \text{ GPa}$ [8]. The fracture toughness of AlN is $0.4 \text{ MPa m}^{1/2}$ using $E \approx 308 \text{ GPa}$ [9]. Table 1 summarizes the hardness and fracture toughness of various materials at RT [3–5, 10–13]. As is evident in the table, AlN is harder than GaN and softer than SiC and $\alpha\text{-Al}_2\text{O}_3$ [13]. ZnO is much softer than such materials. The result suggests that the hardness of semiconductors seems to be related to the bonding distance [15], dependent on the group of semiconductors, the elemental and IV–IV, III–V, and II–VI compound.

Fig. 1. Vickers hardness of bulk single-crystals $\alpha\text{-SiC}$, AlN, GaN, ZnO and ZnSe plotted against reciprocal temperature, with an applied load of 0.5 N and dwell time of 30 s, together with those of Si, GaP, GaAs and $\alpha\text{-Al}_2\text{O}_3$. The hardness of $\alpha\text{-Al}_2\text{O}_3$ obtained with an applied load of 2 N and dwell time of 15 s is superimposed [13].

Fig. 1 shows the hardness H_V of SiC, GaN, AlN, ZnO and ZnSe, obtained with an applied load of 0.5 N and dwell time of 30 s, plotted against reciprocal temperature together with the values for Si, GaP, GaAs and $\alpha\text{-Al}_2\text{O}_3$.

In the whole temperature range investigated, the hardness of SiC, GaN, AlN and ZnO exhibits a gradual decrease from RT to around 600°C, then something resembling a plateau in the range to around 1000°C, and subsequently a steep decrease. This temperature-dependent tendency is common in semiconductors and sapphire, which have the hcp-based structure, although the temperature range and hardness magnitudes of SiC or $\alpha\text{-Al}_2\text{O}_3$ are higher than that of AlN and GaN. The plateau may appear in relation to the operation of different slip systems in the crystal structure. It is found that in the whole temperature range investigated, the hardness magnitudes of ZnO are smaller than those of SiC, AlN and GaN.

Table 1

Vickers hardness and fracture toughness for $\alpha\text{-SiC}$, GaN, AlN and other materials at room temperature or 300°C [3–5, 10–13] with an applied load 0.5 N and dwell time 30 s together with bonding distance [14]

Material	Hardness (GPa)	Fracture toughness ($\text{MPa m}^{1/2}$)	Bonding distance (\AA)
$\alpha\text{-SiC}$ (0001)	22.9 ^a	3.3 (Ref. [10])	1.88
GaN (0001)	10.2 (Ref. [3])	1.1 (Ref. [4])	1.96
AlN (0001)	17.7 (Ref. [5])	0.4 (Ref. [5])	1.92
ZnO (0001)	4.7		1.80
ZnSe (111)	1.1	0.9 (Ref. [10])	2.45
Si (111)	12.0	0.7 (Ref. [10])	2.35
GaP (111)	7.73	0.65 (Ref. [12])	2.36
GaAs (111)	6.8	0.4 (Ref. [11])	2.45
$\alpha\text{-Al}_2\text{O}_3$ (0001)	28 ^b (Ref. [13])	2.5 (Ref. [10])	1.92

^a At 300°C.

^b With an applied load 2 N and dwell time 15 s [12].

At low temperature regions, the hardness of GaN and AlN is comparable to, or a little lower than, that of Si, though the hardness of Si may be affected by the phase transformation that occurs at a pressure of about 11.3 GPa beneath the indenter. It is surprising that up to about 1100°C, GaN and AlN maintain their hardness and are harder than Si. Indeed, Si and GaAs exhibit a steep decrease in hardness from 500°C and 200°C, respectively, with an increase in the temperature, which indicates the beginning of macroscopic dislocation motion and plastic deformation. The present results indicate that this macroscopic dislocation motion and plastic deformation of SiC, GaN and AlN may start at around 1100°C. Over the whole temperature range investigated, ZnSe is known to be most unstable thermo-mechanically in the materials.

From the results it is found that SiC, GaN and AlN are of higher thermo-mechanical stability against deformation during device processing at elevated temperatures as compared with Si, GaP, GaAs, ZnSe and possibly other III–V and II–VI compounds with the sphalerite structure. A more complete physical study of hardness in order to derive the dynamic properties of dislocations is still lacking in the absence of sufficient theory and is a task in the future. However, we assume that the present data provide a useful indication of material strength at elevated temperatures. Further work should be required to determine the dislocation mobility, especially, in GaN and AlN bulk crystals under a defined stress distribution.

4. Summary

The Vickers hardness for wide-bandgap semiconductors α -SiC, AlN, GaN, ZnO and ZnSe of 0.5 mm thickness was compared in the temperature range 20–1400°C. The hardness of SiC, AlN, GaN, ZnO and ZnSe is about 25, 18, 11, 5 and 1 GPa, respectively, at room temperature. SiC, AlN and GaN show a decrease in hardness, originating in the beginning of macroscopic dislocation motion and plastic deformation, only at temperature 1200°C. The results imply that these crystals have a smaller susceptibility to deformation during device processing at high temperatures as compared with ZnO, Si, GaP, GaAs and ZnSe.

Capacitance X-ray absorption fine structure measurement using scanning probe

A new method for local structure analysis of surface defects

Masashi Ishii*

JASRI (Japan Synchrotron Radiation Research Institute), SPring-8, Mikaduki, Sayo-gun, Hyogo 679-5198, Japan

Abstract

A capacitance X-ray absorption fine structure (XAFS) method using a scanning probe is developed for the selective analysis of surface defects in selected local regions. Since capacitance is sensitive to localized electrons in defects, capacitance change owing to X-ray absorption will provide site-selective XAFS spectra of the defects. The capacitance detection by the scanning probe under an X-ray beam gives XAFS spectra dependent on the surface state. An electron transition model, in which the surface density of states is taken into account, reproduces the spectral shape differences between the normal surface and defect surface. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Surface defects; Site-selectivity; Capacitance XAFS; Scanning probe

1. Introduction

The progress in electronics technology over the last several decades has mainly been based on the integration of semiconductor devices. Various efforts have been made toward forming superior microstructures, with the present result being \sim nm order devices by the recent semiconductor fabrication techniques. In these small structures, the atomic coordination of the defects in the electrically active regions determines the device performance. This fact indicates the need for methods to structurally analyze defects in selected \sim nm regions; One of the ultimate objectives of the defect analysis is defect structure mapping on semiconductor surfaces.

In recent years, we proposed a capacitance X-ray absorption fine structure (XAFS) method that obtains absorption spectra by the X-ray photon energy dependence of the capacitance [1,2]. Since the capacitance is sensitive to localized electrons in defects, the photoionization of the defects owing to X-ray inner-shell absorption changes the capacitance, resulting in site-selective X-ray absorption spectra of the defects.

Generally speaking, the XAFS denotes spectral signal oscillations over the energy range of \sim 1 keV from the inner-shell absorption edge, and its Fourier transformation provides structural information, such as the bond length with a neighboring atom and the coordination number of a specific atom selected by the X-ray photon energy [3]. Moreover, the density of unoccupied states above the Fermi energy can also be estimated from the near edge absorption spectrum [4]. Therefore, the capacitance XAFS method can provide a microscopic local structure and the electronic states of only the defects, owing to its site-selectivity.

In this paper, a capacitance XAFS method using a scanning probe is developed with the aim of achieving the defect structure mapping on the semiconductor surface. By capacitance detection in selected local areas, XAFS spectra correlated with surface states can be observed.

2. Experimental details

Fig. 1 schematically shows the experimental apparatus developed in this study. A mechanically sharpened Ta with a purity of 99.95% is used as the scanning probe. A point contact of the Ta tip with a sample

Fig. 1. Experimental setup in this study.

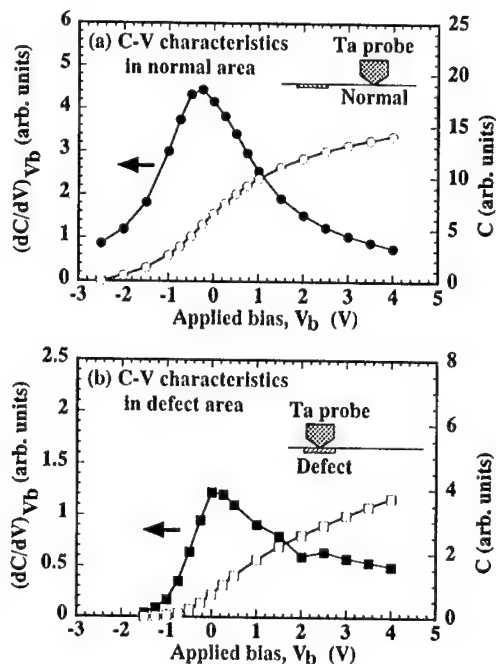

semiconductor surface makes a metal-oxide-semiconductor (MOS) diode structure owing to the native oxide on the semiconductor surface. The MOS diode structure has the capacitance-bias voltage (C - V) characteristics schematically shown by the solid line in the inset of Fig. 1. The X-ray irradiated into this MOS diode induces the photoionization of the surface defects, and the release of localized electrons increases free carriers by ΔN_d . The ΔN_d slightly shifts the C - V characteristics horizontally along the voltage axis as shown by the dashed line, resulting in capacitance changes of ΔC at the specific bias voltage of V_b . In our system, the capacitance of the MOS diode, C , is measured by a capacitance sensor for a videodisc [5]. For the sensitive detection of ΔC , a lock-in amplification technique with V_b modulation is used; the capacitance XAFS signal is observed by derivative of C at V_b (dC/dV) $_{V_b}$, rather than the absolute C . The V_b modulation amplitude, V_{mod} , and modulation frequency, f , are fixed at 500 mV and 131 Hz, respectively.

The sample used in this study is Sn-doped (100) oriented GaAs (GaAs:Sn). The Sn density is $1 \times 10^{17}/\text{cm}^3$. A part of the sample surface is scratched to introduce the surface defects owing to crystal disorder. The sample is mounted on a scanning stage. The substrate temperature is kept at room temperature. Synchrotron radiation (SR) is used as the X-ray source for the XAFS measurements. The beamline for our SR experiments is the BL10XU High Brilliance XAFS station [6] at SPring-8, located in Hyogo Prefecture, Japan.

3. Results and discussions

3.1. Electrical properties of the sample

Fig. 2 shows local C - V characteristics obtained by the Ta probe in (a) a normal (as prepared) surface area and

Fig. 2. C - V characteristics of (a) normal and (b) defect areas.

(b) a defect surface area. The solid circles in (a) indicate the $(dC/dV)_{V_b}$ signal in the normal area. The $(dC/dV)_{V_b}$ has almost symmetrical characteristics with the maximum intensity at $V_b \sim 0$ V. The ordinary C - V characteristics derived from the integration of $(dC/dV)_{V_b}$ are also plotted in this figure by the open circles. As shown in this figure, C - V characteristics with the capacitance saturations at high and low V_b values can be obtained. The characteristics intrinsic to the MOS capacitor indicate the local formation of the MOS diode structure by the Ta point contact.

In contrast, the $(dC/dV)_{V_b}$ signal in the defect area denotes asymmetric characteristics (solid squares in (b)), and the signal intensity is smaller than that in the normal area. Because of these properties, the C - V characteristics have a gentle curve and a small C at a high V_b (open squares). This property of the defect area is consistent with the general fact that electron localized at the surface defects terminate the electric field in the MOS capacitor, resulting in a C reduction.

3.2. Capacitance XAFS measurements using scanning probe

In order to correlate the electric properties shown in Fig. 2 with the X-ray absorption spectrum of the defects, capacitance XAFS measurements using this Ta probe are performed. Fig. 3 shows the capacitance XAFS spectra of (a) the normal area and (b) defect surface

Fig. 3. Capacitance XAFS spectra of (a) normal and (b) defect areas.

area. In this experiment, V_b was fixed at 0 V. As shown in this figure, the edge jumps at the Ga K-edge (10.375 keV), the resonant absorption peaks denoted by α and β , and the following XAFS oscillations in the high energy region can clearly be observed. From a comparison between (a) and (b), we recognized that the spectrum shape depends on the surface state. According to the concept of the capacitance XAFS method, the spectrum differences in (1) the edge jumps and (2) the resonant peaks can be explained as follows.

(1) The actual edge jump minus the resonant peaks for the normal surface (I_N) is higher than that for the defect surface (I_D). As described in Fig. 1, the capacitance XAFS signal is obtained by the photoionization of the defects. Assuming that the photoionization produces almost the same ΔN_d for both areas, it is easily predictable from the inset of Fig. 1 that the gentle $C-V$ characteristics curve yields a small ΔC . In fact, the defect surface has a gentle $C-V$ characteristics curve as shown in Fig. 2, indicating that $I_D < I_N$ in Fig. 3 is consistent with this photoionization model in the capacitance XAFS method.

(2) The resonant peaks of α and β for the normal surface are more intense and sharper than those for the defect surface. Fig. 4 indicates the band diagram of the photoionization process in the capacitance XAFS measurement. Under X-ray irradiation, localized electrons are relaxed into core-holes formed by the inner-shell excitation of the defects. The excitation and following relaxation are identical to a de-localization of the electrons by ΔN_d , resulting in ΔC . In the normal surface area, since the dangling bonds on the GaAs:Sn surface are relatively uniform, the surface density of states (SDOS) is condensed in a narrow energy range as illustrated in Fig. 4(a). The de-localization of the

Fig. 4. Band diagrams of (a) normal and (b) defect areas.

Fig. 5. Comparison between spatial resolution and probe size.

electrons from the condensed level is resonantly induced at the specific photon energy, resulting in the intense and sharp absorption peak. On the other hand, the defect area with various atomic coordinations forms a broad SDOS as shown in Fig. 4(b). In this situation, since the electrons are dispersively trapped in the energy range of ΔE , the resonant absorption becomes broader.

3.3. Spatial resolution

To discuss the spatial resolution of this method, $(dC/dV)_{V_b}$ during a one-dimensional scan is plotted by the open circles in Fig. 5. At this boundary of a defect area and a normal area, the variation of $(dC/dV)_{V_b}$ can be observed. The position derivative of $(dC/dV)_{V_b}$ is also indicated by the solid circles in this figure. From the full-width at half-maximum (FWHM) of the derivative, the spatial resolution can be estimated as $\sim 210 \mu\text{m}$. On the other hand, the diameter of the Ta probe is $\sim 230 \mu\text{m}$ as shown in the inset of this figure. This Ta diameter

comparable to the FWHM indicates that the spatial resolution of this method is limited by the probe size at this time.

4. Summary

A capacitance XAFS method using a scanning probe is proposed for defect structure mapping on a semiconductor surface. Since capacitance is sensitive to localized electrons in defects, the photon energy dependence of the capacitance provides site-selective XAFS spectra of the defects. The capacitance XAFS spectra dependent on the surface states are successfully obtained by using the Ta scanning probe; Since the electrons on the defect surface are dispersively trapped over a wide energy range, the resonant peak at the X-ray

absorption edge becomes broader. We showed that a spatial resolution of $\sim 210\text{ }\mu\text{m}$ is limited by the scanning probe diameter.

Positron lifetime beam for defect studies in thin epitaxial semiconductor structures

A. Laakso*, K. Saarinen, P. Hautojärvi

Laboratory of Physics, Helsinki University of Technology, P.O. Box 1100, 02015 HUT, Finland

Abstract

Positron annihilation spectroscopies are methods for direct identification of vacancy-type defects by measuring positron lifetime and Doppler broadening of annihilation radiation and providing information about open volume, concentration and atoms surrounding the defect. Both these techniques are easily applied to bulk samples. Only the Doppler broadening spectroscopy can be employed in thin epitaxial samples by utilizing low-energy positron beams. Here we describe the positron lifetime beam which will provide us with a method to measure lifetime in thin semiconductor layers. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Positron spectroscopy; Vacancies; Instrumentation; Epilayers

1. Introduction

Positron spectroscopy is a method for direct identification of vacancy defects [1]. It is based on monitoring the 511 keV annihilation radiation emitted when thermalized positrons annihilate in solids with electrons. Positrons get trapped at neutral and negative vacancies because of the missing positive charge of the ion cores. At vacancies, the positron lifetime increases and positron–electron momentum distribution narrows due to reduced electron density.

The spectroscopy gives information on vacancies at concentrations 10^{15} – 10^{19} cm⁻³. Positron lifetime is a direct measure of the open volume of a defect. The Doppler broadening of the 511 keV radiation gives the momentum distribution of annihilating electrons $\rho_v(p)$. The core electron momentum distribution can be used to identify the sublattice and impurity surroundings of a vacancy. In addition, under varying temperature and illumination, the positron spectroscopy can yield information on charge states, optical transitions and thermal stabilities of vacancy defects.

The lifetime and Doppler broadening are easily applied to bulk samples. Thin epitaxial semiconductor layers can also be studied by Doppler broadening spectroscopy using a positron beam. However, positron lifetime spectroscopy, which is essential for obtaining the open volume of the defect, has been mainly limited to bulk samples although some lifetime beams have been constructed [3,4]. The purpose of this work is to describe the need for a pulsed positron lifetime beam designed for the semiconductor studies. In Section 2, we discuss the conventional positron techniques. Section 3 describes the principle of the lifetime beam and Section 4 concludes this work.

2. Methods and background

In conventional positron lifetime spectroscopy (see Fig. 1), positron lifetime is defined as a time difference of gamma emitted in β^+ decay and the gamma emitted when electron–positron pair annihilates. The positron lifetime spectrum is composed of exponential decay components with intensities I_i and lifetimes τ_i as $\sum_i I_i e^{-t/\tau_i}$. The different exponential components are associated to annihilations at different positron states

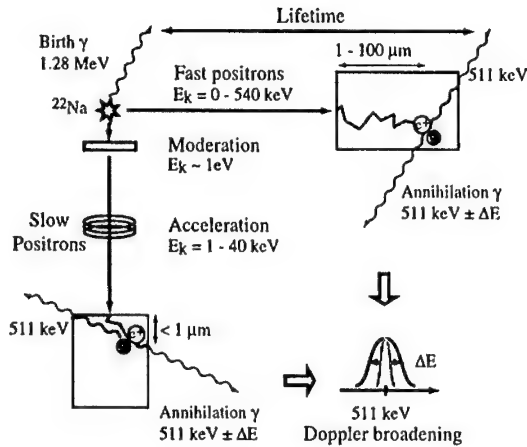

Fig. 1. The principle of positron experiment. Sources and measurable quantities.

Fig. 2. Positron lifetime spectra from two different GaN bulk samples. In the highly Mg-doped sample (white circles) only one lifetime component 165 ps is present. In an undoped n-type sample a longer lifetime component of 235 ps is present due to vacancies [2].

(bulk vs. vacancy). This spectrum can be relatively easily decomposed and the individual lifetimes and their intensities can be extracted.

As an example in Fig. 2, two different lifetime spectra from undoped and highly Mg-doped GaN bulk samples are shown. In the highly Mg-doped sample only one lifetime component, 165 ± 1 ps can be observed. However, in an undoped sample a second lifetime component is present with a time of 235 ± 5 ps. This second component is due to Ga vacancies existing as native defects in n-type GaN. The intensity of the second component provides an estimate of vacancy concentration (10^{17} cm^{-3} in this case).

The average lifetime τ_{av} is defined as the center of mass of the lifetime spectrum,

$$\tau_{av} = (1 - \eta_V)\tau_B + \eta_V\tau_V = \text{C.M.}, \quad (1)$$

where η_V is the fraction of the positrons annihilating in the vacancies and τ_B is the bulk lifetime. It should be noted that τ_{av} is a statistically accurate parameter and changes below 1 ps can be measured.

In Doppler broadening experiments, the momentum distribution of the annihilating electrons is recorded by measuring the Doppler shift ΔE of the annihilation radiation with Ge-detector. The momentum distribution $\rho(p)$ can be characterized by integrated *S*- and *W*-parameters shown in Fig. 3. The measured momentum distribution $\rho(p)$ is composed of the superimposed distributions from annihilations in vacancies $\rho_V(p)$ and in bulk $\rho_B(p)$ as shown in Eq. (2).

$$\rho(p) = (1 - \eta_V)\rho_B(p) + \eta_V\rho_V(p). \quad (2)$$

Very often this cannot be decomposed on its own. However, the decomposition is possible, if the annihilation fraction η_V and the bulk momentum distribution $\rho_B(p)$, determined by measuring a defect-free reference sample, is known.

In practice, the identification of the vacancies is based on measuring both τ_V and $\rho_V(p)$. τ_V is obtained from the decomposition of the lifetime spectra and it can be used to determine $\rho_V(p)$ (Eqs. (1) and (2)). This means that lifetime is normally needed for identification of vacancies. Furthermore, positron lifetime spectroscopy is approximately ten times more sensitive to defects than Doppler broadening spectroscopy.

The fast positrons emitted directly from ^{22}Na source have continuous energy range from 0 up to 540 keV and

Fig. 3. Area normalized momentum distribution of annihilating electrons measured in Doppler broadening experiment. The *S*- and *W*-parameters, which are commonly used to describe the line shape, are defined as integrals over the shaded areas.

a wide implantation profile ranging up to 100 μm . In the conventional lifetime experiment bulk samples with dimensions of 5 mm \times 5 mm and thicknesses $> 100 \mu\text{m}$ are thus needed.

Slow positrons are obtained from ^{22}Na source by thermalizing the fast positrons in a moderator crystal (e.g. single crystalline W foil). The thermal positrons emitted from the surface of the moderator (energies less than 1 eV) are accelerated in an electric field up to 100 keV in order to study layers with thicknesses of 0–5 μm .

Both lifetime and Doppler broadening measurements can be done routinely with fast positrons. On the other hand, slow positron beam experiments are mainly limited to Doppler measurements. This is because the time information of the positron's entrance to the sample is lost in the beam formation. However, a low-energy pulsed positron beam enables the lifetime measurements in thin layers.

3. Positron lifetime beam

A successful method for positron lifetime measurements in thin layers is a pulsed positron beam [3,4]. In this system, the continuous slow positron beam is converted to very short pulses with a well-defined time structure.

In the following, we will describe the pulsed positron lifetime beam presently under construction in the Helsinki University of Technology [5]. Our beam has been designed especially for studies of defects in semiconductors. Unlike in the other existing systems [3,4], in our beam the sample is at ground potential to simplify its manipulation and temperature control. In addition, the sample can be illuminated to study the optical properties of the defects. Also, the beam energy is variable between 3 and 30 keV which enables the measurements of layers with thicknesses of 0–2 μm .

The principle of pulse generation is shown in Fig. 4. The positrons from a ^{22}Na source are thermalized in a W-foil moderator. Thereafter they are magnetically guided and further accelerated to a velocity selector, which separates the remaining fast positrons from the slow ones. This is done by solenoids and coils arranged perpendicular to each other. In the first pulsing stage, the prebuncher, two sinusoidal voltages (33 and 66 MHz) are used to periodically accelerate and decelerate positrons in two gaps between the middle electrode and the end electrodes. The electrodes are also biased so that positrons are accelerated with constant potentials across the prebuncher.

The prebuncher is followed by a drift tube where the energy-modulated beam compresses to pulses. After the drift tube, the first acceleration stage feeds positrons to the chopper, which is used to cut out the background

Fig. 4. The pulsed positron lifetime beam. Short pulses are used to measure positron lifetime in thin layers.

between the pulses. This is done with three electrodes; the upper and the lower ones are grounded and the middle one is in an oscillating voltage with a frequency of 16.7 MHz. This voltage creates an electric field perpendicular to the beam, which increases the transversal velocity and the Larmor radius and makes positrons hit the walls of the chopper slit. By carefully adjusting the phase of the chopper voltage it is possible to cut out the background between pulses and pass the pulses through unmodified.

The main buncher is a resonating cavity with a frequency of 167 MHz. The two narrow spaces between the body of the cavity and the center electrode act as an acceleration–deceleration gaps. In this stage, the pulses are squeezed to a final width of 100 ps.

The pulses from the buncher are further accelerated by a constant voltage and slowed down to final energy in an adjustable decelerator before hitting the grounded sample. This kind of two-stage accelerator–decelerator structure is beneficial as it reduces the variation of the flight time through the acceleration stage with varying acceleration energies. It also helps to reduce the effects of the backscattered positrons in the lifetime spectrum. These positrons are accelerated away from the sample surface and they annihilate in the walls of the large chamber two or three nanoseconds after the arrival of the main pulse.

The pulse generation is controlled by electronics, which also provides the necessary timing signal corresponding to the time when positrons enter the sample. The timing signal for the positron annihilation is

measured by a BaF₂ scintillation detector placed behind the sample. The positron lifetime is obtained as a difference of these signals.

4. Conclusions

Positron annihilation spectroscopy can be used to identify vacancy-type defects in bulk semiconductor crystals and epitaxial layers. The identification of both vacancies and their surrounding atoms can be conventionally done only for bulk samples which can be measured with both lifetime and Doppler broadening spectroscopy. The pulsed positron beam described here will provide us with a method to measure positron lifetime in thin semiconductor layers. This enables direct

identification of the open volume of the defect in the layer, more straightforward determination of vacancy concentrations, and improved sensitivity compared with Doppler measurements.

Measurement of diffusion lengths in quaternary semiconducting thin layers by spectrum imaging

T. Walther*

Institut für Anorganische Chemie, Universität Bonn, Römerstrasse 164, D-53117 Bonn, Germany

Abstract

A method is described to detect and measure diffusion in complex layer systems. The technique of spectrum imaging is a combination of electron energy-loss spectroscopy and imaging in a transmission electron microscope with imaging energy filter. It allows to extract chemical profiles with a spatial resolution of about 1 nm at a compositional sensitivity better than 1 at% for most elements. This has been applied to multilayers of quaternary semiconductors, where simple electron microscopy based imaging techniques cannot distinguish between the diffusion of different atomic species. The diffusivities of sulphur in ZnMgSSe/ZnSe quantum well laser structures and of magnesium and manganese across interfaces in CdMnTe/CdTe/CdMgTe quantum wells have been determined. © 2001 Elsevier Science B.V. 1. Introduction

The (opto)electronic properties of quantum well structures depend strongly on the width and the chemical composition of the thin layers used for carrier confinement, as well as on the quality of interfaces between these and the barrier layers [1]. One of the biggest problems of devices made of such layers is thermal degradation due to diffusion and the generation of extended lattice defects. Latter can be investigated by transmission electron microscopy (TEM). High-resolution TEM has been used to study the abruptness of interfaces at near atomic resolution [2–4], but the accuracy is limited by Fresnel effects [5] and the need to determine precisely the imaging conditions that establish the relationship between image contrast and chemical composition [3,4,6]. Higher chemical sensitivity and reliability can be obtained from electron energy-loss spectroscopy (EELS) [7]. Here, the technique of

spectrum imaging, as first described in Ref. [8], is applied quantitatively to thin layers.

2. Experimental

The experiments have been performed with a Philips CM300UT TEM equipped with a Gatan imaging filter. Spectrum imaging exploits the fact that the dispersion of a magnetic sector field is only in one direction, perpendicular to the electron beam and the magnetic field. With an imaging filter and a two-dimensional detector, spatial resolution can be retained in the direction without dispersion so that line profiles across planar faults or interfaces can be recorded. A spectrum image consists of a series of EEL spectra taken simultaneously across the structure. Line-by-line EEL spectra can then be extracted. The interfaces must be accurately aligned relative to the spectrometer in order to avoid spatial blurring. Details of the procedure are given in Ref. [9].

The Zn(Mg,S)Se samples were grown by metal organic vapour phase epitaxy on GaAs (001) substrates at 330°C [10]. The Cd(Mg,Mn)Te samples studied were

*Corresponding author. Fax: +49-228-73-4-205.

E-mail address: walther@sg4.elmi.uni-bonn.de (T. Walther).

grown by molecular beam epitaxy on GaAs (001) at 280°C via a thick CdTe/CdMnTe buffer layer [11].

TEM cross-sectional samples were prepared by standard methods. Ar⁺ ion milling was employed at low angles of 8° and voltages of only 3 kV until perforation, and the holder was cooled which prevents sample damage known from ion irradiated II/VI compounds [12].

3. Results

Fig. 1a depicts a typical spectrum image recorded in 20 s with an energy offset of 2.4 keV of a 10 nm ZnMgSSe/5 nm ZnSe multiple quantum well laser

Fig. 1. Spectrum image (a), net signal after background subtraction (b) and calculated sulphur profiles (c) for the as-grown specimen (solid line), an annealed (dotted), and an annealed and irradiated specimen (dashed).

structure. After fitting an inverse power law background in front of the S_K edge at 2472 eV and subtracting it off, the S_K edge is well discernible (Fig. 1b). Twenty spectrum images were thus recorded to improve the signal-to-noise ratio, and this was repeated for each of the three specimens analysed (the as-grown, an annealed, and an annealed and irradiated structure). The net S_K intensity was then integrated over 40 eV from the edge onset. Scaling the sulphur profiles in the ZnMgSSe barrier layers far away from the thin quantum wells to the nominal composition of 16 at% S, the concentration profiles of the different samples are directly comparable (Fig. 1c). The sulphur profiles are approximately Gaussian which allows a straightforward solution of Fick's law of diffusion. From the decrease of the amplitudes of the profile during the anneal (30 min at 277°C) the diffusivity of sulphur in this system has been calculated as $D = 6 \times 10^{-22} \text{ m}^2 \text{ s}^{-1}$. The sulphur concentration measured as $(2.2 \pm 0.6) \text{ at\%}$ in the CdTe quantum wells after anneal was later confirmed independently by modelling the observed blue shift of the emission lines with temperature [13,14].

Fig. 2a shows a $\langle 100 \rangle$ lattice image and Fig. 2b the corresponding averaged intensity profile of the thinnest CdTe quantum well embedded between CdMnTe (left) and CdMgTe (right). Thickness and defocus have been chosen so that the CdTe exhibits strong $\{022\}$ fringes

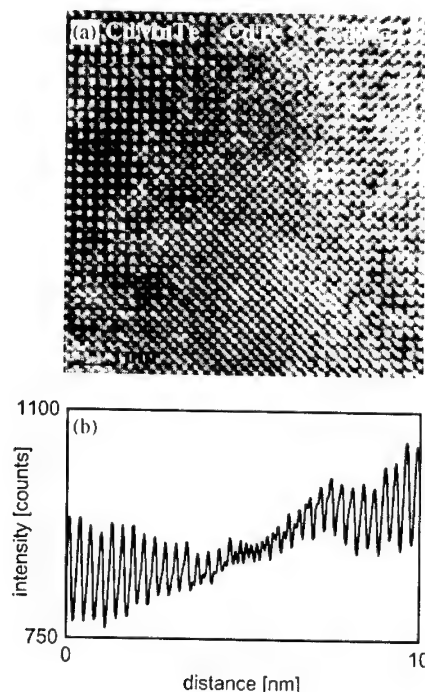

Fig. 2. Lattice image of an as-grown Cd(Mn,Mg)Te quantum well (a) and intensity profile (b), indicating about 3 monolayers transition widths.

while the ternary compounds show dominantly {002} lattice fringes, of opposite contrast. Both interfaces are visible as transition regions about 1 nm wide. Analyses of the other quantum wells gave similar results, with average interface widths of (2.7 ± 1.3) (002) monolayers for the as-grown structures.

Figs. 3a and b depict accumulated spectrum images taken of the as-deposited Cd(Mn,Mg)Te structure with different offsets. Figs. 3c and d show the corresponding net maps after background subtraction before the Mn_L and the Mg_K edges, respectively. The Te_M edge, just in front of the Mn_L edge, makes a background fit to Fig. 3a difficult; the best result was obtained by fitting a reference spectrum of pure CdTe to the wide peak of the Te_M edge. Profiles of the net maps were obtained by integrating over stripes 50 eV wide and are displayed for

all elements in Fig. 3e. The total exposure times for the elemental spectrum images were 5 s for Cd_M, 10 s for Te_M, 20 s for Mn_L and 200 s for the Mg_K edge, to yield comparable count rates. As the count rate, I , of an element (index i) is proportional to its concentration c , the exposure time t , and the ionisation cross-section s , the concentration can be calculated as

$$c_i = \frac{I_i/t_i s_i}{\sum_j I_j/t_j s_j} \quad (1)$$

It is known that the tabulated Hartree–Slater cross-sections used here [15] are accurate for the Mg_K and the Mn_L edge [16] but over-estimate the cross-sections of the delayed Cd_M edge [17]. Hence, the concentration of both Cd and Te will be underestimated and the calculated Mn and Mg concentrations in Fig. 3f will be somewhat too high. However, when the same procedure with the same integration windows is applied to the sample annealed for 15 s at 510°C, then the same systematic error will apply. From the ratios of the maximum concentrations before (c^{T0}) and after (c^{T1}) the anneal, the diffusion length, l , can be calculated from

$$\left(\frac{c^{T0}}{c^{T1}}\right)^2 = \frac{\sigma^2}{\sigma^2 + l^2} \quad (2)$$

where σ describes the standard deviation of the as-deposited profile and can be approximated by the full interface width divided by 2.35 for a Gaussian [18]. From Figs. 3f and 4, the peak concentrations yield diffusion lengths of $l_{\text{Mn}} = 0.53$ nm for Mn and $l_{\text{Mg}} = 0.68$ nm for Mg. These can be converted into diffusivities, D , from the relationship $l = (2Dt)^{0.5}$ where $t = 15$ s is the annealing time. The results are $D_{\text{Mn}} = 9.2 \times 10^{-21} \text{ m}^2 \text{ s}^{-1}$ and $D_{\text{Mg}} = 1.6 \times 10^{-20} \text{ m}^2 \text{ s}^{-1}$, i.e. Mg is diffusing faster in this system than Mn, which is in accord with previous Zeeman studies [11].

Trapped carrier electroluminescence (TraCE)—A novel method for correlating electrical and optical measurements

F.H.C. Carlsson*, L. Storasta, J.P. Bergman, E. Janzén

Department of Physics and Measurement Technology, Linköping University, SE-581 83 Linköping, Sweden

Abstract

SiC is a semiconductor with very good material properties for high power, high frequency and high temperature applications. During device fabrication irradiation with particles is often used, e.g., ion-implantation, which creates intrinsic defects. The most persistent defect in SiC is D_1 that appears after irradiation and subsequent high temperature annealing. A direct method called Trapped Carrier Electroluminescence (TraCE) for correlating minority carrier traps with luminescence measurements is presented. A semi-transparent Schottky diode under reverse bias is illuminated with a laser pulse of above band gap light to create minority carriers that are captured to traps in the space charge region. Majority carriers are introduced when the reverse bias is removed and the space charge region is reduced. The majority carriers recombine with the trapped minority carriers and the emitted light from the recombination is detected. TraCE has been used to study and correlate the D_1 bound exciton luminescence from intrinsic defects in SiC with an electrically observed hole trap HS1. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: SiC; Defects; TraCE; D_1

1. Introduction

SiC is a semiconductor with very good material properties for high power, high frequency and high temperature applications. For device fabrication ion-implantation is used to create selectively doped regions. The ion-implantation will also produce a high amount of intrinsic defects. The most important of these is the so called D_1 defect [1] which is observed as a bound exciton recombination at low temperatures. The D_1 is observed strongly in photoluminescence (PL) or electroluminescence (EL) after irradiation and subsequent high temperature annealing, it can also be seen in as-grown material. It is persistent even after annealing above 1800°C. The D_1 exciton has previously been shown to be bound to an isoelectronic center and to act as a pseudo-donor [2], i.e., a tightly bound hole with a loosely bound electron. The spectrum and energy levels for the D_1 can be seen in Fig. 1. It has also recently been shown that the

D_1 correlates with a hole trap HS1, as seen in minority carrier transient spectroscopy (MCTS) [3]. Electrical or optical methods are commonly used to characterize defects. They can provide different bits of useful information. It is, however, often difficult to draw any conclusions about a common origin for electrically and optically measured defects. Most attempts to do so are based on annealing behavior in a limited temperature range and are prone to errors. In this work we present a direct method called Trapped Carrier Electroluminescence (TraCE) for correlating electrically observed minority carrier traps with luminescence measurements.

2. Experimental

The sample used was a 4H-SiC epitaxial layer grown by hot wall CVD on a standard Cree substrate irradiated with neutrons and subsequently annealed. The n-type doping was $2 \times 10^{15} \text{ cm}^{-3}$ according to capacitance-voltage measurement. A semi-transparent Ni-Schottky contact was evaporated on top and silver

Fig. 1. PL and PLE spectra at 2 K of the D₁-BE in 4H-SiC. In the case of PLE the PL was monitored at the L₁ no-phonon line. The pseudo-donor nature of the D₁-BE is seen in the energy diagram.

Fig. 2. The experimental setup for TraCE measurements.

paste was used as back contact. The experimental setup can be seen in Fig. 2, where the sample was mounted in a nitrogen cooled Oxford cryostat to control the temperature between 130 and 160 K. The emission was detected with a photomultiplier tube in single photon counting

Fig. 3. The pulse sequence that creates the TraCE luminescence.

mode fitted to a 0.46 m spectrometer. For spectral measurements a 1200 l/mm grating with 1.0 mm slits were used and for transient measurements a 300 l/mm and 2.0 mm slits were used. The 1200 l/mm grating and 1.0 mm slits gives a resolution of 12 Å. A bias of -10 V on the Schottky contact was used and it was illuminated with a 300 ms laser pulse, controlled by a mechanical shutter, of above band gap light through the contact to create minority carriers that are captured to the traps in the space charge region. The capacitance was monitored with an oscilloscope to make sure that all the traps were filled with minority carriers. Given enough time and high enough temperature these trapped carriers will thermally be emitted to the band. In a standard MCTS measurement only the capacitance change due to the emitted carriers is observed. In the TraCE measurement a delay is introduced varying between 0.5 and 250 ms after the light pulse where the reverse bias is removed for 200 μs and majority carriers are introduced into the space charge region. The pulses and their individual changes can be seen in Fig. 3. The pulse sequence has a repetition frequency of 1.4 Hz. The majority carriers can then recombine with the remaining trapped minority carriers and create luminescence (see Fig. 4) that was detected through the edge of the sample. A gated photon counter was used to only count photons that were emitted during the emission due to trapped minority carriers. The spectral composition of the luminescence will be similar to that of PL or EL from the defect the minority carrier was trapped at. Experiments have been

Fig. 4. The band diagram and carriers in the sample: (a) With reverse bias after the light pulse, (b) when the reverse bias is removed and recombination giving an emission occurs.

carried out to make sure that the recorded luminescence was the result of trapped minority carriers recombining with the later introduced majority carriers and not by PL or EL. The varied delay will make it possible to compare TraCE intensities with the capacitance transient in MCTS measurements if the recombination process is fast compared to the thermal emission. The capacitance shows that all the trapped minority carriers are removed after the 200 μ s bias removal.

Fig. 5. The emission spectra obtained using TraCE (lower line) and PL (upper line) correspondingly, the PL spectrum is shifted upwards for clarity.

Fig. 6. The TraCE (squares) and MCTS (solid lines) transients for temperatures between 130 and 160 K.

3. Results

In PL and EL D_1 is dominating the spectrum for this sample. In MCTS a high concentration of HSI is seen. The spectrum (see Fig. 5) recorded from the TraCE measurements is identical with that for PL or EL for the same temperatures. Luminescence is only observed from

the sample when the reverse bias is removed. The intensity using the TraCE technique is however much weaker compared to PL or EL due to the low repetition frequency 1.4 Hz of the carrier injection. This gives an effective emission time close to 10^{-5} , with a corresponding intensity reduction. The transients detected by TraCE when the delay of the forward voltage pulse was varied agrees very well with the transients from MCTS for HS1 for the whole temperature range, as can be seen in Fig. 6, proving that the optical and electrical signal originates from the same defect. TraCE has been used to study and correlate the D_1 bound exciton luminescence from intrinsic defects in SiC with an electrically observed hole trap HS1. This correlation is consistent with the proposed model of the defect as a pseudo-donor [2], i.e., a hole is first tightly bound to a neutral defect and an electron is then captured by the coulomb attraction and becomes loosely bound.

4. Discussion

TraCE can correlate electrical measurements by MCTS with optical measurements such as EL and PL.

The luminescence intensities from TraCE are very low, since the luminescence time is only 10^{-5} of the total time, and great care must be taken to avoid any stray light or other sources of noise. The technique has so far only been applied to the D_1 (HS1) defect but can also be used for other minority carrier traps to correlate any luminescence emission with the corresponding electrically observed defect. The direct correlation between electrical and optical measurements avoids mistakes that can be made from other correlation attempts.

Abstract

The defects responsible for the charge leak of dynamic random access memory (DRAM) memory cells were revealed by a novel type of electrically detected magnetic resonance measurements. The detection sensitivity was greatly improved by using reverse-biased p–n junctions, which enabled us to specify the defect structure. Two types of defects were identified as the origin of the leakage currents; the spin-1 Si dangling-bond (DB) pair in divacancy-oxygen complexes ($V_2 + O$ and $V_2 + O_2$) or Si DBs of a different kind from the well-known Si DB center ($g = 2.0055$). It is notable that such defects remain in the device structure in spite of their low thermal stability in Si bulk. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

In the present and future Si ultralarge scale integrated circuits (ULSIs), process-induced point defects become increasingly crucial, due to downsizing of the device regions as well as complicated processing steps. At present, microscopic information on defects in ULSIs is quite limited. One major reason is that the amount of the defects is far below the detection limit of electron paramagnetic resonance (EPR). Alternatively, electrically detected magnetic resonance (EDMR) technique was developed (for a review see Ref. [1]) and a successful detection of residual defects in Si planar p–n junctions was demonstrated [2]. Since this technique monitors the magnetic resonance of defects via resonant changes in the device current, it is applicable to small sample volumes of ULSIs; moreover, only defects present along the current path and thus related to the device performance can be selectively detected. These advantages make it possible to approach a very few but important defects in actual ULSIs.

We present an EDMR study on the nude $n^+ - p$ junctions of the dynamic random access memory (DRAM) cells. This type of memory device is one of the most sensitive ULSIs to the influence of residual defects. For DRAMs, leakage currents in reverse-biased p–n junctions (junction leakage current, JLC) have to be suppressed in order to keep the capacitor charges as long as possible. The defects in the $n^+ - p$ junctions, however, act as an efficient source of additional JLC. We thus study the defects responsible for the JLC of DRAM cells. In order to directly correlate the defects with the JLC, the key issue is to measure EDMR under a reverse bias, which was very occasionally reported in previous literatures [3]. We carefully examined the reverse-bias characteristic of EDMR and eventually found that the detection under reverse bias is quite possible and even surprisingly sensitive to defects. Based on such EDMR experiments, we discuss the microscopic structures of point defects that cause the JLC.

2. EDMR measurements on reverse-biased p–n junctions

Fig. 1 shows the basic structure of the chip examined. This sample mimics the DRAM cells fabricated by the

Fig. 1. Sample structure. The p- and n-type regions were produced by the implantation of B and P in a p-type (100) Si wafer.

0.3- μm rule ULSI process. Each cell has an n^+ -p junction with an adjacent switching metal-oxide-semiconductor-FET gate. The leakage current of the n^+ -p junction is used for EDMR. Our EDMR setup is based on a modified X-band EPR spectrometer [2]. The measurement temperature was carefully determined as follows. At low temperatures, the device current (I) decreases due to freeze out of carriers, while a low noise level of the resonant change (ΔI) is achieved due to reduction of the current noise. To gain the highest signal-to-noise ratio and keep the normal current-voltage characteristics, the measurement temperature was set at 230 K. No illumination was done to prevent the generation of photo-excited carriers.

It has been believed that the JLC under reverse bias is unfavorable for EDMR because of the too low current level. However, we found that the reverse JLC becomes extremely sensitive to the defects when high reverse voltages are applied to the junction (Fig. 2). The rate of the resonant current change ($\Delta I/I$) steeply increases over 100 ppm above 5 V. This $\Delta I/I$ value is much higher than observed under forward biases (30 ppm, independent of the forward bias). The reason why such an enhancement occurred will be simply because the reverse JLC was dominated by the defect-induced leakage currents. In contrast, p-n junctions under forward bias or photo illumination generate only a small fraction of recombination currents related to the defects as compared to the diffusion current. Thus, EDMR under a reverse bias has potential as a powerful technique to raise the defect detection sensitivity.

The location of defects can be known by changing the gate bias. Fig. 3(a) and (a') schematically show a role of the gate bias. When the gate is negatively biased with respect to the p-type substrate, the channel region becomes p-type. Further applying a high negative bias, the p-type layer, and thus depletion layer, expands into the near-surface n-type region (a'). The defects in the newly formed depletion region can cause the JLC and EDMR. Actually, both of the JLC (I) and the resonant change (ΔI) are found to increase exponentially with the gate bias [Fig. 3(b)]. This indicates that the defects are

Fig. 2. Reverse bias dependence of the resonant change in a total current ($\Delta I/I$). The magnitude of $\Delta I/I$ is shown in the peak-to-peak intensity of a first-derivative signal. The gate voltage was set to be -3.2 V. V_{BD} represents the breakdown voltage.

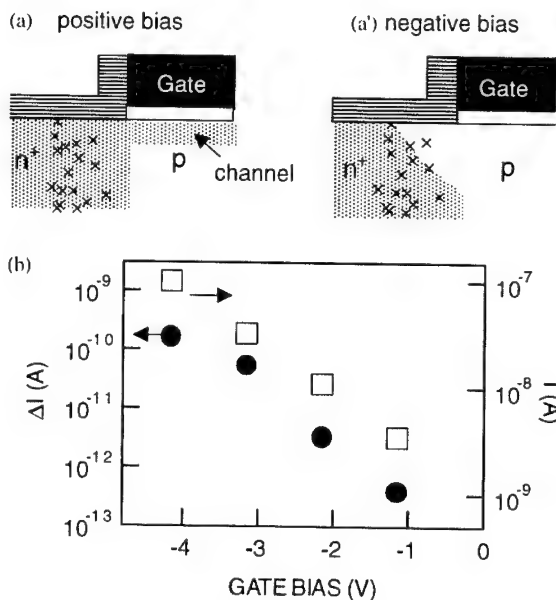

Fig. 3. (a)–(a') Schematic views of the gate-induced expansion of the depletion region. Crosses represent the defects. (b) Gate-bias dependence of ΔI (solid circles) and I (open squares), measured at a reverse bias of 7.3 V.

located in the n-type side of the junction. Also, there is a good correlation between the JLC and ΔI .

3. Identification of defects

A typical EDMR spectrum for the JLC is shown in Fig. 4(a). The spectrum consists of two parts: one main broad resonance at g (g value) = 2.0055 and weak multi lines at the both sides. The main broad signal resembles to those from the well-known Si dangling bond (DB)

observed in amorphous Si [4] and also in Si crystals damaged by implantation [5], radiation [6,7], or mechanical stress [8]. Their isotropic and single-peak features are thought to indicate that the Si DBs are randomly oriented and isolated from each other. However, the same picture of the DBs cannot be applied to the present case, because the n^+ -p junction of our sample is fully composed of crystalline Si lattice. A similar DB signal has been observed in the other type of planar Si p-n junctions which are also composed of crystalline Si lattice [2]. In Ref. [2], the DB signal was so weak that detailed spectroscopic features could not be resolved. On the other hand, very-low-noise spectra we obtained [Fig. 4(b)] reveals that the present DB signal really has anisotropy. As seen in the figure, when the external magnetic field (**B**) is aligned to the [100] direction, the peak moves toward lower magnetic field and becomes slightly sharp. This anisotropy evidences that the Si DBs are not randomly oriented in our samples. We consider that the observed anisotropy is related to the crystalline matrix of the relevant Si DBs, which will be studied in detail elsewhere.

The weak multi-lines seen in Fig. 4(a) seem to be a new EDMR signal. We tentatively call it signal A, hereafter. In contrast to the main DB signal, the signal A showed a strong **B** dependence. Fig. 5(a) shows its angular dependence with respect to a magnetic field rotation in the (0 $\bar{1}$ 1) plane. One notable character of this pattern is that the ratio between the splitting widths at **B**||[100] and **B**||[110] is just 1:2. This strongly suggests that the signal splitting originates from the fine (electron spin–electron spin) interaction which is nearly

Fig. 4. (a) EDMR spectra for the JLC of the DRAM cells, and (b) the main signal. The magnitude of the JLC was 100 nA at reverse and gate voltages of 7.3 V and -4.2 V, respectively. The spectra in (a) and (b) were measured using the magnetic field modulation of 0.9 and 0.4 mT, respectively.

Fig. 5. (a) Angular dependence of the signal A. In the gray area, this signal is not clearly resolved due to the overlapped main signal. (b) The microscopic origins of the signal A.

axial symmetric around the $[011]$ direction. Previously, similar fine interactions were reported for a series of the spin-1 vacancy-oxygen complexes in radiation damaged Si [9–12]. Such complexes retain a pair of Si DBs, which generate the fine interaction. The solid lines in Fig. 5(a) are calculated by adopting the same defect system known for the divacancy plus one oxygen ($V_2 + O$, the A14 center) [10] or that plus two oxygen atoms ($V_2 + O_2$, the P2 center) [9]. The best fit between the calculation and experimental data was obtained with averaged EPR parameters of the two centers. Therefore, we conclude that the signal A originates from a combination of the P2 and A14. The microscopic origins of this signal are given like Fig. 5(b). The oxygen incorporation possibly occurs during the dopant implantation through surface oxides and/or the thermal oxidation process.

Since our chips never received radiation damages or other intentional damages, it is reasonable to consider that the present defects are created by the dopant (phosphorous) implantation. This assignment is also supported by the fact that they are present in the n^+ -type region, which was formed by the ion implantation. After the implantation, our chips were subjected to annealing at a temperature of higher than 800°C . This is much higher than the anneal-out temperature for $V_2 + O$ and $V_2 + O_2$ ($< 400^\circ\text{C}$) observed in radiation damaged Si [9]. Also the DB signal ($g = 2.0055$) usually disappears when implantation damaged Si wafers are annealed at the relevant temperature range [5]. Therefore, our observation indicates that the thermal annihilation of the defects is suppressed in the device structures. The device regions are usually surrounded by the substrate surface and isolation structures. These may inhibit the annihilation of the defects.

For the Si DB pairs in $V_2 + O$ and $V_2 + O_2$, it is reasonable to treat their DBs individually, because of the large separation between the DBs [9]. Also the DB center of $g = 2.0055$ can be regarded as a single-DB system [2–4]. Thus, we discuss the EDMR mechanism using a simple system, which consists of one carrier and one unpaired electron (an electrically neutral Si DB) in reverse-biased junctions. This system allows only one primary spin-dependent process in which the DB captures a valence-band electron in p-type Si. On the other hand, the carrier generation via the DB (electron emission to the conduction band of n-type Si) is not a spin-dependent process [13]. Therefore, the appearance of the EDMR signals is supposedly a consequence of the electron tunneling from p-type Si to the DB's levels. Such a tunneling probability naturally increases with the reverse voltage. Besides, the relatively high reverse voltage is necessary to extend the depletion region into

the n^+ -region where the DBs are present. We speculate that the drastic signal increase at high reverse voltages is attributed to these factors.

The actual reverse bias for keeping the capacitor charges is typically 1 or 2 V, which is lower than used for EDMR measurements. At such low voltages, the electron tunneling discussed above is largely suppressed. However, the carrier generation via the DB's levels can effectively contribute to the JLC. Therefore, in order to suppress the defect-induced JLC, it is necessary to remove the DBs from the n^+ -region. This will be achieved by optimizing the ion-implantation process and the subsequent annealing.

4. Summary

We have found implantation-induced point defects in the n^+ -p junctions of DRAM cells by means of a novel EDMR technique. The EDMR results clearly showed that such defects are responsible for the JLC in the reverse-biased junctions. The defect structures were assigned to be Si DBs or the spin-1 Si DB pairs of the divacancy-oxygen complexes ($V_2 + O$ and $V_2 + O_2$). We pointed out that the thermal annihilation of the defects is suppressed in the device structure than in the bulk, which indicates a significance of probing actual device regions.

Process-induced defects in nitrogen doped Czochralski silicon in diode processes

J. Lu, D. Yang*, J. Yang, D. Tian, Y. Shen, X. Ma, L. Li, D. Que

State Key Laboratory of Silicon Materials, Zhejiang University, Hangzhou 310027, People's Republic of China

Abstract

The process-induced defects in nitrogen doped CZ silicon (NCZ-Si) are investigated during diode processes. It was found that in the phosphorous predeposition (1230°C for 2 h), stacking faults and dislocations were formed in NCZ-Si, but in the common CZ silicon (ACZ-Si) only dislocations were observed. In boron diffusion process (1260°C for 30 h), the interstitial oxygen (O_i) concentration in NCZ-Si specimens fell to the corresponding solubility and all supersaturated O_i was precipitated. On the contrary, only slight oxygen precipitates were generated in ACZ-Si wafers. Correlated to oxygen precipitates, more dislocations were produced in the high resistance active region in NCZ-Si specimens in comparison with ACZ-Si. It is concluded that nitrogen enhances oxygen precipitation during diode processes. In phosphorous predeposition process, these oxygen precipitates in NCZ-Si resulted in not only dislocations, but also stacking faults. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

In recent years, nitrogen behavior in single crystal silicon has been intensively studied. In general, nitrogen is used as a protective gas or a carrier gas in manufacture processes of very large scale integration (VLSI) circuits. It is well known that nitrogen in silicon can suppress microdefects [1,2], and lock dislocations to increase wafer mechanical strength [3–5]. It is also reported that nitrogen in silicon can enhance oxygen precipitation [6–8]. Elevated temperature treatment and high concentration doping are two features of the power diode process. In the early studies of oxygen precipitation in NCZ silicon [6–8], the annealing temperatures were all no higher than 1150°C; whereas in the power diode process, the processing temperature is over 1250°C. Usually at those elevated temperatures, grown-in oxygen precipitate nuclei are dissolved and the nucleation rate for new oxygen precipitates is very

slow. Therefore, it is expected that little interstitial oxygen can be precipitated during the diode processes. Furthermore, high concentration phosphorous diffusion during power diode processes generates supersaturated self-interstitial silicon that will impede oxygen precipitation [9–10]. However, up to now, there are few reports about the influence of nitrogen on oxygen precipitation during diode process.

Related to oxygen precipitates, extended defects can be generated in silicon. The difference between the volume of oxygen precipitates and silicon lattices causes strain field near the precipitates, which can then act as heterogeneous nuclei for stacking faults while supersaturated silicon interstitials exist [11]. Meanwhile, oxygen precipitates can also punch out dislocation loops to release the strain energy. This process usually takes place during annealing at medium temperatures or during cooling down processes following high temperature treatment [12]. It was also reported that nitrogen can increase the mechanical strength of silicon wafers by locking dislocations [3–5,13]. Thus, it is interesting to investigate whether and how nitrogen affects process-induced defects during the power diode processes.

E-mail address: mseyang@dia1.zju.edu.cn (D. Yang).

In this paper, the influence of nitrogen on oxygen precipitation and the related defects during power diode processes has been investigated by means of FTIR measurement and optical microscopy technique. It was found that nitrogen enhanced oxygen precipitates, induced stacking faults in the active region in diodes and generated more dislocations during cooling process. Finally, the effect of nitrogen on dislocations caused by thermal stresses is also demonstrated.

2. Experiment

In nitrogen and argon atmosphere respectively, n-type $\langle 111 \rangle$ oriented NCZ and ACZ silicon ingots with the same phosphorous doping level were grown. The specimens marked N0, N1, N2 and N3 were cut from the different positions of the NCZ silicon ingot from seed end to tail end. The specimens marked A0, A1, A2 and A3 were cut from the ACZ silicon at the same positions as those of the NCZ specimens. The wafers with the resistivity of 20–40 Ωcm were about 300 μm in thickness. At first the specimens were annealed at 650°C for 30 min to annihilate thermal donors. And then the wafers were used to fabricate diodes.

The main diode fabrication processes were as follows: phosphorous pre-deposition at 1230°C for 2 h, boron main-diffusion at 1260°C for 30 h and nickel metallization at 650°C for 60 min. After phosphorous pre-deposition and boron diffusion process, the wafers were respectively cleaved off and etched in Sirtl etchant to delineate dislocations and stacking faults by optical microscopy.

The wafers with the thickness of 2 mm were cut from the same positions as those used in diodes fabrication. Those wafers were used to follow diode processes and to monitor the interstitial oxygen concentration in the diode processes. The interstitial oxygen concentration and oxygen precipitates were characterized by FTIR at room temperature according to the absorption lines at 1107 and 1224 cm^{-1} , respectively. The calibration factor of $3.14 \times 10^{17} \text{ cm}^{-2}$ was used for calculating interstitial oxygen concentration.

3. Results and discussion

3.1. Oxygen precipitates and dislocations in NCZ silicon

Fig. 1 shows the interstitial oxygen concentration in ACZ and NCZ silicon before and after diode processing. It demonstrates that in NCZ silicon, the interstitial oxygen concentration fell to the corresponding solubility concentration in the diode process, and all supersaturated interstitial oxygen was precipitated. For the ACZ silicon, only in the A0 specimen with high

Fig. 1. Interstitial oxygen concentration in silicon wafers before and after diode processes.

oxygen concentration, the interstitial oxygen precipitated slightly. In the A1, A2 and A3 specimens, the interstitial oxygen concentrations have not changed in the diode processes.

In the experiments of Sun [6] and Aihara [7], typical high-low-high annealing as intrinsic gettering sequence and ramp-up annealing were used. They pointed out the enhanced nucleation effect of nitrogen on oxygen precipitation. In the experiment of Yang [8], where one and two step annealing methods were used to investigate the effect of nitrogen on oxygen precipitation, it was found that nitrogen in silicon can enhance oxygen precipitation at lower temperature ($< 750^\circ\text{C}$). In their experiments, the heat treatment temperature was not higher than 1150°C. In our experiments, the phosphorous pre-deposition and boron diffusion were carried out at 1230°C and 1260°C, respectively. It is found that, even in the elevated temperature treatments of diode processes in NCZ silicon, some oxygen precipitates were generated (Fig. 1).

The starting temperature and ramping up rate of the first step annealing during high temperature processes, which determine how many grown-in oxide nuclei can survive and continue to grow in subsequent high temperature treatments, are essential for oxygen precipitation. To avoid oxygen precipitate nuclei to be dissolved in ramping up processes, the ramping up rate must be low enough to guarantee that grown-in oxygen precipitate nuclei grow up and their radius are larger than the critical radius at high temperatures. The ramping up rate is usually chosen at 1–1.5°C/min [7,14]. In the phosphorous pre-deposition process of our experiments, the starting temperature (600°C) was lower and the ramping up rate (2°C/min) was a little higher. Therefore, in ACZ-Si the higher ramping up rate made no precipitated nuclei survive, and the nucleation rate at high temperatures was very slow, so that little oxygen precipitates could be generated in diode processes. During the phosphorous pre-deposition process

supersaturated self-interstitial silicon were produced [9], which also resulted in the dissolution of the grown-in nuclei and oxygen atoms were not easy to precipitate. As for the A0 specimen which was cut from the seed end and had higher oxygen concentration, it has undergone longer heat treatments during crystal growth, and more grown-in oxygen precipitates were formed. In the ramping up process of the diodes a few of grown-in nuclei would not be dissolved so that the smaller amount of interstitial oxygen atoms could precipitate in subsequent high-temperature treatments.

For all of the specimens from NCZ-Si, interstitial oxygen concentration decreased and oxygen precipitates were produced. There are three possible reasons. The first is that due to the enhancement of nitrogen a larger number of oxygen precipitates as nuclei during crystal growth were produced. In the diode processes some grown-in oxygen precipitates survived and oxygen precipitates could be formed. This reason is almost the same as that for the A0 specimen. The second is that although grown-in oxygen precipitates were dissolved in the diode processes, nitrogen as heterogeneous site could enhance oxygen precipitation even at higher temperatures, so that oxygen precipitates were generated. The third is that due to the effect of nitrogen, the grown-in oxygen precipitates nuclei with higher density were more stable and did not dissolve in the diode processes.

3.2. Stacking faults generated in NCZ silicon

After phosphorous pre-deposition process, the wafers were cleaved and were etched in Sirtl etchant for 5 min. The photos are shown in Fig. 2. It can be found that in NCZ specimens not only dislocations, but also stacking faults were generated, while in ACZ-Si wafers, no stacking faults were generated.

On the one hand, oxygen precipitates can induce formation of dislocations or stacking faults which is dependent of the annealing temperature and the structure of oxygen precipitates. If nitrogen was doped into crystal, the structure of oxygen precipitates could be changed [9], and both of stacking faults and dislocations might be generated. On the other hand, it is known that supersaturated self-interstitials are generated during phosphorous diffusion [10]. Normally, stacking fault embryos will be formed at strain centers in the bulk and at the surface [11]. Oxygen precipitates can also act as these strain centers. In the NCZ specimens, more oxygen precipitate nuclei survived as the nucleation centers of stacking faults after the phosphorous pre-deposition.

After boron diffusion process, the wafers were cleaved and were etched in Sirtl etchant for 5 min. The photos are shown in Fig. 3. It can be seen that in NCZ specimens the stacking faults disappeared. Considering the elevated temperature (1260°C) and the prolonged treatment time (30 h), the supersaturation of self-

Fig. 2. Optical microscopic photos of ACZ and NCZ specimens cleaved and etched in Sirtl etchant for 5 min, after phosphorous pre-deposition process.

interstitials cannot be sustained in this process because of surface recombination, so the stacking faults will shrink and disappear.

3.3. Dislocations in NCZ silicon

From the photos shown in Fig. 3, it has been found that higher density dislocations were formed in the high resistance active region in the NCZ-Si specimens in comparison with the ACZ specimens, especially in the specimens with high initial oxygen concentration. Furthermore, the more oxygen precipitated, the more dislocations were generated. It can be deduced that those defects were oxygen precipitates related dislocation loops, but not misfit dislocations induced by high concentration diffusion [15]. In prolonged diffusion process, ripening process took place and larger precipitates grew up at the expense of smaller ones' dissolution. As a result, the residual oxygen precipitates

Fig. 3. Optical microscopic photos of ACZ and NCZ specimens cleaved and etched in Sirtl etchant for 5 min. after boron diffusion process.

with lower density grew up to large dimensions and could punch out dislocation loops to release the strain energy. This process usually takes place during cooling down process following high temperature treatment because of the big expansion coefficient difference between oxygen precipitates and silicon bulk [12].

4. Conclusion

In this paper, the behavior of oxygen precipitation and related defects in NCZ and ACZ silicon was investigated. It was found during the diode processes: (1) nitrogen in silicon can enhance oxygen precipitation; (2) in phosphorous pre-deposition process, not only dislocations, but also stacking faults were generated in NCZ specimens, while in ACZ-Si wafers only dislocations were generated. The stacking faults in NCZ silicon

disappeared in the subsequent boron diffusion process; (3) associated with oxygen precipitates, more dislocations were formed in NCZ silicon, especially in high oxygen concentration specimens.

n-Channel conductance spectroscopy of deep defects in low temperature grown GaAs

C. Steen*, P. Kiesel, S. Tautz, S. Krämer, S. Soubatch,
S. Malzer, G.H. Döhler

Institute for Technical Physics I, University of Erlangen, Erwin-Rommel Str. 1, 91058 Erlangen, Germany

Abstract

We report on a new technique to characterize the deep defects in low temperature grown GaAs (LT-GaAs), based on a thin LT-GaAs layer embedded in the intrinsic zone of a pin diode. At this structure we have performed steady state and time dependent measurements of the n-channel conductance. Thus we deduce information about the activation energy and the capture time constant of the deep defects. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: LT-GaAs; Electron emission rate; As_{Ga} -antisite defect

1. Introduction

GaAs, grown by molecular beam epitaxy (MBE) at low substrate temperatures (190–300°C) has unique electrical and optical properties which drastically differ from those of standard GaAs. Low temperature GaAs (LT-GaAs) has a very short lifetime of photogenerated carriers and close-to-intrinsic conductivity (after annealing) [1–3]. These properties are caused by a high excess of arsenic atoms, which are incorporated into the regular crystalline GaAs lattice as Ga sites (As_{Ga} -antisite defect). This leads to a point defect concentration of the order of 10^{20} cm^{-3} in as-grown material. The As_{Ga} -antisite defects are partially compensated by relatively shallow acceptors [4]. The concentration of As_{Ga} -antisite defects is reduced by thermal annealing at temperatures $> 400^\circ\text{C}$. The annealing process is associated with the formation of As-precipitates [5]. The attractive properties of the material persist in the annealed material. Currently it is not clear, how far the As_{Ga} -antisite defects or the clusters are responsible for the unusual properties of LT-GaAs.

Most investigations of LT-GaAs have been performed on “bulk” material (i.e. layers of about $1 \mu\text{m}$ thickness).

In LT-GaAs samples annealed at temperatures less than 600°C the penetration depth of space charge fields at the contacts is of the order of less than 10 nm, due to the high defect density. So standard methods like capacitance vs. voltage (CV) measurements or deep level transient spectroscopy (DLTS) are not suitable to study the deep defects in this material.

To overcome this drawback we have fabricated pin diodes with a thin layer of LT-GaAs (8 nm e.g.) in the i-layer [6]. In this case the sheet density of deep centers $n_{\text{T}}^{(2)} = N_{\text{T}} d^{\text{LT}}$ becomes so small that possibly all of them can be depleted under reverse bias. Here N_{T} is the concentration of deep defects and d^{LT} the thickness of the LT-GaAs layer. We have performed steady state and transient n-channel conductance measurements at different temperatures. From these investigations we can deduce the charge density $\rho_{\text{LT}}^{(2)}$, the activation energy ΔE and the electron capture cross section of the deep defects in the LT-GaAs layer.

2. Sample design

Here we report on two different pin diodes. A schematic band diagram of the double-hetero p–i–n diode, sample A is shown in Fig. 1. In sample B the $\text{i-Al}_{0.15}\text{Ga}_{0.85}\text{As}$ layer is replaced by an i-GaAs layer and

E-mail address: steen@physik.uni-erlangen.de (C. Steen).

Fig. 1. Schematic band diagram of sample A for different voltages $V=0$, $V < V_C$ and $V > V_C$. For voltages $V \neq 0$ only the conduction band is depicted.

vice versa. The thickness of the $\text{Al}_{0.15}\text{Ga}_{0.85}\text{As}$ is 200 nm whereas the GaAs layer is 400 nm thick. During sample growth the LT-GaAs layer has been annealed in situ at 540°C. Thus, it exhibits both, a high density of As_{Ga} -antisite defects as well as small arsenic precipitates with an average diameter of 3–4 nm and a density of $1.5 \times 10^{17} \text{ cm}^{-3}$. In order to enable a precise evaluation of the effects related to the LT-layer reference samples were grown with the same layer structure except for a GaAs layer grown at 540°C instead of the LT-layer.

In this contribution we present measurements of the n-channel conductance G_{nn} . According to Poisson's equation the sheet carrier density $n^{(2)}$ and, hence, also the conductance of the n-layer, G_{nn} , is linearly related to the electric field F_l on the left side of the LT-GaAs layer. This n-layer is moderately doped (10^{17} cm^{-3}) and sufficiently thin so that it is possible to detect minor changes of F_l . According to Poisson's equation also the difference between F_l and the field F_r on the right side of the LT-GaAs layer depends on the sheet charge density $\rho_{\text{LT}}^{(2)}$ stored in the LT-GaAs layer. Thus from the observed changes of G_{nn} as a function of reverse bias $\rho_{\text{LT}}^{(2)}$ can be deduced [6].

We have investigated both the steady state n-channel conductance as a function of reverse bias and as a function of time under a sudden bias change. Comparing the steady state n-channel conductance curves of the LT-samples and the reference samples we can determine the maximum sheet charge density in the LT-GaAs layer, $\rho_{\text{LT,max}}^{(2)}$. Measurements of the n-channel conductance as a function of time under a sudden change of bias, taken at different temperatures, provide information about the activation energy of the deep defects and their electron capture cross section.

3. Measurement of the steady state n-channel conductance

In Fig. 2 results of steady state measurements on the LT-GaAs and the reference samples are shown. In the reference diodes the n-channel conductance G_{nn} decreases with increasing reverse bias as expected due to the linear decrease of the width of the n-conducting channel. In LT-sample A, however, G_{nn} is almost constant up to a characteristic voltage V_C of about -9 V. For higher reverse bias the n-channel conductance decreases in the same way as in the reference diode.

In sample B the n-channel conductance is almost constant only up to a much lower voltage V_C of about -2 V. Up to around -10 V the slope of the curve is smaller than in the reference diode. For higher voltages the slope of the curve is the same as in the reference sample.

We interpret this behavior in the following way. The Fermi level of the traps Φ_T is pinned to the quasi Fermi level Φ_n of the top n-layer if we apply a reverse bias U_{pn} smaller than the voltage V_C . So the electric field F_l on the left side of the LT-GaAs layer remains almost constant for these voltages, whereas the electric field on the right side is increasing. The activation energy for electrons in sample B is larger than in sample A due to the Al content on the left side of the LT-GaAs layer. Correspondingly, the activation energy for holes in sample B is smaller than in sample A. Thus, in sample B less defects have to be charged than in sample A, until the hole emission rate becomes comparable to the electron emission rate. So if the hole emission rate becomes comparable to the electron emission rate the Fermi level Φ_T is no longer pinned to Φ_n and F_l increases in the same way as in the reference sample. The sheet charge density caused by singly charged deep donors and acceptors $\rho_{\text{LT}}^{(2)} = (n_D^- - n_A^+)d^{\text{LT}}$ or charged As-precipitates can be determined from the increasing electric field kink, as mentioned above, using Poisson's equation $\Delta F = F_l - F_r = \rho_{\text{LT}}^{(2)} / \epsilon_0 \epsilon_{\text{GaAs}}$.

Fig. 2. The n-channel conductance versus applied reverse bias voltage for the reference and the sample A on the left side. The right graph shows the curves for the sample B.

Fig. 3. The charge density in the LT-layer from sample A and B as calculated from the conductance measurements.

By comparison of curves obtained from the LT-GaAs samples and reference samples one can directly deduce the sheet charge density, depicted in Fig. 3. First we discuss the charge carrier density of sample A. The charge carrier density increases from $\rho_{\text{LT}}^{(2)} = -0.5 \times 10^{11} \text{ cm}^{-2}$ at zero bias to a value of $\rho_{\text{LT}}^{(2)} = 0.9 \times 10^{12} \text{ cm}^{-2}$ at a reverse bias of $V_C = -9 \text{ V}$. This charge carrier density screens the field F_1 on the left side of the LT-GaAs layer and so the n-layer conductance does not change up to V_C . For higher voltages the sheet charge carrier density remains practically constant. This corresponds to a density $\rho^{(3)} = \rho_{\text{LT}}^{(2)} / d^{\text{LT}} = 1.15 \times 10^{18} \text{ cm}^{-3}$. At reverse bias exceeding -9 V the field F_1 increases at about the same rate as for the reference sample (see also Fig. 2), indicating that there are no more electrons in deep traps.

The charge carrier density of sample B increases from $\rho_{\text{LT}}^{(2)} = -0.7 \times 10^{11} \text{ cm}^{-2}$ at zero bias (estimated from the equilibrium band picture for $U_{\text{pn}} = 0$) to a value of $\rho_{\text{LT}}^{(2)} = 0.15 \times 10^{12} \text{ cm}^{-2}$ at a reverse bias of $V_C = -2 \text{ V}$. From -2 up to -10 V the charge carrier density increases again to a value of $\rho^{(2)} = 0.3 \times 10^{12} \text{ cm}^{-2}$. For higher voltages the sheet charge carrier density does not change.

4. Measurement of the n-channel conductance under sudden bias change

In thermal equilibrium the electron emission rate of the deep traps, $N_{\text{T,em}}^0$ is equal to the electron capture rate, $N_{\text{T,capt}}^0$. Assuming a sharp trap level we have

$$N_{\text{T,em}}^0(t) = w_{\text{C} \rightarrow \text{T}} \exp\left(\frac{\Delta E}{k_B T}\right) N_{\text{T}}^0(t) N_{\text{C}}(T). \quad (1)$$

Here ΔE is the activation energy for electron emission and N_{T}^0 the number of neutral defects. The microscopic capturing probability $w_{\text{C} \rightarrow \text{T}}$ is related to the electron capture cross section Σ_{C} by $w_{\text{C} \rightarrow \text{T}} N_{\text{C}}(T) = v(T) \Sigma_{\text{C}} N_{\text{C}}(T)$, where $v(T)$ is the thermal velocity of the electrons and $N_{\text{C}}(T)$ the effective conduction band

density of states. The electron capture rate is given by

$$N_{\text{T,cap}}^0(t) = v(T) \Sigma_{\text{C}} N_{\text{C}}(T) \exp\left(\frac{E_{\text{C}}(x_{\text{LT}}) - \Phi_{\text{n}}}{k_B T}\right) N_{\text{T}}^+(t), \quad (2)$$

where N_{T}^+ stands for the concentration of ionized traps, $E_{\text{C}}(x_{\text{LT}})$ for the energy of the conduction band at the position of the LT-GaAs layer x_{LT} , and Φ_{n} for the quasi Fermi level in the n-layer.

In the following we confine ourselves to sample A. In Fig. 4 the n-channel conductance as a function of time is depicted. During the first 10 ms zero bias is applied to fill the defect states with electrons. This time is sufficiently long to reach the equilibrium value $\rho^{(2)} = -0.5 \times 10^{11} \text{ cm}^{-2}$ and the n-channel conductance reaches its equilibrium value as well. After that a reverse voltage U_{pn} is switched on with a time constant less than 1 ms, which is much shorter than the time constant for electron escape processes. The charge $\rho_{\text{LT}}^{(2)}(t)$ and therefore also the kink in the electric field at the LT-GaAs layer cannot change instantly. Therefore, we observe a discontinuous decrease of G_{nn} . Now $\rho_{\text{LT}}^{(2)}$ increases, according to Eq. (1), whereas the contributions due to Eq. (2) are negligible for short times. Shortly before G_{nn} reaches the steady state value corresponding to the applied reverse voltage U_{pn} the conductance change is slowed down rather abruptly, because $E_{\text{C}}(x_{\text{LT}}) - \Phi_{\text{n}}$ approaches the equilibrium value and the electron capture rate becomes relevant again. This will occur soon at a low reverse bias and later at higher U_{pn} as shown in Fig. 4a.

Note that the time constant of the exponential behavior is the same for all curves. Also, the transients occur only in the LT-GaAs sample. In the reference sample no changes are observable so we can be sure that the transients are associated with the LT-GaAs material.

To determine the activation energy we have measured the transients for a bias change of -8 V at different temperatures. Fig. 4b shows some typical transients for a reverse bias of $U_{\text{pn}} = -8 \text{ V}$ at different temperatures

Fig. 4. The n-channel conductance under an abrupt bias change versus time for different reverse bias at room temperature (a) and for different temperatures (b).

Fig. 5. The Arrhenius plot for the time constants.

with the corresponding exponential fits. The analysis of the exponential part provides the characteristic time constants. In Fig. 5 the Arrhenius plot of the time constants is depicted. Under the assumption of a T^2 dependence of the prefactor we deduce an activation energy $E_T = (710 \pm 60)$ meV and an electron capture time constant $\tau_{\text{cap}} \approx 1/N_T W_C - T \approx 2 \times 10^{-13 \pm 1}$ s.

This activation energy close to midgap, and the time constants favor the interpretation that we observe the effects of As_{Ga} -antisite defects and not of the As-precipitates. Also the density of clusters ($1.5 \times 10^{17} \text{ cm}^{-3}$) is hardly compatible with the large value of space charge in the LT-GaAs layer ($1.15 \times 10^{18} \text{ cm}^{-3}$).

5. Conclusions

The investigation of the n-channel conductance of a pin diode with an embedded LT-GaAs layer is a versatile technique to characterize the deep defects in LT-GaAs. We have deduced a concentration of deep traps $N_T = 1.15 \times 10^{18} \text{ cm}^{-3}$, with an activation energy $E_T = (710 \pm 60)$ meV. In particular we point out that the electron capturing time constant of $\tau_{\text{cap}} = 2 \times 10^{13 \pm 1}$ s agrees well with the value obtained from optical fs-pulse experiments. Further studies will be devoted to samples with modified design. The results obtained from sample B, e.g., indicate that also hole emission can be studied in samples with suitable design.

Abstract

Defects in p-InGaP produced by low-energy protons have been investigated by deep-level transient spectroscopy (DLTS). A new majority-carrier (hole) trap HP1 has been observed in low-energy proton-irradiated p-InGaP at 0.90 ± 0.05 eV above the valance band for the first time. The HP1 introduction rate for 100-keV proton-irradiated p-InGaP is 1500 cm^{-1} , which is 6 times higher than that (260 cm^{-1}) for the 380-keV proton-irradiated one. Isochronal annealing is found to annihilate the proton-induced HP1 defect above 300°C that is higher than the annealing stage (100°C) for 1-MeV electron-induced H2 center in p-InGaP. The carrier removal rates are found to be 61433 and 8640 cm^{-1} for 100 and 380-keV proton irradiation, respectively. Proton energy-dependent effects include decrease in both the carrier removal rate and in the defect introduction rate with increase in proton energy by creating HP1 trap.

1. Introduction

Studies of radiation effect in $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ materials have become vital as a high-efficiency solar cell for space application [1–3]. Recently, 1-MeV electrons and 3-MeV protons irradiation effects in InGaP have been reported by the authors and others in Refs. [4–6]. Radiation-induced defects and the carrier removal effects are the important investigations to evaluate the performance of solar cells for their use in space, however, no reports were available on the aspects of the carrier removal effect and the nature of defects in p-InGaP by low-energy proton irradiation. Proton-induced displacement damage generally increases with decreasing particle energy [7]. Therefore, the contribution of low energy (<1 MeV) protons to the total degradation of solar cells

in a space environment containing protons with energies ranging from a fraction of keV to hundreds of MeV could be quite significant. In this paper, we present the investigation on the low-energy proton-induced deep level defects in n^+/p InGaP solar cells.

2. Experimental procedure

$\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ layers were grown on Zn-doped GaAs substrates with orientation of 5° off (1 0 0) towards [0 1 1] direction by the metallorganic chemical vapor deposition (MOCVD) method. For deep-level transient spectroscopy (DLTS) measurement, n^+/p junction with junction depth of $0.05 \mu\text{m}$ and area of $9 \mu\text{m}^2$ diodes were fabricated with base carrier concentration of $6.6 \times 10^{16} \text{ cm}^{-3}$. Samples were irradiated with 100 and 380 keV protons for the fluences of 1×10^{10} – $5 \times 10^{12} \text{ cm}^{-2}$ at room temperature using a 400 kV ion

E-mail address: dharmar@toyota-ti.ac.jp (N. Dharmarasu).

implanter. These diodes were characterized with DLTS and capacitance–voltage (C – V) measurements to find out the generations of defect levels and changes in the carrier concentration, respectively. Isochronal annealing has been carried out on the irradiated diodes for 30 min under inert atmosphere. The projected range calculated by stopping and range of ions in matter (SRIM [8]) for 100 and 380 keV protons into InGaP are 0.6 and 3.0 μm , respectively.

3. Results and discussion

3.1. Deep-level defect

DLTS spectra of the pre-irradiated and proton-irradiated p-InGaP layer are shown in Fig. 1. It was recorded with reverse bias 2 V and filling pulse width 1 ms and diodes scanned for the temperature range from 70 to 500 K. In the pre-irradiated p-InGaP, only two minority-carrier (electron) peaks E1 and E2 were observed below room temperature. Arrhenius plots used for the calculation of emission energy of the observed traps are shown in Fig. 2. Also, the native minority-carrier traps E1 and E2 appeared at $E_c = 0.20$ and 0.36 eV below the conduction band, with concentrations of 2.3×10^{15} and $5 \times 10^{14} \text{ cm}^{-3}$, respectively, and

Fig. 1. DLTS spectra of pre-irradiated and 100-keV proton ($5 \times 10^{11} \text{ cm}^{-2}$)-irradiated p-InGaP layer.

Fig. 2. Arrhenius plots used to calculate the activation energies for emission processes from traps E1 and HP1. E2 did not change with emission rate.

there were no majority-carrier peaks. The trap E1 that appeared during both majority and minority-carrier scans is attributed to the DX center [4]. The peak E2 could not be accurately evaluated, as it did not change with emission rate but its energy was in the range of 0.36 eV. A detailed characteristic of the native traps E1 and E2 are discussed by the authors in Ref. [4].

On the low-energy proton-irradiated p-InGaP, a new majority-carrier (hole) trap labeled HP1 has been observed in p-InGaP at $0.90 \pm 0.05 \text{ eV}$ above the valance band for the first time. The HP1 majority-carrier trap appears at $E_v + 0.90 \text{ eV}$ for both 100 and 380 keV proton-irradiated p-InGaP, which means that the same kind of defect is produced for two different energies of proton irradiation. Majority-carrier traps in 1-MeV electron and 3-MeV proton-irradiated p-InGaP have been reported by the authors in Ref. [4] and others in Refs. [5,6]. In all these reports, the traps appear at relatively lower temperature compared to the present low-energy proton-induced hole trap. All this betokens that the defects induced by low-energy protons are of a different kind than that of the high-energy proton and electron-induced defects in p-InGaP.

Fig. 3 shows the HP1 trap concentration as a function of proton fluence and thermal annealing temperature. HP1 trap concentration increases with increasing proton fluences. The amplitude of HP1 peak provides the concentration N_T and thus the introduction rate $I_i =$

Fig. 3. HP1 trap concentration observed by DLTS as a function of proton fluence and thermal annealing temperature.

N_T/ϕ , where ϕ is the proton fluence. The calculated HP1 defect introduction rate for 100 keV proton-irradiated p-InGaP is 1500 cm^{-1} , which is 6 times higher than that (260 cm^{-1}) for the 380 keV proton-irradiated sample. However, the introduction rate decreases with increasing proton fluences.

To identify the origin of HP1 defect, thermal annealing experiments were carried out on the irradiated diodes. Upon isochronal annealing, it is found that the proton-induced defect HP1 is annihilated and the minority-carrier trap E1 increases with increasing annealing temperature (Fig. 4). The concentration of HP1 begins to decrease for the annealing temperature above 300°C for 30 min (Fig. 3), whose annealing stage is higher than that (100°C) of the 1-MeV electron-induced H2 center in p-InGaP [4]. The high temperature annealing indicates that the HP1 defect may be due to phosphorus-related vacancy complexes. Other possible defects such as In- or Ga-related vacancies are expected to anneal out at room temperature because of their lower migration energy. It has been reported that phosphorus vacancy (V_P) related interface trap is distributed in the energy range of 0.5–0.9 eV below the conduction band in InGaP and the V_P -related defects are expected to offer both acceptor and donor levels [9]. Therefore, HP1 defect is most likely to arise from the phosphorus vacancy-related complex, as the energy matches with trap levels reported in Ref. [9]. However,

Fig. 4. Isochronal annealed DLTS spectra of the 100 keV proton-irradiated p-InGaP layer for the fluence of $5 \times 10^{12} \text{ cm}^{-2}$.

further work is underway to elucidate the properties and the exact origin of the HP1 defect.

3.2. Carrier removal rate

To find out the HP1 defect influence on the carrier concentration of the proton-irradiated p-InGaP, capacitance–voltage (C – V) measurements were carried out. The change in carrier concentration measured by C – V at room temperature, as a function of proton fluence is shown in Fig. 5. It is seen that there is a remarkable decrease in carrier concentration of p-InGaP base layer as a function of proton fluences for 100 and 380-keV protons. The carrier removal rate R_C is determined by fitting the curve to Eq. (1):

$$p_\phi = p_0 \exp\left(\frac{-R_C \phi}{p_0}\right), \quad (1)$$

where p_0 is the initial carrier concentration, p_ϕ is the carrier concentration as a function of proton fluences, ϕ is the proton fluence and R_C is the carrier removal rate. The carrier removal rates for 100 and 380-keV protons were 61433 and 8640 cm^{-1} , respectively. These are very high rates compared to the carrier removal rate of 0.93 cm^{-1} for 1-MeV electron-irradiated p-InGaP [4]. Carrier removal rate also depends on proton energy and it is observed to increase with decreasing proton energy. The carrier removal rate is 7 times higher for 100-keV

Fig. 5. Analytical and experimental changes in carrier concentrations of 100 and 380-keV proton-irradiated p-InGaP layer, as a function of proton fluence.

protons compared to 380-keV protons, while the HP1 defect introduction rate for 100-keV protons is 6 times higher than that for 380-keV protons. However, it is difficult to explain larger carrier removal rates (61433 and 8640 cm^{-1}) for 100 and 380-keV protons by creating only HP1 defect with lower defect-introduction rates (1500 and 260 cm^{-1}) for 100 and 380-keV protons. Further study is necessary to delineate other centers in p-InGaP. As a result of the decrease in the carrier concentration by creating deep-level defects such as HP1 defect in the p-InGaP layer with proton irradiation, a significant increase in the series resistance of the InGaP cell is induced. Therefore, an increase in the series resistance of the InGaP cell is thought to be one of the causes for the decreases in solar cell properties.

4. Conclusions

In conclusion, deep-level defects in proton-irradiated p-InGaP have been characterized by DLTS. For the first

time, low-energy proton-induced new majority-carrier (hole) trap HP1 in p-InGaP has been observed at $0.90 \pm 0.05\text{ eV}$ above the valance band. The introduction rates and possible origin of HP1 defect have been reported. Isochronal annealing has been found to annihilate the proton-induced HP1 defect above 300°C that is higher compared to the annealing stage for 1-MeV electron-induced H2 center in p-InGaP. Carrier removal rates have also been found to be 61433 and 8640 cm^{-1} for 100 and 380-keV proton-irradiated p-InGaP, respectively. Proton energy-dependent effects include decrease in both the carrier removal rate and the defect introduction rate with increase in proton energy by creating HP1 trap.

Abstract

Results of a study are presented on the degradation of InGaAsP laser diodes by high-temperature γ -ray and electron irradiation. It is shown that the optical power decreases after irradiation. One hole trap is observed in the $\text{In}_{0.76}\text{Ga}_{0.24}\text{As}_{0.55}\text{P}_{0.45}$ multi-quantum well active region after room-temperature γ - or e^- -irradiation. The deep levels are thought to be associated with the Ga-vacancy. The decrease of the optical power is ascribed to the carrier removal and to the mobility reduction by carrier scattering, through the induced lattice defects. The change of device performance and the introduction rate of lattice defects decrease with increasing irradiation temperature. The optical power after a 200°C irradiation is nearly identical as before, for the fluence range studied. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: InGaAsP laser diode; Radiation damage; Induced deep levels

The $\text{In}_{1-x}\text{Ga}_x\text{As}_y\text{P}_{1-y}/\text{InP}$ semiconductor system has attained much interest for optoelectronic devices in the 0.95–1.65 μm wavelength region. Such detectors are good candidates for use in the telecommunication system of a spacecraft. Therefore, it is worthwhile to investigate the operation of such photodevices in a radiation environment. Some results on the radiation damage of laser diodes by proton and neutron irradiation have been reported before e.g. Refs. [1,2].

In the present paper, results are presented of an extensive study on the degradation of InGaAsP laser diodes by γ -ray and 2 MeV electron irradiation. The data are compared with previous neutron irradiation results [2]. In addition, the impact of the irradiation temperature is investigated, to assess the device behaviour in extreme space conditions (100°C and 200°C).

1.3 μm InGaAsP double channel planar buried hetero-structure (BH) laser diodes with an $\text{In}_{0.76}\text{Ga}_{0.24}\text{As}_{0.55}\text{P}_{0.45}$ multi-quantum well (MQW) active region were used in this study. The thickness of the MQW active region fabricated by MOVPE is 0.22 μm . Diodes were fabricated by a two-step LPE process. Pairs of 7 μm -wide and 3 μm -deep channels were formed by chemical etching to make a stripe mesa on a double heterostructure wafer which consisted of an n-InP buffer layer, an undoped InGaAsP active layer and a p-InP cladding layer on a (001) n-InP substrate. CrAu/TiPtAu and AuGeAuNi/TiAu were evaporated for anode and cathode contacts, respectively. Fig. 1 shows the schematic structure of the used InGaAsP laser diodes. More detailed on the diode process are described in previous paper [2].

Diodes were irradiated by an 8150.1 TBq ^{60}Co source at Takasaki JAERI. The fluence of the γ -ray was 1×10^7 rad (Si). Packaged diodes were also irradiated

E-mail address: ohyama@ee.knct.ac.jp (H. Ohyama).

with 2-MeV electrons to a fluence of $1 \times 10^{15} \text{ e/cm}^2$ produced by the Dynamitron at Takasaki JAERI. The sample temperature was fixed at 20°C, 100°C or 200°C and was controlled by a panel heater, mounted in a chamber with a Ti window of 50 μm thickness.

Before and after irradiation, the current/voltage (I/V) and capacitance/voltage (C/V) characteristics of the diodes were measured at room temperature. The optical power (P_L) as a function of forward current (I_F) was also characterised at 300 K. Fig. 2 shows the typical P_L/I_F characteristics before irradiation. As shown in this figure, the threshold current (I_{th}) before irradiation is around 9.4 mA. The induced deep levels in the $\text{In}_{0.76}\text{Ga}_{0.24}\text{As}_{0.55}\text{P}_{0.45}$ MQW active region were studied using the deep level transient spectroscopy (DLTS) method in the temperature range between 77 and 300 K. The emission rate window used in the measurements ranged from 1.18 to 26.51 ms. The applied filling pulse

ranged from -1 to 0 V , allowing to observe electron capture levels, and from -1 to 0.8 V to observe hole capture levels as well.

Fig. 2 shows the typical DLTS spectra for hole traps in the $\text{In}_{0.76}\text{Ga}_{0.24}\text{As}_{0.55}\text{P}_{0.45}$ MQW active region of InGaAsP laser diodes before and after a γ -ray irradiation, at different device temperatures. One hole trap with near mid gap energy level (H_1 ($E_v + 0.49 \text{ eV}$)) is observed after γ -ray irradiation at 20°C, while two hole capture levels are induced by a 1-MeV neutron irradiation [2]. The deep level in Fig. 2 is thought to be associated with the Ga-vacancy. After a 200°C irradiation, the levels are not observed, within the measurement resolution. The decrease of the optical power is ascribed to the induced lattice defects in the $\text{In}_{0.76}\text{Ga}_{0.24}\text{As}_{0.55}\text{P}_{0.45}$ MQW active region. The change of the device performance and the introduction rate of the lattice defects decrease with increasing irradiation temperature. This correlates with the behavior of the hole trap, suggesting it to be mainly responsible for the degradation of the optical power as mentioned below.

Both the reverse and forward current increase after irradiation. As shown in Fig. 3, the optical power decreases after a 1-MeV fast neutron irradiation at room temperature, while the threshold current increases [2]. The reason for the positive shift of the threshold current is mainly related to the decrease of the electron density due to the formation of radiation-induced lattice defects in the $\text{In}_{0.76}\text{Ga}_{0.24}\text{As}_{0.55}\text{P}_{0.45}$ MQW active region. The capacitance also decreases after irradiation. Two hole capture traps H_1 ($E_v + 0.25 \text{ eV}$) and H_2 ($E_v + 0.49 \text{ eV}$) are observed after a $1 \times 10^{16} \text{ n/cm}^2$ irradiation. These deep levels are thought to be associated with a Ga vacancy. The decrease of optical

Fig. 1. Cross-sectional view of the InGaAsP laser diodes.

Fig. 2. DLTS spectra of InGaAsP laser diodes for γ -ray irradiations at different device temperatures.

Fig. 3. Influence of 1-MeV neutron irradiation at room temperature on P_L/I_F characteristics.

power is related to the induced lattice defects in the $\text{In}_{0.76}\text{Ga}_{0.24}\text{As}_{0.55}\text{P}_{0.45}$ MQW active region, causing a reduction of the non-radiative recombination lifetime and of the mobility due to carrier scattering [2].

Figs. 4(a) and (b) shows the typical P_L/I_F characteristics for different irradiation temperatures and corresponding with γ -ray and 2-MeV electron exposures, respectively.

One can calculate the damage coefficient of P_L at $I_F = 20$ mA for different radiation sources at room temperature irradiation, defined by the following equation [3].

$$P_L(\phi) = P_L(0) + K_{PL} \phi, \quad (1)$$

where $P_L(\phi)$ and $P_L(0)$ are the P_L after and before irradiation, respectively, ϕ is the fluence.

Fig. 4. P_L/I_F characteristics for different irradiation temperature for γ -ray (a) and 2-MeV electron (b) irradiated InGaAsP laser diodes.

The equivalent 1-MeV electron fluence for 1 rad γ -rays is $1.08 \times 10^7 \text{ e/cm}^2$ [4]. K_{PL} for neutron, electron and gamma (equivalent 1-MeV electrons) irradiation is calculated to be $-3.4 \times 10^{-13} \text{ n}^{-1} \text{ mW cm}^2$, $-6.4 \times 10^{-15} \text{ e}^{-1} \text{ mW cm}^2$ and $-8.3 \times 10^{-16} \text{ e}^{-1} \text{ mW cm}^2$, respectively. The K value for neutrons is about three orders of magnitude larger than the one for electrons. The non-ionizing energy loss (NIEL) of GaAs for 1-MeV neutron and 1-MeV electron irradiation is calculated to be 0.8×10^{-3} and $1.8 \times 10^{-6} \text{ MeV cm}^2 \text{ g}^{-1}$, respectively. Based on this consideration, the radiation source dependence of the performance degradation is attributed to the difference of mass of the incident particle and the possibility of nuclear collision for the formation of lattice defects [5].

Fig. 5 shows the normalized P_L at $I_F = 20$ mA as a function of irradiation temperature for γ -rays and 2-MeV electrons. The optical power after a 200°C irradiation is nearly identical as before. The same tendency was observed for the I/V characteristics. Consequently, during high-temperature exposure, thermal annealing of the radiation damage takes place at the same time, reducing the device degradation.

In conclusion, the optical power decreases after irradiation, while the threshold current increases. One hole capture trap with near mid gap energy level is observed γ or electron after irradiation. The deep level is thought to be associated with the Ga vacancy. The degradation of the diode performance for neutron irradiation is about three orders of magnitude larger than for electron irradiation. The radiation source dependence of the performance degradation is attributed to the difference of mass of the incident particle and the possibility of nuclear collision for the formation of

Fig. 5. Normalized P_L at $I_F = 20$ mA as a function of irradiation temperature for γ -rays and 2-MeV electrons.

lattice defects. The decrease of the optical power becomes smaller for higher device temperatures. The optical power after a 200°C irradiation is nearly identical as before, in the fluence/dose range studied.

Defect characterization by DLTS of AlGa_xN UV Schottky photodetectors

M.J. Legodi*, S.S. Hullavarad, S.A. Goodman, M. Hayes, F.D. Auret

Department of Physics, University of Pretoria, Pretoria 0002, South Africa

Abstract

Deep traps are studied in MBE grown n-Al_xGa_{1-x}N Schottky photodiodes using deep level transient spectroscopy (DLTS). These daylight blind UV photodetectors have cut-off wavelengths of 300 and 250 nm, for $x = 0.12$ and 0.41 , respectively. Other investigations of deep centers are those by Gotz et al. who studied MOCVD Al_{0.12}Ga_{0.88}N (Appl. Phys. Lett. 69 (1996) 2379); and by Polyakov et al. who looked at p-AlGa_xN using an AlGa_xN/GaN heterojunction LED p-i-n structure (Solid State Electron. 43 (1999) 1929). Our photodiodes were MBE grown with carrier density $(5-9) \times 10^{17} \text{ cm}^{-3}$. We detect two levels, EOA2 and EOA1 in each photodetector, below 320 K, independent of the Al mole fraction, x . For Al_xGa_{1-x}N with $x = 0.41$, EOA2 has a DLTS signature ($E_C - 0.567 \text{ eV}$; $1.1 \times 10^{-14} \text{ cm}^2$) while the signature for the second defect, EOA1, is ($E_C - 0.274 \text{ eV}$; $3.1 \times 10^{-13} \text{ cm}^2$). From a comparison with as-grown defects in MBE grown n-GaN, it would appear, based on DLTS signatures that EOA1 is the same as E_1 ($E_C - 0.234 \text{ eV}$) observed by Wang et al. (Appl. Phys. Lett. 72 (1998) 1211) and EOA2 is the 0.61 eV level reported by Gotz et al. (Appl. Phys. Lett. 69 (1996) 2379). Furthermore, proton irradiation introduces an additional electron trap, EpR1, at 0.187 eV . We also determine that He-ions remove carriers in AlGa_xN, at a rate of $23\,770 \text{ cm}^{-1}$, eighty times higher than in GaN. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Aluminium gallium nitride; Defects; UV photodetectors

The III-Nitrides with bandgap energy 2–6.2 eV, are fast becoming the materials of choice for optoelectronic applications in the blue to ultra violet (UV) region. In particular, recent successes [1] with very low cut-off wavelength ($\sim 230 \text{ nm}$) Al_xGa_{1-x}N-based, visible-blind UV photodetectors, can open up new avenues for space applications. Potential applications include highly sensitive missile plume detectors, flame detectors, ozone monitoring and secure space communications. The materials system is also known for its insensitivity to environmental factors: e.g. corrosion and temperature. Temperature extremes $\pm 200^\circ\text{C}$ and particle irradiation from a few eV to MeVs are characteristic of the outer space environment.

We know from Silicon, GaAs and GaN how defects influence device performance. This knowledge is essen-

tial for predicting device failure and/or engineering desired properties in devices. From the limited investigations into deep levels in Al_xGa_{1-x}N photodetectors, we know that defects are responsible for the UV/visible contrast, the noise equivalent power (NEP) and the device response speed [2,3]. For example, GaN-based photodetectors grown with a GaN or AlN nucleation layer have sharper cut-off wavelengths and an enhanced UV/visible rejection than those grown directly on sapphire substrates. However, the device structure also influences device properties. For example, whereas photoconductors have a slow response of the order of milliseconds, Schottky photodetectors have typically fast response times of the order of nanoseconds.

Gotz et al. [4] detected a prominent deep level at 0.61 eV below the conduction band of MOCVD Al_xGa_{1-x}N ($x = 0.12$). They believed it to be the same as the 0.58 eV deep level in as-grown GaN. To our best knowledge, there are no DLTS reports on “as grown” or particle irradiation induced deep levels in MBE

$\text{Al}_x\text{Ga}_{1-x}\text{N}$ Schottky photodetectors. In this study we observed that: the presence of as-grown defects, EOA1 and EOA2 in MBE $\text{Al}_x\text{Ga}_{1-x}\text{N}$ is independent of the Al mole fraction; EOA2 is similar to the level reported by Gotz et al. [4] in MOCVD AlGaIn ; and, EOA1 is similar to a level at $E_C - 0.234\text{ eV}$ that we detect in MBE GaN. We also characterized a proton irradiation induced level, EpR1. We also performed dose dependency experiments and determined the carrier removal rate of 1.8 MeV He-ions, which is about 80 times greater than for GaN similarly irradiated.

The photodetector diodes used were metal/ $\text{Al}_x\text{Ga}_{1-x}\text{N}$ Schottky-type structures with cut-off wavelengths of 250 and 300 nm, corresponding to Al mole fraction $x = 0.41$ and 0.12. The photodetectors were grown on sapphire substrates with a thin low temperature AlN nucleation layer. A 1000 nm thick n^+ - $\text{Al}_x\text{Ga}_{1-x}\text{N}$ Si-doped region was deposited in between the AlN nucleation layer and the 500 nm n - $\text{Al}_x\text{Ga}_{1-x}\text{N}$ Si-doped active layers. The free carrier concentration in the active layers were determined by conventional capacitance–voltage (C – V) measurements to be in the range $(5\text{--}9) \times 10^{17}\text{ cm}^{-3}$. A 10 nm semi-transparent Au Schottky contact facilitated the gathering of light by the diodes while a recessed alloyed Ti/Al contact on the n^+ layer acted as the ohmic.

A van de Graaff accelerator was used for both 1.8 MeV protons and 1.8 MeV He-ion irradiations. During the particle irradiation, the sample temperature did not rise above a few degrees from room temperature. A lock-in-amplifier (LIA) based DLTS [5,6] system with a closed-cycle liquid-Helium cooled cryostat capable of spanning the 20–350 K range was employed for defect characterization. The DLTS defect “signatures” which consist of the energy position, E_T , of the defect in the bandgap together with the defect’s majority carrier capture cross section, σ_n , were extracted from Arrhenius plots of e/T^2 vs. $1/T$, where e is the defect’s emission rate at a temperature T .

The photodetectors we used had responsivities $\sim 0.01\text{ A/W}$ and we typically measured room temperature currents of $\sim 10^{-8}\text{ A}$ with the diode at 1 V reverse bias. DLTS spectra of the diodes before particle irradiation show the presence of two “as grown” peaks, labeled EOA1 and EOA2 as depicted in Fig. 1. For the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ photodetectors we looked at, i.e. with cut-off wavelengths of 300 nm ($x = 0.41$) and 250 nm ($x = 0.12$), EOA2 was always the most prominent defect. However, for $x = 0.41$ the FWHM for EOA1 and EOA2 are broader than for the same defect set in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ with $x = 0.12$. We also find that EOA1 and EOA2 are uniformly distributed (in the area probed by DLTS) as shown by the inset in Fig 1. The depth profile in the inset was obtained using the fixed bias variable pulse mode of DLTS and the formalisms of Zohta [7]. We recorded the DLTS spectra of Fig 1 at a quiescent

Fig. 1. DLTS spectra of the Schottky diodes before particle irradiation showing the presence of EOA1 and EOA2. The spectrum was recorded with the sample at a quiescent reverse bias of 0.5 V and filling pulse of 0.6 V at a LIA of 22 Hz. The inset is the DLTS depth profile of EOA1 and EOA2 recorded using the fixed bias variable pulse mode of DLTS.

reverse bias of 0.5 V and a pulse amplitude of 0.6 V, a pulse width of 0.2 ms at an LIA frequency of 22 Hz.

Using the LIA-based DLTS between 20 and 320 K, we have determined the defect signatures of the as-grown defects as: ($E_C - 0.567\text{ eV}$; $1.1 \times 10^{-14}\text{ cm}^2$) and ($E_C - 0.274\text{ eV}$; $3.1 \times 10^{-13}\text{ cm}^2$) for EOA2 and EOA1, respectively, for $x = 0.41$; and, $E_C - 0.537\text{ eV}$; $7.2 \times 10^{-14}\text{ cm}^2$ and $E_C - 0.159\text{ eV}$; $1.1 \times 10^{-16}\text{ cm}^2$ for EOA2 and EOA1, respectively, for $x = 0.12$. The prominent defect EOA2 is similar to the 0.61 eV defect detected in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ $x = 0.12$ by Gotz et al. [4]. The differences in the measured values could be accounted for by alloy broadening. Another possibility is the enhancement of the defects’ emission rates by the electric field due to high doping levels. From a comparison with an as-grown defect we detected at 0.262 eV, with a capture cross section of $8.6 \times 10^{-13}\text{ cm}^2$ in MBE grown n -GaIn, it would appear, based on DLTS signatures that EOA1 is the same as E_1 ($E_C - 0.234\text{ eV}$) observed by Wang et al. [8]. Table 1 summarizes DLTS data for the deep levels detected in the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ UV Schottky photodetectors.

From TRIM95 simulations, the projected range of 1.8 MeV protons is greater than the 3.6 μm for 1.8 MeV He-ions, which in turn lies outside the active region of our diodes. After irradiation with 1.8 MeV He-ions, the resulting spectra is no different from the one shown in Fig. 1. However, after proton irradiation, we detected a small peak, EpR1, on the lower temperature side of EOA1. EpR1 was detected using a pulse width of 500 μs and a much higher LIA frequency of 1200 Hz. Fig. 2 is an Arrhenius plot of e/T^2 vs. $1/T$, where e is each defect’s emission rate at a temperature T . Since we do

not readily see EpR1 after He-ion irradiation, its presence was confirmed by TSCAP measurements. EpR1's signature was determined as 0.187 eV, $8.8 \times 10^{-16} \text{ cm}^2$.

Fig. 3 shows the current–voltage (I – V) characteristics of a diode before and after it was irradiated with $5.5 \times 10^{12} \text{ He-ion cm}^{-2}$. The leakage current deteriorates

Fig. 3. I – V plots of the Schottky photodetector before and after irradiation with $5.5 \times 10^{12} \text{ He-ions cm}^{-2}$. The leakage current deteriorates from $\sim 10^{-8}$ to $\sim 10^{-3} \text{ A}$ after this dose. After particle irradiation, the I – V curve has a Generation–Recombination component pointing to deep levels.

from $\sim 10^{-8}$ to $\sim 10^{-3} \text{ A}$ after irradiation. After particle irradiation, the I – V curve has a Generation–Recombination component pointing to the presence of deep levels.

Fig. 4. Removal of carriers near the surface of the photo-detector by He-ions is fairly uniform in the $\text{Al}_x\text{Ga}_{1-x}\text{N}$. He-ion doses between 1.4×10^{11} and $5.2 \times 10^{12} \text{ cm}^{-2}$ were used. The inset shows the carrier removal by 1.8 MeV He-ions at various doses. A carrier removal rate, $\eta = 23\,770 \text{ cm}^{-1}$ was extracted from the slope.

In order to determine the rate, η , at which free carriers are being removed by the He-ions, we irradiated samples from dose 1.4×10^{11} to $5.2 \times 10^{12} \text{ cm}^{-2}$. Fig 4 shows that the He-ion dose removes carriers fairly uniformly in the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ diodes, and the inset, which shows the variation with He-ion dose of the free carrier concentration, is used to determine the carrier removal rate, η . Using the equation $\eta = \Delta N_d / D$, where ΔN_d is the change in free carrier concentration resulting from dose D , we calculated that 1.8 MeV He-ions remove carriers at a rate of $23\,770 \text{ cm}^{-1}$. This value of η is about eighty times greater than for a similarly irradiated GaN.

In conclusion, we have characterized two as-grown defects, EOA1 and EOA2 and a proton irradiation induced defect EpR1 in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ Schottky photo-detectors. The DLTS signatures for EOA1 is 0.274 eV, $3.1 \times 10^{-13} \text{ cm}^{-2}$, and for EOA2 it is 0.58 eV, $1.1 \times 10^{-14} \text{ cm}^{-2}$. The signature for EpR1 is 0.187 eV, $8.8 \times 10^{-16} \text{ cm}^{-2}$. We believe EOA2 is the 0.61 eV level in MOCVD AlGaIn (12% Al), and that EOA1 is the E_i defect in GaN. Furthermore we determined that AlGaIn is radiation “softer” than GaN.

Anomalous temperature dependence of electroluminescence intensity in InGaN single quantum well diodes

A. Hori, D. Yasunaga, A. Satake, K. Fujiwara*

Kyushu Institute of Technology, Tobata, Kitakyushu 804-8550, Japan

Abstract

Temperature dependence of electroluminescence (EL) spectral intensity of the super-bright green InGaN single quantum well (SQW) light emitting diodes (LEDs), fabricated by Nichia Chemical Industry Ltd., has been studied over a wide temperature range ($T = 15\text{--}300\text{ K}$) and as a function of injection current level. It is found that, when T is decreased slightly to 140 K, the EL intensity efficiently increases probably due to reduced non-radiative recombination processes and/or increased carrier capture by the localized radiative recombination centers. However, by decreasing T , further, down to 15 K, it drastically decreases due to the reduced carrier capture and population, accompanying the disappearance of injection current dependent line shape changes (blue-shift) caused by band filling of the localized recombination centers. These results indicate that the efficient carrier capture by SQW is crucial to enhance the radiative recombination of injected carriers in the presence of the high dislocation density. © 2001 Elsevier Science B.V. Keywords: Wide band gap semiconductors; Electroluminescence; Recombination

1. Introduction

Super-bright green and blue light emitting diodes (LEDs) using group III-nitride semiconductor quantum structures have been manufactured successfully [1–3]. Such a quantum well LED shows very bright emission characteristics in spite of the existence of high density misfit dislocations, and the origins of the high quantum efficiency have been receiving much attention [4–8]. Previously, quantum confinement effects on the InGaN alloy well and efficient carrier capturing by the localized radiative recombination centers in the quantum-dot-like states [4–7] have been claimed to be important for origins of the high recombination efficiency. In this paper, the temperature dependence of electroluminescence (EL) spectral intensity of the green InGaN single quantum well (SQW) LEDs with a high recombination quantum efficiency, fabricated by Nichia Chemical Industry Ltd. [2], has been studied over a wide

temperature range and as a function of injection current level. In contrast to a commonly expected trend of reduced non-radiative recombination with decreasing lattice temperature, an anomalous temperature dependence of the EL intensity has been observed at lower temperatures below 100 K. A careful analysis of the detailed EL spectral line shape as a function of injection current reveals that the efficient carrier capture by SQW is crucial to enhance the radiative recombination when the dislocation density is very high ($10^{10}/\text{cm}^2$).

2. Experimental

EL spectral characteristics of the super-bright green InGaN SQW-LED sample, fabricated by Nichia Chemical Industry Ltd. [2], have been studied as a function of lattice temperature. The nominal InGaN well width is 3 nm and the claimed In concentration in the SQW layer is 0.45 [2]. The InGaN SQW layer is confined by p- $\text{Al}_{0.2}\text{Ga}_{0.8}\text{N}$ and n-GaN barrier layers. The detailed diode heterostructure was described previously [1,2].

E-mail address: fujiwara@ele.kyutech.ac.jp (K. Fujiwara).

The SQW-LED sample was mounted on a Cu cold stage of a temperature-variable closed-cycle He cryostat to vary the sample temperature over a wide range ($T = 15\text{--}300\text{ K}$). EL spectra were measured by a conventional lock-in technique, employing a GaAs photomultiplier, as a function of current injection level up to 10 mA. In order to get information about the absorption spectra, photocurrent (PC) spectra were also measured using a combination of a halogen lamp and a monochromator for illumination and a DC electrometer for current detection.

3. Results and discussion

EL and PC spectra of the green SQW-LED have been measured between 15 and 300 K. Fig. 1 shows the typical EL (solid curves) and PC (dotted curves) spectra normalized by the respective peaks at 260 and 15 K. The injection current level for EL is 10 mA and the reverse bias voltage for PC is -0.5 V . At 260 K, the green SQW-LED shows an emission band centered around 2.3 eV (540 nm) at the current level of 10 mA with multiple fine structures due to Fabry–Perot fringes. The emission peak shows a blue-shift with increasing injection current (from 0.1 to 10 mA) and is red-shifted from the broad absorption peak located around 3.0 eV (410 nm) as confirmed by the PC spectrum, indicating strong

localization of the injected carriers within the SQW region [4,7]. The peaked nature of the transition that is rather enhanced at 15 K directly indicates the excitonic origin of the absorption transition in the SQW layer, although the line width is very large (170–300 meV) due to inhomogeneous broadening of the confinement potentials. At 15 K, the emission peak energy is also observed at 2.3 eV in Fig. 1 which does not show any significant shifts from the one at 260 K. In Fig. 1 (at 15 K), an absorption peak is observed at 3.45 eV due to the A and B excitonic transitions of the GaN barrier layer [9]. It shows a blue-shift with decreasing temperature, following the temperature dependence of the band gap energy [10,11]. In addition, a weak emission around 3.1 eV is observed at 15 K in Fig. 1. We attribute the emission band to the GaN layer, although the exact origin of the Stokes shift is not clear at present.

The EL spectral intensity from the green SQW layer varies significantly with changing sample temperature. The temperature dependence of the EL spectra is plotted in Fig. 2 at a fixed value of the injection current (10 mA). When T is slightly decreased from 300 to 140 K, the EL spectral intensity efficiently increases. This enhancement of the radiative recombination efficiency at 140–220 K is similar to those usually expected for the reduced non-radiative recombination at lower T in many cases of the GaAs based LEDs. However, by decreasing T down to 15 K furthermore, a drastic reduction of the EL intensity is observed. That is, it is found that the EL efficiency at lower T is quite low. This is in strong contrast to the

Fig. 1. EL (solid curves) and PC (dotted curves) spectra of the green SQW-LED at 260 and 15 K. For EL spectra the injection current level is fixed at 10 mA, while for PC spectra the reverse bias voltage is -0.5 V .

Fig. 2. Three-dimensional plot of EL spectra of the green SQW-LED as a function of lattice temperature at a fixed value of injection level of 10 mA.

usual cases of GaAs based LEDs where significantly reduced non-radiative recombination processes are expected at lower T . This reduction of the EL efficiency at lower T is also seen at other injection currents between 0.5 and 10 mA. In Fig. 3, the spectrally integrated EL intensity is shown as a function of current and temperature to illustrate three-dimensional light-output versus current and temperature characteristics. The EL intensity versus injection current characteristics at intermediate to low temperature regimes are quite astonishing, since the EL intensity shows saturation phenomena at lower output levels above 1 mA. At higher injection currents, say 10 mA, the EL intensity is very low at 15 K. This phenomenon observed at 15 K is obviously not because of the heating effects and reflects the particular recombination characteristics of the InGaN SQW heterostructures by current injection. We note that this trend is even stronger at 15 K than at 120 K.

In order to investigate the causes of the reduced EL efficiency at lower T , the detailed EL spectral line shape has been studied as a function of injection current. The results at 260, 140 and 20 K are shown in Fig. 4. At 140–300 K where the EL efficiency is very high, the spectral line shape changes drastically with increasing current, when the injection level is increased by two orders of magnitude. That is, the EL intensity significantly increases at higher energy sides with the current level due to the band filling of the localized recombination centers [6]. This result indicates that the injected carriers (electrons and holes) are efficiently captured by SQW at those temperatures and more carriers captured by the SQW layer are filling the localized states at higher energies when the current is

Fig. 3. Three-dimensional plot of integrated EL intensity of the green SQW-LED as a function of injection current and lattice temperature.

Fig. 4. EL line shape variations of the green SQW-LED as a function of injection current at 260, 140 and 20 K.

increased. On the other hand, it is clear in Fig. 4 that the line shape does not change with the current at 20 K where the EL efficiency is quite low. Absence of the band-filling effects at lower T suggests that carriers are not effectively captured by SQW at lower T , but are transferred to non-radiative recombination centers within the barrier layers. The carrier overflow to the barrier layers is consistent with the appearance of the GaN emission at 3.1 eV, which is observed only at lower T (see Fig. 1). These results indicate that the efficient carrier capture by SQW is crucial to enhance the radiative recombination when the dislocation density is very high ($10^{10}/\text{cm}^3$).

4. Conclusion

Temperature dependence of EL spectral intensity of the super-bright green InGaN SQW-LED has been studied. We find that, when the temperature is decreased down to 15 K, the EL intensity drastically changes due to decreased carrier capture by the localized radiative recombination centers. The injection current dependent line shape changes (blue-shift) caused by band-filling effects of the localized recombination centers allows us to evaluate the population at the localized states at various temperatures. The reduced carrier population due to the carrier overflow to the barriers at lower temperatures conversely indicates that the efficient carrier capture is crucial to enhance the radiative recombination of injected carriers in the presence of the high dislocation density.

Abstract

In order to develop electroluminescent and laser devices based on the ultraviolet exciton emission of ZnO, it will be important to fabricate good p–n junctions. As-grown ZnO is normally n-type because of intrinsic donor defects such as oxygen vacancies and zinc interstitials, or unintended hydrogen. Making p-type ZnO has been more difficult, possibly due to self-compensation by easily formed donor defects. In this work, we demonstrate that reactively sputtered, annealed ZnO films can be changed from n-type to moderate p-type by adjusting the oxygen/argon ratio in the sputtering plasma. We report the properties of p–n homojunctions fabricated in this way, and characterize transport in the films by the Hall measurements. Ohmic contacts were formed by deposition of Au/Al films. Our finding of p-type conductivity in apparently intrinsic ZnO formed by reactive sputtering is not inconsistent with calculated defect formation enthalpies if account is taken of the higher chemical potential of the dissociated oxygen reservoir represented by the sputter plasma, compared to the molecular oxygen reservoir assumed in the calculation of formation enthalpies. If hydrogen turns out to be the main compensating donor, the role of oxygen pressure in controlling incorporation of background hydrogen during sputtering may also be implicated. © 2001 Elsevier Science B.V. Keywords: ZnO; p–n junction; Ohmic contact

1. Introduction

ZnO with n-type conductivity can readily be produced as intrinsic (undoped) material if grown in zinc-rich conditions, or by extrinsic doping with group-III elements such as Al. Intrinsic ZnO is thought to be n-type primarily because of donor defects such as zinc interstitials (Zn_i) and oxygen vacancies (V_O) [1,2]. It has been suggested that hydrogen in ZnO is also a donor [3]. It is difficult to grow p-type ZnO, although recent studies have reported p-type conductivity achieved by growth in the presence of excited N_2O [4,5] or by codoping N with H [6] or Ga [4].

Zhang et al. [1] discussed the asymmetry of n- vs. p-type doping in the framework of defect formation

enthalpies calculated on the assumption of growth of ZnO in equilibrium with zinc metal and molecular O_2 . The conclusion of their literature survey was that intrinsic p-type ZnO has not been demonstrated [1]. Butkhuzi et al. reported in 1992 that heat-treating ZnO in atomic oxygen produced p-type conduction [7], but aside from that report, it seems that up to now there has not been another demonstration of p-type conductivity in ZnO undoped by foreign atoms.

In the present paper, we demonstrate that ZnO deposited by reactive sputtering of a Zn target in O_2 /Ar atmosphere produces n-type ZnO at low O_2 /Ar ratios and moderately p-type ZnO at higher O_2 /Ar ratios. The I – V curves of p–n homojunctions formed from these films exhibit rectification characteristics, and the Hall effect measurements verify p- and n-carrier type and concentration. Photoluminescence measurements have been measured on the same materials and will be reported elsewhere.

2. Experiment

ZnO films were deposited by reactive sputtering from a Zn metal target (99.99%) in O_2/Ar atmosphere using a DC planar magnetron source (US Gun II) in a turbomolecular pumped stainless steel chamber. The substrate was heated during deposition, typically to $350^\circ C$. The substrate used in this work was (100) silicon, based on the observation of Fu et al. [8] that efficient near-band-edge cathodoluminescence could be obtained from sputtered and air-annealed ZnO on Si(100) substrates but not on Si(111). Substrate dependence of sputtered ZnO film properties will be investigated in future work.

The p–n junctions were formed by deposition of two sequential layers under oxygen-poor and oxygen-rich conditions. At a total O_2/Ar sputtering pressure of 3×10^{-2} Torr, a fractional composition of 50% oxygen produced n-type ZnO and 83% oxygen produced p-type ZnO, as two examples. The sputtering power was 20 W and a typical sputtering time of 30 min produced films about $5 \mu m$ thick, measured by SEM on a freshly cleaved edge. The deposition rate depends on the fraction of Ar in the O_2/Ar mix at constant pressure. A mask was used during the second layer deposition to expose contact areas on the lower layer. We have found that annealing in vacuum ($\sim 10^{-6}$ Torr) at $750^\circ C$ for 30 min gives good band-edge photoluminescence as well as lowering resistivity, and this annealing treatment was employed for the films studied here. Ohmic contacts were formed by depositing Al and Au. The I – V characteristics of an Au/Al contact on both p- and n-type ZnO are shown in Fig. 1.

3. Results and discussion

X-ray diffraction shows a strong peak at 34.5° (2θ) consistent with c -axis oriented wurtzite ZnO. As shown

Fig. 1. I – V curves for Au/Al ohmic contacts on n- and p-type ZnO.

Fig. 2. X-ray rocking curves (2θ degrees) for a ZnO film after sputter deposition at $350^\circ C$ (bottom) and after vacuum annealing at $750^\circ C$ (top).

in Fig. 2 for a film sputtered at $350^\circ C$, annealing in vacuum at $750^\circ C$ sharpens the diffraction peaks significantly. Atomic force microscopy¹ shows crystallite sizes in the 40–65 nm range before annealing, and 80–200 nm after annealing.

The I – V curves for homojunctions of n-type ZnO on p-type ZnO films prepared by controlling oxygen partial pressure during sputtering, as described above, are shown in Fig. 3. Part (a) corresponds to a junction which was not annealed after sputtering, and part (b) corresponds to an annealed junction. Rectification is clearly displayed in both cases. The current conduction (as well as forward and reverse leakage) are significantly greater for the annealed junction in this example. The turn-on voltage is about 1 V, rather than being near the band gap energy of 3.3 eV as we expect in the ideal case. Our diode has low carrier concentrations in both p and n sections, which reduces the expected turn-on voltage somewhat. In this context it is worth comparing the I – V curves measured by other workers for ZnO homojunctions [9] and heterojunctions [10] which were demonstrated to be light-emitting diodes. The turn-on voltage was about 1 V in the homojunction LED [9] and variously 1 and 3 V in two different samples of ZnO heterojunction LEDs [10]. The low turn-on voltage remains a puzzle, but it seems to occur commonly in ZnO junctions qualified by electroluminescence as good p–n junctions.

The Hall effect measurements yielded the approximate parameters summarized in Table 1 for selected films of annealed p- and n-type ZnO. The n-type film represented in the table was optimized for band-gap photoluminescence yield relative to the green

¹ AFM images were taken by Xiaodong Cui at Arizona State University.

Fig. 3. I - V curves for p-n homojunctions formed by depositing n-type ZnO on p-type ZnO: (a) without annealing, and (b) another junction after annealing.

luminescence attributed to oxygen vacancies and has low conductivity. In the p-type film, we found a hole concentration of about $5 \times 10^{15} \text{ cm}^{-3}$.

The ability to form p-n homojunctions, as illustrated in both Fig. 3 and the Hall effect data in Table 1, show that moderate p-type conductivity has been achieved in ZnO films reactively sputtered in oxygen-rich conditions but not intentionally doped with impurities. This appears to be the second published report of p-type conductivity in intrinsic ZnO exposed to atomic oxygen during preparation. The first was the 1992 work of

Butkhuzi et al. [7], who heat-treated ZnO after growth, in a beam of atomic oxygen. The present study is the first to achieve p-type ZnO by reactive sputtering and vacuum annealing. Since the discussion of intrinsic defect formation enthalpies in Ref. [1] stated that intrinsic p-type ZnO cannot be produced by thermal equilibrium growth processes, it is of interest to examine the present results in light of the works on defect formation enthalpies in ZnO [1,2], and especially the very recent theoretical considerations of nitrogen doping on the same basis [11,12].

It is important to note that a molecular oxygen reservoir is assumed for the calculation, whereas an atomic or ionic oxygen reservoir characterizes the post-treatment of Butkhuzi et al. [7] and the reactive sputtering environment in which the present films were grown. The difference is important because presenting the oxygen reservoir with the O_2 molecular bond already broken (bond energy 5.17 eV [13]) raises its chemical potential by half the O_2 bond energy per atom. It is correspondingly easier to insert oxygen from such a reservoir into the growing crystal to make the acceptor defect V_{Zn} , and harder to remove oxygen to the reservoir forming the donors Zn_i and V_{O} .

The basic equation given in Ref. [1] for formation enthalpy of a structural defect α of charge q is

$$\Delta H^{(q,\alpha)} = \Delta E^{(q,\alpha)} + n_a \mu_a + q E_F, \quad (1)$$

where $\Delta E^{(q,\alpha)}$ contains the calculated total energy of a unit cell including the host material with defect α in charge state q minus the total energy of a unit cell of the host only, and n_a is the number of atoms being removed during the defect formation from the host crystal to the atomic reservoir. The sign of n_a is negative if atoms are moved from the reservoir to the host crystal. The chemical potential of the reservoir is μ_a , assumed in Ref. [1] to correspond to molecular oxygen. E_F is the Fermi energy. Employing the notation of Ref. [1], the formation enthalpies of the intrinsic donor and acceptor defects V_{O} and O_i can be written, respectively, as

$$\Delta H^{(2+, \text{V}_{\text{O}})} = \Delta E^{(2+, \text{V}_{\text{O}})} + \mu_{\text{O}} + 2e E_F, \quad (2)$$

$$\Delta H^{(2-, \text{O}_i)} = \Delta E^{(2-, \text{O}_i)} - \mu_{\text{O}} - 2e E_F. \quad (3)$$

Table 1

Resistivity, mobility, and carrier concentration derived from the Hall effect and resistivity measurements on n- and p-type intrinsic ZnO, before and after annealing at 750°C

	n-type ZnO		p-type ZnO	
	Not annealed	Annealed	Not annealed	Annealed
Resistivity ($\Omega \text{ cm}$)	$> 10^4$	100	200	30
Mobility (cm^2/Vs)	N/A	20	30	130
Concentration (cm^{-3})	N/A	6×10^{15}	5×10^{15}	5×10^{15}

Thus raising the chemical potential of the oxygen, such as by electronic excitation to a dissociated state, will raise the formation enthalpy of the donor V_O and lower the dissociation enthalpy of the acceptor O_i . A similar role of electron cyclotron resonance (ECR) dissociation of nitrogen or N_2O gas in doping ZnO with nitrogen was discussed recently by Yan et al. [11,12].

The suggestion by Van de Walle [3] that hydrogen should be an important shallow donor in ZnO has been supported by very recent experiments reported in these proceedings, particularly experiments on spin rotation of muonium in ZnO [14–16] and optically detected ENDOR in ZnO [17]. Increasing the oxygen pressure relative to a fixed background of H_2 or H_2O in the sputtering chamber may have a dilution effect to suppress hydrogen incorporation in the growing film, in agreement with the trend we report, and in addition to the effect on intrinsic defects already discussed.

Abstract

We describe luminescent (spectral and kinetic) properties of $\text{ZnS}_x\text{Se}_{1-x}$ ($x = 0.5–1.0$) solid solutions doped with different impurities (Ag, Cu as activators, Al as co-activator), and prepared large transparent polycrystalline blocks (with the diameter up to 100 mm, and the thickness up to 5 mm). The light yields of all the studied samples were compared with that of CsI:Ti and varied from sample to sample. These variations depend on impurity concentrations, native defect concentrations and presence of a hexagonal (wurtzite) phase. The best results (120% yield of that CsI:Ti) were obtained for the solid solution with $x = 0.5$ doped with Cu (Al). This sample also exhibits the shortest decay time constant, about 25 ns. A detailed comparison of defect properties of our solid solutions with the known data for similar crystalline systems has been carried out. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: $\text{ZnS}_x\text{Se}_{1-x}$; Native defects; Optical properties

1. Introduction

Applications of A^2B^6 compounds for scintillating detectors of ionized radiation [1–3] are determined by a high conversion efficiency, a short decay time and wide possibilities for spectra (emitting and detector's) adjustment. Using A^2B^6 compounds we can join in one block scintillator and photodiode. In this work we present the results of solid solutions $\text{ZnS}_x\text{Se}_{1-x}$ ($x = 0.5–1.0$) investigation. By varying x (S content) we can shift the maximum in an emission spectrum and fit it to the spectrum of receiver's sensitivity. Solid solutions give us more opportunities to counteract undesirable native defect appearance.

2. Sample preparations

Samples were grown by physical vapor deposition (PVD) in a closed reactor placed in a two-zone vertical furnace. At the bottom of a high temperature zone a capsule with re-crystallizing powder compounds (pre-

viously synthesized at 1000°C ZnS–ZnSe mixture) was placed, and at the top of a low temperature zone (the temperature in that zone, the deposition temperature, is pointed in Table 1) the seed was placed. Doping with Cu, Al, and Ag was carried out at the synthesis stage. We added different solvents (BaCl_2 , CsCl, NaCl) at this stage in order to speed up the synthesis. Solvent concentrations were reduced at every stage of the process. For example, in an initial mixture Na contamination was 0.8%, after synthesis 0.15%, and in a solid solution after PVD was less than 0.01%. The Al contamination in samples after PVD was about 0.01%. In this work we deal with 50 mm diameter samples with 5 mm thickness. The crystallizer gives us an opportunity to grow samples with the diameter up to 100 mm and the thickness up to 10 mm. After the growth samples were cut and polished. The transmittance for most samples (with 1 mm thickness) was not less than 50%.

X-ray diffraction investigations of different phases contamination show that for $x < 0.57$ there is only one cubic modification in samples, for $0.6 < x < 1$ there is only one hexagonal modification, and for $0.57 < x < 0.6$ there are both modifications in the samples. The dependence of the unit cell volume on x is shown in Fig. 1. As one can see in the sample with $x = 0$ (pure

ZnSe) unit cell parameter is equal to 0.565 nm—almost the same as for single-crystal (0.5668 nm). The density of this sample corresponds to the calculated density, 5.42 g/cm³. Sample characteristics are summarized in Table 1.

3. Experimental details

Luminescence spectra were measured at constant X-ray excitation (45 keV) in a 100–500 K temperature range with the monochromator MDR-2, and the photo-multiplier tube FEU-83. Kinetic measurements were carried out with the pulse X-ray source (1 ns X-ray pulse duration) described earlier [4] in a 100–500 K temperature range. Thermo-luminescence measurements were carried out after an X-ray irradiation at 100 K and subsequent heating (in the same cryostat) at 0.5 K/s rate. Relative light yields (compared to that of CsI:Ti) were measured by two different methods: (1) at a continuous excitation, and (2) at a pulse excitation (using photon counting). In the latter case an average excitation level was three orders less.

4. Results and discussion

Main properties of the investigated samples are arranged and displayed in Table 2. At the second column we indicate peak positions and in brackets line relative intensities for 300 K. The third column with light yields is divided into two columns: (a) yields at continuous excitation, and (b) at pulse excitations. At the fourth column we indicate decay constants for an initial part of decay curves. The last column contains TSL results. In spite of the equal conditions at TSL measurements (sample dimension and the excitation level) we cannot properly compare trap concentrations for different samples because of entirely different sample light yields. Let us comment on all the results: (1) a very strong dependence of luminescent properties on the deposition temperature—samples #1 and #2; (2) bad reproducibility with a solvent variation—samples #2 and #3; (3) a strong dependence of kinetic properties on used solvents—samples #4 and #5. The Cu-related band (518 nm—#1, 534 nm—#2, 528 nm—#3) in our samples is well known [5]. The shift (0.3 eV for x varying from 1 to 0.5) of this band with λ_m 528 nm (#3, $x = 1$), 556 nm (#6, $x = 0.8$), and 601, 604 nm (#4 and #7, $x = 0.5$) correlates with E_g variation (0.4 eV for x varying from 1 to 0.5). The difference of light yield at different excitations (a, b columns of Table 2) is connected with different traps and non-emission centers contamination. Only sample #2 shows a large light yield drop at continuous excitation, and a giant trap contamination. To clear up this effect we need heat treatment investigations, because the preparing conditions for samples #1–3 were similar. Peak positions in Ag-doped samples with $x = 0.5$ coincide with those for ZnSe:Ag single crystal [6]. This fact can be explained by following an impurity center level after a band (valence or conducting) edge, or by the different natures of the center in solid solutions. Decay curves of all samples (except #1–4 with BaCl₂ solvent) have an initial exponential part, and a hyperbolic decay at 50 μs gate. Cu-doped samples show the first order kinetic, and the Ag-doped samples the second

order kinetic. Shallow traps in samples #5 and #8 are different: in Cu-doped sample we have only the 115 K trap (by TSL measurements), and in Ag-doped we have 115 and 135 K traps. So, the difference in kinetic (first and second orders) can be explained by two different means: (1) a recombination cross section σ_r of an Ag-related center is much lesser than that of Cu-related center (115 and 135 K traps have similar cross sections σ_r); or (2) the 135 K trap has a cross section much higher than σ_r of an Ag-related center.

Samples doped with Ag do not show a good performance, the light yields for them are too low.

For some samples with a high light yield we measured temperature dependencies of luminescence intensities for different peaks. The intensities usually drop with increasing temperature. For sample #5 such dependence is shown in Fig. 2. One can observe the spectrum transformation with temperature: the Gaussian shape at 300 K, and the second peak appearing at 100 K with $\lambda_m = 525$ nm, and the half-width two times less—42 nm in comparison with 83 nm at 300 K (the first line at 100 K has a 75 nm half-width). The drop of integral band intensity (the inset in Fig. 2) in a temperature range 130–150 K is connected with 525 nm line disappearance. Decay curves for sample #5 measured at

Fig. 2. The temperature dependence of the Cu-related X-ray excited emission spectrum in $\text{ZnS}_{0.5}\text{Se}_{0.5}:\text{Cu}, \text{Al}$ (sample #5). At 100 K the spectrum was fitted with two gaussian curves (dashed lines) also shown. Inset—the temperature dependence of the integral emission band intensity.

different temperatures are shown in Fig. 3. The decay time temperature dependence is shown in the inset of Fig. 3. An activation energy defined from the dependence (similar analysis for a linear case in Ref. [7]) $E_i = (0.26 \pm 0.06)$ eV correlates well with the trap energy corresponding to the 245 K TSL peak (Fig. 4) $E_t = (0.26 \pm 0.03)$ eV. The last value was defined by analyzing the glow peak initial exponential part.

Fig. 4. Thermo-stimulated luminescence curves of different samples.

5. Conclusions

Large transparent samples doped with Cu and prepared by the described technology with CsCl solvent show good scintillating properties for $x = 1-0.5$. However the reproducibility is not satisfactory. It depends, maybe, on the difference in post-growth conditions (differences in cooling rates, etc.), so we need thermal treatment experiments.

Interface defects in integrated hybrid semiconductors by wafer bonding

P. Kopperschmidt*, St. Senz, R. Scholz

Max-Planck-Institute of Microstructure Physics, Weinberg 2, D-06120 Halle, Germany

Abstract

The integration of materials by wafer bonding offers novel device fabrication for applications in micromechanics, microelectronics, and optoelectronics. Two mirror-polished surfaces are brought into intimate contact by adhesive forces regardless of their crystallography, crystalline orientation and lattice mismatch. Followed by a thermal treatment at several hundred degrees centigrade, the interface energy of the material combination is increased to energies of covalent interatomic bonds. Attempts to break the bond lead to fracturing of the materials. In particular, thermomechanic stress in dissimilar material combinations may result in bending, gliding and cracking of the bonded wafers during annealing. The bonding interface of various hybrid semiconductor materials was studied by transmission electron microscopy. Occasionally, microscopic imperfections at the bonding interface were found in Si/Si, Si/GaAs, GaAs/GaAs, GaAs/Al₂O₃, GaAs/InP and moreover Al₂O₃/Al₂O₃ bonded wafer pairs. The imperfections were identified as voids, negative crystals, and oxide-containing precipitates ranging from 5 to 20 nm in diameter. Microscopic defects at the bonding interface in integrated bulk materials do not affect the mechanical and electrical properties of the device very much. However, in bonding of thin films the defects or precipitates may thread through the thin film, if the diameter of the precipitate surpasses the thickness of the film. These pinholes-containing thin films have a high leakage current, low electrical breakthrough and crystallographic disorder. Epitaxy of material on a pinholes containing, disordered surface results on deposition of bicrystalline grains. In between the grains tilt grain boundaries were observed raising from the bonding interface. Bonding related defects at the interface can be avoided by alternative bonding techniques like UHV wafer bonding and low temperature wafer bonding. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

The wafer bonding technique has been established in research and development in terms of integrating various materials [1]. Two mirror-polished wafers are brought into intimate surface contact at room temperature and adhere by van der Waals forces. To receive high bonding strength, the wafer pair must be annealed at elevated temperatures. Two major problems arise for

conventional wafer bonding including a high-temperature annealing step. During heating of wafer pairs containing different materials, thermomechanical stress is introduced into the material leading to bending in analogy to bi-metals. If the stress is sufficiently high, either the two wafers separate by breaking the bonds at the interface or one wafer will fracture [2]. The second problem of the high-temperature procedure arises from the occurrence of voids, crystalline grains and precipitates at the bonding interface. These imperfections are revealed in many materials combinations, e.g. silicon/silicon, GaAs/silicon, GaAs/GaAs, Al₂O₃/GaAs, Al₂O₃/Al₂O₃ and GaAs/InP [3–7].

If two bulk materials are joined together, microscopic interface defects may not have a disturbing effect on the mechanical and electrical properties of the device, if the density of the cavities is small. In thin films, however, where the size of the interface defect surpasses the thickness of the thin layer, the surface is decorated with trenches and pinholes and the associated device structure may have preventable properties [2]. In electronic applications these pinholes will lead to high leakage currents and a low electrical breakthrough across the interface. Incidentally, a twist in between a thin pinhole-containing crystalline layer and a single crystalline substrate has some interesting morphological features, as a template for bi-crystalline structures or selected area growing films.

By cross sectional and plan-view transmission electron microscopy (TEM) bonding interfaces of various materials combination are inspected and briefly discussed in the following.

2. Silicon/silicon bonding interfaces

In Czochralski grown silicon (CZ-Si) oxygen is incorporated in silicon with a concentration close to the solubility at the silicon melting point [8]. Oxide precipitates are formed at sufficient temperatures by diffusion processes. Large precipitates grow at the expense of smaller precipitates to reduce the surface energies. Grain boundaries often reduce the velocity of the diffusion and are therefore attractive nucleation centers for precipitates and void formations. In Fig. 1 a high-resolution TEM cross section is presented at the twist-grain boundary between two (001) bulk CZ-Si wafers after Ref [4]. The wafers are bonded hydrophobically with an intentional misorientation of 12° . Similar results were observed in thin silicon layer bonded to silicon substrates by Chen et al. They identified the defects as SiC containing precipitates [3].

3. GaAs/GaAs bonding interfaces

In GaAs/GaAs wafer bonding at 580°C in hydrogen atmospheres two types of interface defects were found. A representative TEM cross section is given in Fig. 2. In addition to amorphous precipitates, well-ordered grains of not-identified crystalline phases were observed at the bonding interface. These grains may be probably formed at elevated temperatures by lowering the surface energy at the boundary between two bonded surfaces with twist and miscut. In thin GaAs films with thickness of a few nm bonded to GaAs substrates, interface defects or cavities occasionally thread through the thin layer [7,9]. The decorated surface of the substrate may play an important role in the strain relaxation during lattice

Fig. 1. High-resolution TEM cross-section at the bonding interface of two slightly twisted (001) silicon wafers. The SiO_2 containing precipitate consists of two tilted pyramids (after Ref. [4]).

Fig. 2. Crystalline grain at the GaAs/GaAs bonding interface revealed by cross sectional TEM inspection. The crystallographic planes of the grain boundaries are close to $[111]$. Due to a small surface miscut of the (001) GaAs wafers, the grain is not exactly square-shaped.

mismatched heteroepitaxy on the so-called 'compliant substrates'. Fig. 3 shows a TEM micrograph pointing out the interface of a twist bonded thin GaAs film bonded to GaAs substrate with a cavity defect. While removing the sacrificial layer AlAs, the interface cavities partly open to the surface of the transferred film. Patriarche et al., recently reported on GaAs/GaAs bonding interfaces containing a high density of a regular network of unbonded cavities [9]. Since their thin GaAs layer has a thickness of 20 nm, the cavities do not thread through the thin layer.

4. Si/GaAs bonding interfaces

Since the thermal expansion coefficient of GaAs is nearly twice that of Si, thermomechanical stress cannot

Fig. 3. Cross sectional (large picture) and plan-view (small picture) TEM micrograph of a defect at the interface of a thin GaAs layer bonded to a GaAs substrate. The GaAs thin film is denoted with CL. After removing the sacrificial AlAs layer, the GaAs layer is transferred to the GaAs substrate. If the size of the defect surpasses the thickness of the thin layer, pinholes or trenches are introduced into the thin layer after transfer.

Fig. 4. Defect in Si/GaAs wafer bonding revealed by cross sectional TEM investigation. A Fourier-filtered image shows the bonding interface in detail. Due to the lattice misfit of 4.1%, extra (100) Si lattice planes are introduced (marked by rings).

Fig. 5. Interface defect in GaAs/Al₂O₃ wafer bonding. The high-resolution TEM cross section shows the [111] and [100] oriented boundaries of the precipitate within the GaAs wafer. The precipitate is filled with Ga-rich and As-rich compounds.

be suppressed in GaAs/Si wafer bonding followed by an annealing procedure at elevated temperatures. Instead of using silicon wafers, 3 in silicon-on-sapphire (SOS) wafers with 500 nm of epitaxial silicon were bonded to GaAs. Due to the low thermal mismatch between GaAs and sapphire, the thermally induced mechanical stress is insignificant over a wide temperature range [6]. The bonding of SOS/GaAs was performed under arsenic pressure at 800°C for several hours. A high-resolution TEM cross section is presented in Fig. 4. Extra Si lattice planes are introduced at the GaAs/Si bonding interface to balance the lattice mismatch of 4.1%. Precipitates at the GaAs/Si interface, which contain mostly amorphous material, are occasionally observed with diameters ranging from 5 to 20 nm.

5. GaAs/Al₂O₃ bonding interfaces

Precipitates were also found at the bonding interfaces of GaAs and Al₂O₃ (see Fig. 5). The wafers were bonded as received after flushing in hydrogen atmosphere at a few hundred degrees centigrade. Further annealing at 500°C for several hours was necessary in hydrogen to maximize the bonding energies. Precipitates at GaAs/Al₂O₃ interfaces are settled in the GaAs. Since diffusion velocities in Al₂O₃ are rather low at the applied temperature, the defects contain mostly gallium-rich and arsenic-rich precipitates [10]. A closer look at the interface by plan-view TEM investigation reveals unbonded channel-like regions with strong bending contours. These channels can be responsible for the growth of precipitates by providing the mass transport to the interface.

6. Al₂O₃/Al₂O₃ bonding interfaces

Annealing temperatures near 1200°C are required to increase the interface energy of r-cut Al₂O₃/Al₂O₃ bonded wafer pairs to the binding energy of covalent bonds. At these high temperatures, a change of the interface morphology to form low energetic grain boundaries is evident. Wafers with small miscut show atomic steps or terraces at the surface. These steps are moveable during high temperature annealing. In bonded wafers with small surface miscut voids or negative crystals are achieved at the interface. The arrangement of well-ordered voids is shown in the plan-view TEM in Fig. 6. The density of the voids, which is in the range of 10⁸ cm⁻², can be reduced by increasing the annealing time. The ripening of the voids continues at the gain of size.

Conclusively, bonding related defects and imperfections at the interface were observed in many integrated materials. At elevated temperatures, the diffusion length increases for impurities and interstitials within the considered material. Grain boundaries, interfaces or dislocations, however, reduce the diffusion length and

Fig. 6. Voids formation at the $\text{Al}_2\text{O}_3/\text{Al}_2\text{O}_3$ bonding interface revealed by plan-view TEM. During further annealing at 1200°C the density of voids is reduced while the diameters increase. The driving force for changing the surface morphology is to lower the surface energy of bonded wafers with rotational misorientation and surface miscut.

are attractive nucleation centers for the generation of voids, precipitates and novel crystalline phases. The bonding interface of two wafers is due to the material contrast, due to a miscut of the wafers and due to rotational misorientation between the two wafers.

Avoiding high temperatures in dissimilar materials integration, e.g. by low-temperature bonding techniques, is required to prevent the defect formation at the bonding interfaces.

Abstract

Proton irradiation (80 keV) effect on the electrical properties of Au/n-GaAs Schottky barrier diodes (SBDs), fabricated on an epitaxially grown undoped n-GaAs has been studied for a range of particle fluences from 1×10^{13} to 1×10^{15} particles/cm². Current–voltage (I – V), capacitance–voltage (C – V) and deep level transient spectroscopy (DLTS) measurements have been carried out to study the change in characteristics of the devices and the defects introduction due to implantations, respectively. Reverse leakage current (I_R) of the device is the most sensitive parameter to the incident proton irradiation. The I_R was increased (1.0×10^{-9} to 7.95×10^{-5} A) upon irradiation and it strongly depends on the particle fluence. Annealing of irradiated diodes shows reduction in the I_R and particularly, enhancement in barrier heights of the diodes. A change of effective free carrier concentration in the material has been observed from the C – V measurements for the irradiated diodes when compared to the unirradiated diode. From DLTS measurements, it was found that the low energy proton irradiation of the SBDs increases the concentration of EL2 defects and the concentration was estimated to be 6.42×10^{14} cm⁻³. © 2001 Elsevier Science B.V. Keywords: Gallium arsenide; Schottky barrier diode; Proton irradiation; DLTS

1. Introduction

Ion implantation is mainly used to obtain inter device electrical isolation [1]. With the implant isolation technique, free carriers are compensated by either irradiation-induced damages or chemically related deep levels. Significant improvements in the electrical isolation of devices in closely spaced gallium arsenide (GaAs) integrated circuit (IC) have been achieved with low energy proton implantation [2]. Further, proton-induced damages reduce the carrier lifetime in GaAs and very short switching times can also be achieved. Another aspect is that proton environment in space, particularly at low altitudes in trapped radiation belts and during solar events, can have a detrimental effect on semiconductor components and other materials used in spacecraft [3]. In view of this and also

the potential applications of proton irradiation in GaAs, it is of interest to know the proton irradiation induced defects and also to study their effects on the properties of device components like Schottky barrier diodes.

In contrast to electron irradiation, which introduces mainly point defects, implantation with particles such as protons, α -particles may introduce additional defects and various deep levels. Radiation damage produces many defect levels within the depletion layer of the GaAs SBDs [4]. Deep traps of majority carriers can cause variation of field effect transistor (FET) device parameters [5] and can affect the electron mobility at high electric fields [6]. In this paper, we also present the results of DLTS measurements on the low energy proton-irradiated SBDs.

2. Experimental details

Undoped n-type (carrier concentration = 4.4×10^{15} cm⁻³) GaAs epilayers of thickness 4 μ m,

grown on semi-insulating (SI) GaAs substrate by metal organic vapour phase epitaxy (MOVPE) technique were used. Samples were cleaned well and chemically etched (wet) in order to remove the presence of native oxides on the surface. Ohmic contacts were realised by evaporating Au:Ge (88:12) alloy under a vacuum of 2×10^{-6} mbar and then annealing the samples at 723 K under the high pure argon atmosphere for 5 min. Schottky contacts were formed (planar structure) by evaporating gold dots of area $7.85 \times 10^{-3} \text{ cm}^2$ and of thickness 1500 Å using electron beam evaporation system. The fabricated SBDs were characterised through I - V and C - V measurements carried out under dark condition, at room temperature.

The SBDs were irradiated by 80 keV protons at room temperature for various particle fluences (or ion doses) of 1×10^{13} , 1×10^{14} and $1 \times 10^{15} \text{ p/cm}^2$ using a 150 KV accelerator under a vacuum of 10^{-6} mbar. The irradiation energy was chosen in such a way that the irradiation-induced defects have been introduced at the metal-semiconductor (M - S) junction and/or within the depletion layer of the Au/GaAs Schottky junction. Penetration depth of 80 keV proton particles in Au/n-GaAs structure has been calculated to be 4580 Å (with straggling, $\Delta R_p = \pm 1270 \text{ Å}$) using TRIM [7] theoretical calculations. The estimated depletion width for a background doping level of 10^{15} cm^{-3} for GaAs is around 5000 Å at zero bias. The irradiated SBDs were annealed at different temperatures (373, 473, 573 and 673 K) for 10 min and they were characterised using I - V and C - V measurements before and after annealing. DLTS measurements have been performed on the as-grown as well as proton-irradiated samples in the temperature range 77–400 K, with -0.2 V reverse bias, 10 ms pulse width.

3. Results and discussions

I - V characteristics of the unirradiated SBDs and the diodes annealed at different temperatures are shown in Fig. 1. The quality of the control SBDs (unannealed, unirradiated) are good with nearly ideal behaviour and low leakage current (about $1 \times 10^{-9} \text{ A}$) as seen from Fig. 1. Barrier height (ϕ_B) and ideality factor (n) of the control diodes fabricated on low free carrier density ($4.4 \times 10^{15} \text{ cm}^{-3}$) samples are 0.79 eV and 1.08, respectively. No significant change in the I - V characteristics of the control diodes has been observed up to the annealing temperature of 573 K. But samples further annealed to 673 K were found to be highly leaky ($I_R \approx 10^{-5} \text{ A}$). It was known that about 623 K, gold starts to in-diffuse into GaAs material. Hence, the high leakage current may be attributed to the metal inter-diffusion at the junction and the M - S interface becomes non-abrupt.

Fig. 1. I - V characteristics of unirradiated (control) Au/n-GaAs SBDs annealed at different temperatures for 10 min.

3.1. Characteristics of irradiated diodes

For proton-irradiated Au/n-GaAs SBDs, the reverse leakage current was observed to be most sensitive parameter to the incident irradiation. Further, the change in $I_R (\Delta I_R)$ was found to increase with increasing particle fluence (Fig. 2). The change in I_R can be attributed to the irradiation-induced defects at the interface and/or nearby regions. Implantation of semiconductors with ion beams introduces electrically active defects which can behave either as traps or as recombination centres in the material, depending on their capture cross section for electrons and holes [8]. The defects that act as recombination centres introduce generation-recombination currents in rectifying devices. Thus the irradiation-induced recombination centres are responsible for the increase in the reverse leakage current. But such changes due to these defects depends on to an extent determined by their concentration. The linear dependence of change in I_R with fluence is in accordance with the increase of concentration of defects, which increases as the incident particle fluence is increased. Moreover, it has been observed that the barrier height decreases and the ideality factor of the diode increases as a function of ion fluence. This fluence dependency is probably connected with the shift (or movement) of Fermi level pinning position at the GaAs surface, since irradiation-induced defects also creates various interface states. Similar behaviour and particle fluence dependency of the ideality factor and apparent barrier height on the neutron bombardment [9] and on helium ion bombardment [10] has been reported. The increase of ideality factor is indicating an increase of

Fig. 2. Change of reverse leakage current and barrier height (inset) with dose, for as-irradiated and irradiated-annealed SBDs.

defect density at the interface with increasing ion dose. For higher fluence of $1 \times 10^{15} \text{ p/cm}^2$, the I - V curve exhibits almost ohmic behaviour and the current flow mechanism is mainly due to tunnelling.

Damage produced by light ions like protons may usually be unstable and tend to anneal or form complex clusters at higher temperatures. The irradiated diodes have been subjected to thermal treatment to investigate the effect of annealing. Annealing of the irradiated diodes decreases the reverse leakage current as shown in Fig. 2 and the reduction in the reverse leakage current exhibits a strong dependence on the annealing temperature. This is due to annihilation of irradiation-induced defects upon thermal annealing. The reverse leakage current for the 673 K annealed irradiated diodes was slightly higher than that of the unirradiated diode (control diode). This shows that the defects that were produced are not completely annealed out. The annealing of irradiated diode also decreases the ideality factor and increases the apparent barrier height. An enhancement in barrier height (0.812 eV) has been observed for 673 K annealed, irradiated ($1 \times 10^{13} \text{ p/cm}^2$) SBDs as against the control diode (0.789 eV). Interestingly, it was found that the light ion irradiation and subsequent annealing improves the properties of SBDs, especially the barrier height (inset of Fig. 2).

From C - V measurements, it was observed that the capacitance decreases for irradiated diodes and has weak dependence on the applied bias. This may be due to reduction of effective doping level at the GaAs surface. Implantation can introduce traps that reduce the free carrier density of the semiconductor. A decrease in the capacitance was also attributed to the change in dielectric constant at the interface [11].

Fig. 3. DLTS spectra and Arrhenius plot (inset) of the unirradiated and as-irradiated (dose = $1 \times 10^{13} \text{ p/cm}^2$) samples.

3.2. Deep level transient spectroscopy analysis

DLTS spectra for control and $1 \times 10^{13} \text{ p/cm}^2$ proton irradiated samples are shown in Fig. 3. For the as-grown samples, a trap level corresponds to deep level defect EL2 was observed. From Arrhenius plot (inset of Fig. 3), the activation energy and the concentration of the trap level was found to be 0.758 eV and $1.1 \times 10^{14} \text{ cm}^{-3}$, respectively. The electron trap level, EL2, is assigned to native arsenic antisite (As_{Ga}) defect with activation energy values of 0.76–0.80 eV [12–14]. Upon low energy proton irradiation, the trap level concentration was found to be increased ($6.42 \times 10^{14} \text{ cm}^{-3}$) with activation energy of 0.788 eV. It may be noted that there is a shift of nearly 15 K ($\sim 30 \text{ meV}$) in the peak temperature for this defect signature. This may be because at higher defect concentrations their interactions intensified, changing the electrical properties of EL2 defect, thereby changing the thermal activation energy which results such peak shift [15]. Also, due to irradiation, possibility of conversion of the EL2 defect into some other complex defects with the energy close to that of EL2 cannot be excluded.

4. Conclusions

Low energy proton irradiation effect on the electrical properties of Au/n-GaAs SBDs, fabricated on MOVPE grown undoped n-GaAs epilayer has been analysed. I - V measurements show that there is an increase in the reverse leakage current with increase of incident particle fluence. Also, the ideality factor increases and the barrier height decreases as a function of fluence. Annealing of the irradiated diodes improves the diode's properties.

Further, an enhancement of barrier height as compared to the unirradiated diode has been obtained for annealed (673 K), 1×10^{13} p/cm² irradiated SBDs. From these studies it seems that the increase of reverse leakage current depends on the irradiation induced defects (particle fluence). Moreover, the removal of defects and the recovery strongly depend upon annealing temperature and the concentration of defects introduced, respectively. A change in the effective free carrier density in the material has been observed from the *C–V* measurements. DLTS measurements of the irradiated diodes show an increase in the concentration of the deep level defects.

Abstract

Due to its tissue-equivalence, radiation hardness, resistivity to chemicals and thermal stability, diamond is becoming an interesting material for developing dosimeters of ionising radiation. Several types of CVD diamonds grown at the Institute for Materials Research at the Limburg University, Belgium, were used to construct detectors working in ionisation chamber mode, applicable in medical physics. CVD diamonds with substrate removed, cut into $3\text{ mm} \times 3\text{ mm} \times 0.8\text{ mm}$ pieces and with deposited Au contacts, exposed in an external field of 320 kVp X-rays demonstrated sensitivity which varied from 50 to 630 nC/Gy, and a sublinear response with dose rate. A pencil-shaped holder was developed and used for testing the diamond detectors. The main deficiency of the system so far are extended periods required to reach signal saturation and recovery after irradiation. We expect this deficiency to be overcome by improving the quality of CVD diamonds. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: CVD diamonds; Detectors; Ionising radiation

1. Introduction

Detectors based on natural diamond crystals have been developed to measure relative dose distributions in high energy photon and electron beams used in cancer radiotherapy [1]. The most important features which make diamond detectors attractive for medical applications are their tissue equivalence, their small sensitive volume (of a few mm^3) allowing good spatial resolution to be achieved, and the relative lack of dependence of their response on beam energy, dose rate and ambient temperature. A major advantage of a diamond detector in comparison with a gas-filled ionisation chamber is in its small size and high sensitivity, due to the high solid state/gas density ratio (about 3×10^3) and to the lower energy required to produce ion pairs [2]. At present, diamond detectors for dosimetry in radiotherapy beams are produced only by the group of Khrunov at Dubna

(Russia) and offered commercially by PTW Freiburg. The main problem with diamond detectors is to find suitable gems to be used as detecting material. Detector-grade natural diamonds are extremely rare, which limits the availability of such dosimeters.

The development of the chemical vapour deposition (CVD) technique for growing artificial diamonds brought about an effort to produce a CVD diamond-based dosimeter. The CVD technique allows one to control the crystal-growing process in order to obtain materials with well-defined properties. An ideal detector should consist of a single diamond crystal. All substitution impurities of diamond act as trapping centres for free carriers and consequently reduce its radiosensitivity [3]. Polycrystalline CVD diamonds usually consist of columnar grains, which are smaller on the substrate side and increase in size with film thickness [4]. The presence of grain boundaries and of intra-grain defects limits the lifetime of the carriers, giving rise to a high density of localised energy levels in the diamond band gaps. This results in different mechanisms of electrical transport. Han and Wagner [5] showed that the presence of grain

*Corresponding author. Fax: +48-12-6375441.

E-mail address: barbara.marczevska@ifj.edu.pl (B. Marczevska).

boundaries degraded the detection properties of a CVD diamond by a factor of two or three, as carriers are then more likely to drift across grain boundaries and become trapped or scattered. In spite of the presence of a network of grain boundaries, CVD diamonds could operate as detectors of ionising radiation. The Sheffield group published several papers [6,7] summarising their work on the development and application of CVD diamonds as dosimeters in radiotherapy beams.

Within this work, five batches of CVD diamonds grown at the Institute for Materials Research at Limburg University, Belgium, were used to construct detectors working in ionisation chamber mode. The aim of these studies was to test the CVD diamond detectors in different radiation fields. The construction of the detector holder was optimised in order to eliminate the spurious signal interfering with that from the diamond detector.

2. Materials

Five different batches of CVD diamonds were grown at the Institute for Materials Research at Limburg University, Belgium. The thickness of the CVD diamonds varied between 500 and 800 μm and the grain size, determined by means of scanned electron microscopy (SEM) at the Institute of Metal Cutting in Kraków, varied between 50 and 150 μm . The diamond plates used to produce detectors were typically of an area between 4 and 9 mm^2 .

Contact preparation and detector irradiation was performed at the Institute of Nuclear Physics (INP) in Kraków. The as-received CVD diamond samples were annealed for 30 min at 400°C. Samples were cleaned in

hot chromic acid to eliminate any graphite or non-diamond material from the diamond surface, and then rinsed with de-ionised water and dried. Electrical contacts were prepared on opposite sides of the diamond samples. The side of the diamond which had been in contact with the Si substrate during growth, was flat, and the other featured a polycrystalline structure. On the polycrystalline side, the central contact was surrounded by a guard ring. Au or Cr/Au contacts of thickness of about 500 Å were deposited by evaporating metal in a 10^{-5} Torr vacuum chamber. The Cr/Au contacts were annealed at 400°C for 10 min. Finally, a gold wire, 0.1 mm in diameter, was glued to each side of the detector. The CVD diamond detectors were mounted (i) on small isolating plates with electrical contacts (PCBs), (ii) in a 10 cm \times 10 cm \times 5 cm steel box acting as a Faraday cup and (iii) in a specially developed, pencil-shaped holder.

The CVD diamond detectors were irradiated by ^{90}Sr , 5.3 MeV α -particles of fluence about $7 \times 10^6/\text{cm}^2$ from an ^{241}Am source, and by a Philips X-ray tube. The dose rate varied from 19.6 mGy/min at 100 kV (tube current: 1 mA) to 13.32 Gy/min at the 320 kV (tube current: 12 mA). The current and charge generated in the diamond detector were measured by an UNIDOS (PTW Freiburg) electrometer. The bias voltage of the detector could be increased only in 50 V steps. A Markus ionisation chamber was used to monitor the dose rate during X-ray irradiation.

3. Results and discussion

In our first tests, all detectors with their gold contacts were mounted on a small PCBs free-in-air and tested in

Fig. 1. Response of the S8 detector after irradiation with different sources. I_d means the value of the dark current of the detector S8 before irradiation.

Fig. 2. Saturation of the response of the S8 detector after different dose rates, in a 320 kV X-ray beam.

Fig. 3. Best fitted value of saturated current value (squares) and of measured current value (circles) in the S8-type active diamond detector, versus tube current, in a 320 kV X-ray field. Values observed 5 min after turning the X-ray field on were taken as the measured value of current.

the ^{90}Sr field (dose rate: 20 mGy/s). At a 50 V bias voltage detectors showed a dark current of about 10^{-12} A, and a current of a few pA when placed in the ^{90}Sr field. Under these conditions, such a small signal could not be measured in a reproducible and stable manner. Therefore the PCBs-mounted detector was placed inside a grounded metal box acting as a Faraday cup to eliminate distortions caused by external electric fields. Fig. 1 demonstrates the response of one of the detectors (symbol S8) to different radiation fields. The dark current I_d of the S8 detector encapsulated in the

Faraday cup was about 0.032 pA. The detector exposed to day-light showed a current of the 2–3 pA, of about 10 pA under ^{241}Am irradiation and of 140 nA in the 320 kV X-ray beam.

Detectors built from all batches of detectors available to us were tested in the X-ray beam at different dose rates. The response of our CVD detectors varied from 50 to 630 nC/Gy. The signal of the detector is here the total signal, with the signal of the Faraday cup with PCBs plate and electrodes, but without the diamond, subtracted. This spurious signal originated from ions induced by X-rays in air, collected on the electrodes. In Fig. 2 the response of the S8-batch diamond detector, which showed the highest response, is presented as a function of dose rate. The signal of the S8 detector reaches saturation after a period of over 300 s. For all detectors tested, of thickness 0.5 or 0.8 mm, the time required for the signal to saturate was about 5–8 min. After switching the X-ray beam off, the dark current, initially about 2–5 pA, decreased to about 1 pA within 10 h. The initial dark current of virgin (not irradiated) diamond detector ranged between 0.020 and 0.050 pA.

The response of the S8 detector as a function of X-ray dose rate is presented in Fig. 3. Linear response with dose-rate is an absolute requirement for any dosimetric application. On the other hand, the relation between diamond current and the dose rate D provides information on the character of diamond conductivity σ which shows a power dependence with dose-rate, $\sigma \sim D^d$ [7]. The dependence of the S8 detector current versus time since irradiation began, t , was fitted with the function $f(t) = abt^{1/2}/(1 + bt^{1/2})$ (extended Langmuir function) where a (saturation current) and b are free parameters

Fig. 4. Construction of the CVD diamond detector holder. The diameter ϕ of the holder is 12 mm and its length is 70 mm.

(Fig. 2). The saturation current a was determined at each dose rate and plotted against the current of the X-ray tube (Fig. 3). The relation between the saturation current and the dose rate was found to be sublinear ($\Delta = 0.59 \pm 0.02$). It has been reported [7] that Δ approaches 1 for some diamond batches and at higher applied voltages. Linearity of response with dose rate is a crucial parameter if medical applications of CVD detectors are to be considered. More work is planned in this area, with new batches of diamonds placed in much smaller holders than those used presently.

Due to the high level of spurious signal encountered during measurements with the Faraday cup, we developed a pencil-shaped holder, to better separate the electrodes of the diamond detector and to minimise other side-effects. This brass holder was designed for the PMMA structure to fit snugly, keeping electrodes well isolated and eliminating as much as possible air gaps inside the detector (Fig. 4). The dark current of the holder and its background signal in the X-ray beam (with no diamond) was too low to be measured with the UNIDOS electrometer. This type of holder can easily be made waterproof, enabling detectors to be placed in a water phantom. Several detectors with Au and Cr/Au contacts were installed in the holder and tested in the X-ray beam. The response of these detectors was similar to that presented in Fig. 2, but no spurious current had to be subtracted.

4. Conclusions

Several batches of CVD diamonds produced at the Limburger University were tested as possible active detectors for the dosimetry of radiotherapy beams. In an

external field of 320 kVp X-rays, pieces of CVD diamonds with deposited Au contacts demonstrated sufficient sensitivity, varying from 50 to 630 nC/Gy, but, unfortunately, also a sublinear response with dose rate. Another major disadvantage of these detectors is in the extended time periods required to achieve signal saturation and recovery. A pencil-shaped holder was developed and used for testing the diamond detectors. More work is planned with new batches of diamonds and with improved detector encapsulation.

Abstract

Results are presented of a deep level transient spectroscopy (DLTS) investigation of the radiation induced lattice defects in shallow trench isolation (STI) silicon diodes by 20 MeV proton and 2 MeV electron irradiation. The correlation between the deep levels and the post-rad device performance will be studied, together with the recovery behavior by isochronal thermal annealing. It will be demonstrated that the reverse and forward current increase after irradiation, which is caused by a decrease of the generation and recombination lifetime, respectively. Two electron capture levels were observed in meander diodes after 10^{14} p cm⁻² proton irradiation. The degraded device performance recovers by isochronal thermal annealing and correlates well with the annealing of the radiation-induced electron traps. During the annealing, the electron traps transform in other more stable defect centers. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Shallow trench isolation diodes; Irradiation; Induced deep levels; Degradation

1. Introduction

For sub 0.25 μ m CMOS shallow trench isolation (STI) is the only viable scheme for achieving the required packing density and speed performance, by decreasing the parasitic capacitance of the isolation region, enduring the device isolation, and moderating the lithography process margin. It is also considered that the STI is inherently hardened in a radiation-rich environment because of the used process scheme whereby the thickness of the isolation oxide is significantly reduced. Although some reports on the radiation performance of STI structures recently became available [1,2], no systematic studies outlining the relations between

radiation induced lattice defect and the degradation of the electrical performance are available. In this paper, the induced lattice defects and device performance degradation of STI diodes irradiated by 20 MeV protons and 2 MeV electrons were investigated. Moreover, isochronal thermal annealing is performed to study the recovery behavior of the electrical properties of the irradiated diodes.

2. Experimental

The process flow of the STI diodes was based on IMEC's standard 0.18 μ m CMOS technology. The STI process module consists of (1) a dry etching of trenches in the Si substrate, (2) oxidation of the trench sidewalls, (3) filling step with a TEOX oxide, and (4) chemical-mechanical polishing for planarization. A combination

E-mail address: hayama@tc.knct.ac.jp (K. Hayama).

of a deep (200 keV, $1.2 \times 10^{13} \text{ cm}^{-2}$) and a shallow (55 keV, $1.5 \times 10^{15} \text{ cm}^{-2}$) boron ion implantation and subsequent dopant activation anneal at 850°C for 10 min is used to form a retrograde p-well. The studied n^+p diodes are fabricated by a shallow As implantation (70 keV, $4.0 \times 10^{15} \text{ cm}^{-2}$) followed by a thermal anneal at 1100°C for 10 s, resulting in a junction depth of about 0.1 μm . The back-end of the process consists of a Co/Ti silicidation, a TEOS IMD layer and an Al-Si-Cu metallization. In order to examine the leakage currents resulting from the bulk and peripheral depletion region, different square (SQ1, SQ2) and meander (ME1) diodes have been characterized. The diodes were irradiated at room temperature by 20 MeV protons and 2 MeV electrons at the Takasaki JAERI in Japan. The current/voltage (I/V) characteristics were recorded before and after irradiation. The radiation induced lattice defects were investigated by deep level transient spectroscopy (DLTS) using a bipolar rectangular weighting function [3]. To study the recovery behavior of the irradiated STI diodes, 30 min isochronal thermal anneals were carried out at temperatures up to 300°C.

3. Results and discussion

The current/voltage (I/V) characteristics of a 20 MeV proton irradiated square and meander STI diodes are represented in Fig. 1. Both the reverse and forward current increase by irradiation, which is caused by a decrease of the generation and recombination lifetime.

Fig. 1. I/V characteristics of a 20 MeV proton irradiated STI SQ1 and ME1 diode, respectively.

The forward current is, however, lower after irradiation for a forward voltage larger than 0.4 V, which is due to a radiation-induced increase of the p-well resistivity. It is also observed that the increase in current of square diodes is larger than that of meander diodes. This result points to the different influence of irradiation on the bulk and peripheral leakage current, which dominate in square and meander diodes, respectively. The meander diode was more degraded by electron irradiation compared to proton irradiation.

Fig. 2 shows the recovery behavior of the I/V characteristics for STI diodes irradiated with 2 MeV electrons. The device performance was significantly restored by the isochronal thermal annealing.

The degradation of the electrical performance results from the induced lattice defects in the STI diode. The corresponding DLTS spectra have been reported in a recent study [4,5]. Fig. 3(a) and (b) show the DLTS spectra of 20 MeV proton and 2 MeV electron irradiated STI diodes, respectively. In the case of proton irradiation, two electron capture levels E_{14pM1} ($E_c - 0.21 \text{ eV}$) and E_{14M2} have been observed in a meander diode, while only the E_{14pS1} ($E_c - 0.24 \text{ eV}$) level was found in the large area square diode. It was concluded, that E_{14pS1} and E_{14pM1} are most likely associated with the B_{I-O_i} level [6], while E_{14pM2} is related to radiation-induced SiO_2/Si interface states at the STI sidewalls [5]. In the case of electron irradiation, the E_{15eS1} and E_{15eM1} levels were observed in square and meander diodes, respectively. The E_{15eM1} level might be related to STI interface state. The E_{15eS1} level is thought to be originating from the induced lattice defects in the p-well region.

Fig. 2. Recovery of the I/V characteristics for a 2 MeV electron irradiated STI diode (SQ1).

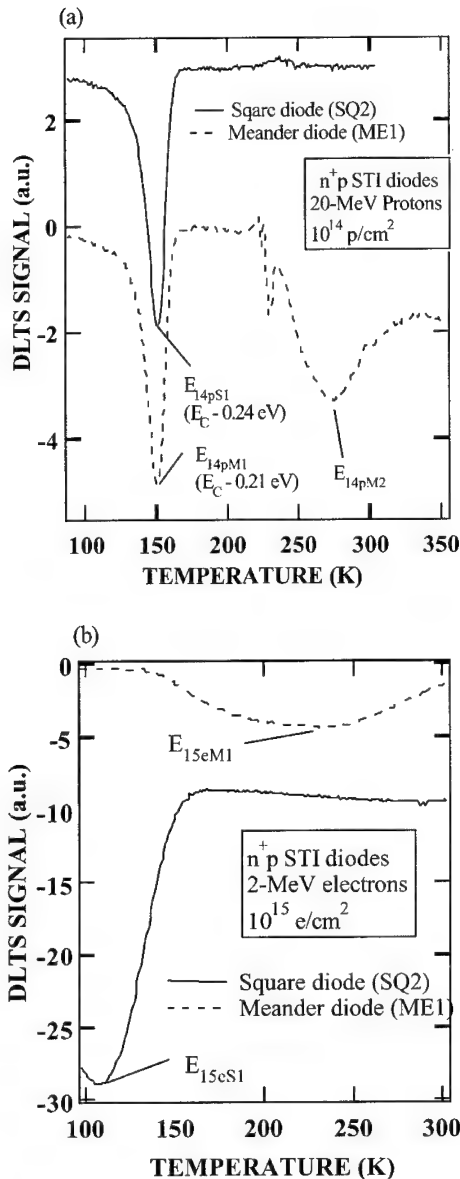

Fig. 3. DLTS spectra at $\tau_{\max} = 7.6$ ms for electron traps in 20 MeV proton (a) and 2 MeV electron (b) irradiated STI diodes (SQ2 and ME1).

Fig. 4 illustrates the impact of an isochronal anneal on the DLTS spectra of a 2 MeV electron irradiated meander diode. As shown in this figure, the E_{15eM1} peak decreases by thermal annealing and disappears after a 200°C annealing.

Fig. 5 shows the electron traps at different τ_{\max} in a 20 MeV proton irradiated STI diode (ME1), after 250°C annealing. The shape of the DLTS spectrum changes significantly with the rate window $1/\tau_{\max}$. The E_{14pM1}

Fig. 5. DLTS spectra at different τ_{\max} for electron traps in a 20 MeV proton irradiated STI diode (ME1) after 250°C 30 min thermal annealing.

peak transformed from a single level peak to a double peaked feature for a higher rate window, while the E_{14pM2} amplitude reduces markedly. It is believed that the E_{14pM1} B_i-O_i level decomposes into the B_i-O_i and

Table 1

Activation energy of recovery of the electron capture levels (E_{AL}) and the reverse current (E_{AI}) of diodes, subjected to 20 MeV protons and 2 MeV electrons

Radiation sources	E_{AL} (eV)	E_{AI} (eV)	
		Square diode	Meander diode
20 MeV protons	E_{14pM1} : —	0.26	0.17
	E_{14pM2} : 0.1	0.26	0.17
2 MeV electrons	E_{15eM1} : 0.11	0.12	0.12

Table 2

Total defect density (N_T), defect introduction rate (η) and damage coefficients for the reverse current of square (K_{SQ}) and meander (K_{ME}) diodes, irradiated by different radiation particles

Radiation sources	N_T (cm ⁻³)	η (cm ⁻¹)	K_{SQ} (A cm ² /particle)	K_{ME} (A cm ² /particle)
20 MeV Protons	2.3×10^{14}	2.3	3.1×10^{-22}	2.5×10^{-23}
2 MeV Electrons	1.5×10^{14}	0.15	5.7×10^{-25}	1.6×10^{-24}

the A center upon annealing at 250°C. A similar transformation was found for the E_{14pS1} level in a SQ diode. The E_{14pM2} interface state peak in Fig. 5 clearly splits up into two new peaks at $\tau_{max} = 68$ ms, while for higher rate windows, its amplitude becomes marginal.

The defect densities of the electron capture levels decrease and the reverse current recovers by thermal annealing. The activation energies of the recovery behavior corresponding with each electron trap (E_{AL}) and with the reverse current for square and meander diodes (E_{AI}) were calculated; the results of this calculation are shown in Table 1. E_{AL} for E_{14pM2} and E_{15eM1} are nearly the same, which is not surprising since they are both thought to be associated with SiO₂/Si interface states. E_{AI} for the electron-irradiated diode was nearly the same as E_{AL} for E_{15eM1} . This demonstrates that the degradation of the reverse current for electron irradiated square and meander diodes is mainly caused by the peripheral damage at the STI sidewalls. In case of proton irradiation, the larger value of E_{AI} for square diodes indicates that the recovery of electrical characteristics is more dependent on the recovery of the radiation-induced lattice defects than on the peripheral damage at the STI edges. On the contrary, the rather small value of E_{AI} for meander diodes indicates the recovery of the I/V curves is caused by the annealing of the peripheral damage.

The total defect density (N_T) of the irradiated meander diodes and the defect introduction rate ($\eta = N_T/\text{fluence}$) have been calculated for the different experimental conditions, as summarized in Table 2. The damage coefficients of the reverse current for square

(K_{SQ}) and meander (K_{ME}) diodes are also indicated in the table. In case of square diodes, the K_{SQ} for proton irradiation was three orders of magnitude larger than for electron irradiation. It has been shown that the higher radiation-induced defect density is related to the difference of particle mass and the possibility of nuclear collision [5]. K_{ME} for protons was about one order of magnitude larger than for electrons. Interestingly, the ratio of K_{ME} for protons and electrons agrees with the ratio of η for protons and electrons. It should be remarked, however, that N_T for the meander diode is not really a physical quantity, as it sums the bulk and interface traps, without making any distinction. Furthermore, the electron traps are minority carrier traps in this case, rendering a quantitative analysis rather difficult. Therefore, N_T should be considered here as an empirical parameter, which shows a good agreement with the respective damage coefficients.

4. Conclusions

The main conclusions from this work are that the device degradation observed after 2 MeV electron, 20 MeV proton irradiation or subsequent isochronal annealing scales well with the observed radiation-induced electron traps. In case of the meander diodes, the degradation is governed by interface traps created at the STI sidewalls. For square diodes, bulk traps in the p-well (B_iO_i or the A center) dominate the device performance after proton irradiation, while both

interface and bulk traps contribute for electron irradiated SQ1 diodes.

Abstract

We have studied a porous structure on silicon surfaces that is introduced by electron irradiation. The structure consists of nanometer-sized holes arranged on silicon surfaces. Investigating the size and the distribution of surface nanoholes in a temperature range from about 4 K to about 600 K, we have estimated the porosity on a surface with nanoholes. We have fabricated a periodic dielectric multilayer structure on a silicon surface by introducing nanoholes periodically in one direction: alternating layers with different dielectric constants (the dielectric contrast of about 1.08), spaced by a distance of 100 nm. We can form periodic dielectric layers at arbitrary locations on surfaces by scanning an electron beam, changing the periodicity and the dielectric constant by varying irradiation condition. © 2001 Elsevier Science B.V. Keywords: Silicon; Surface nanohole; Photonic crystal; Transmission electron microscopy

1. Introduction

The modification of surface structure involving point defects has attracted attention because of its potential application in future nanotechnology as well as its novel physics in nonequilibrium states. Even though growth kinetics at the atomistic level on surfaces has been revealed by means of scanning tunneling microscopy (STM) and other experimental techniques, growth kinetics on surface structures involving a number of atoms has not been fully described yet.

In the present paper, we have investigated a porous structure that is introduced on a silicon surface by electron irradiation, namely, surface nanoholes [1]. An array of nanoholes is uniformly nucleated and gradually grown on an electron irradiated surface. The spatial distribution of nanoholes is varied by an irradiation condition such as irradiation temperature. Analyzing the experimental data, the formation mechanism of nano-

holes has been described in terms of the reaction of point defects [1,2].

The size of nanoholes is much smaller than the wavelength of visible light. However, the dielectric constant of the silicon surface with nanoholes is definable from a macroscopic point of view. The dielectric constant of silicon surface with nanohole is, on average, lower than that of flat silicon surface. We have fabricated a periodic dielectric multilayer structure by introducing nanoholes periodically in one direction. Such a periodic multilayer structure is expected to act as a photonic crystal and is potentially useful for optical devices such as waveguides and reflection mirrors.

2. Experiments

Specimens were nondoped Czochralski Si {001} wafers. Disks of 3 mm diameter were cut from the wafers. The surface of a disk was dimpled until the center of the disk was sufficiently thin for TEM observation. The thickness of each disk (about 100 nm) was estimated by convergent beam electron diffraction technique. Some disks were irradiated

in an ultrahigh vacuum (UHV) TEM (1.8×10^{-7} Pa), and the rest were irradiated in a conventional TEM (1.8×10^{-5} Pa).

3. Results

3.1. Formation of surface nanoholes

Fig. 1 shows the formation process of nanoholes observed by TEM. The formation mechanism of nanoholes [1] is schematically shown in Fig. 2. As the primary event of the formation of nanoholes, single surface vacancies are introduced on an electron exit surface due to sputtering of atoms on the surface (Fig. 2(a)), by irradiation of high-energy (above 40 keV) electrons [2]. The introduced surface vacancies agglomerate on the surface via their diffusion under prolonged electron irradiation (Fig. 2(b)). Indeed, the formation of shallow nanoholes on an electron exit surface is confirmed at the early stage when only a few topmost surface layers are removed by electron irradiation [3]. The excavating follows due to an unisotropic diffusion of surface vacancies on the walls of nanoholes against the ongoing direction of electrons (Fig. 2(c)). The excavation rates for nanoholes on the $\{001\}$ surface is estimated to be 1.3×10^{-23} nm/($e\text{ cm}^{-2}$) [2].

Nanoholes are formed in a wide temperature range (from about 4 K to 610 K), and the average diameter and the planar density of nanoholes vary with temperature [2].

3.2. The porosity of surface with nanoholes

The volume of a nanohole is estimated to be the opening area of the nanohole multiplied by its depth. The porosity of a surface with nanoholes increases as the nanoholes are excavated. The porosity has a maximum value when all nanoholes penetrate the disk. In this case, the porosity is estimated as the ratio between the sum of the opening areas of all nanoholes and the irradiated area.

Fig. 3(a) indicates that the maximum porosity is independent of incident electron energy. The maximum porosity is also independent of electron flux (not shown). We have found that the maximum porosity increases monotonously with increasing irradiation temperature (Fig. 3(b)).

3.3. Fabrication of nanohole periodic multilayer structure

By scanning a focused electron beam (the probe size of about 50 nm) on a silicon disk, we have fabricated a periodic multilayer structure consisting of crystalline silicon and nanoholes (Fig. 4(a)). Fig. 4(b) shows a schematic view of the structure: repeats of the alterna-

Fig. 1. Nucleation and growth of silicon surface nanoholes. Electron doses are 0.0, 0.4×10^{24} , 0.8×10^{24} , and $1.2 \times 10^{24} e\text{ cm}^{-2}$ in (a), (b), (c), and (d), respectively [300 K, UHV]. The circle in (a) indicates the irradiated area.

Fig. 2. The formation mechanism of surface nanoholes.

tion of the $(50\text{ nm}) \times (1.6\text{ }\mu\text{m}) \times (100\text{ nm})$ crystalline silicon layer and the $(50\text{ nm}) \times (1.6\text{ }\mu\text{m}) \times (100\text{ nm})$ nanohole layer. The nanohole layers received an electron dose of about $7.2 \times 10^{24} e\text{ cm}^{-2}$, and the depths of the nanoholes are estimated to be about 95 nm. The nanoholes almost penetrate the disk. With the data in Fig. 3, we have estimated the porosity of the nanohole layers to be about 8%.

Fig. 3. The maximum porosities of the silicon surface with nanoholes as a function of (a) incident electron energy [300 K] and (b) irradiation temperature. [small triangles: UHV, large triangles: 1.8×10^{-5} Pa].

Fig. 4. (a) A TEM image of a periodic nanohole/crystalline silicon multilayer structure. (b) A schematic view of the multilayer structure shown in (a). (c) The calculated photonic band structure.

The dielectric constant of the nanohole layers can be estimated for averaging the dielectric properties of air (in nanoholes) and crystalline silicon. For instance, the dielectric constant at the wavelength of 700 nm is

estimated to be 13, at which wavelength the dielectric constant for crystalline silicon is 14 [4] (the dielectric contrast is about 1.08).

4. Discussion

We discuss the photonic band structure for the periodic multilayer structure shown in Fig. 4(a). Even though it has finite (13) periods of crystalline silicon/nanohole layers, we consider the structure as consisting of the infinite repeats of crystalline silicon/nanohole layers. Fig. 4(c) shows the calculated (for the calculation, we apply the theorem by Joannopoulos et al. [5]) photonic band structure for the infinite multilayer structure. In the calculation, the direction of the wave vector is normal to the layers. A frequency gap in which no mode can exist regardless of wave vectors (photonic band gap) exists: the center frequency of $2.65 \times 10^{14} \text{ s}^{-1}$ (about 710 nm in wavelength) and the width of $8 \times 10^{22} \text{ s}^{-1}$. Both the center frequency and the width of photonic band gap increase on increasing the dielectric contrast. Since the porosity in nanohole layers depends on irradiation temperature and electron dose, the photonic band gap of nanohole periodic multilayer structure can be controlled by varying the irradiation condition. The gap is also controlled by changing the periodicity of the multilayer.

We have measured the reflectance of the periodic multilayer structure shown in Fig. 4(a), and no distinct evidence for photonic band gap is observed at the present moment. Further works, including the theoretical consideration for the effect of finite periods of multilayer on the photonic band gap, are necessary to understand the optical properties of nanoholes.

Some photonic crystals based on porous silicon are fabricated by an electrochemical etching technique and their optical properties are examined [6,7] (for a recent review see Ref. [8]). We have first attempted to fabricate, to our knowledge, a silicon-based photonic crystal on a surface on which the dielectric is periodic parallel to the surface. We have also expected that nanoholes themselves, an array of small holes on surfaces, exhibit the novel optical properties, since the dielectric response is basically due to electrons of which properties are affected in confined systems.

5. Conclusion

We have shown a potential application of nanoholes to photonic crystal. Nanoholes are also expected to exhibit novel optical properties due to the quantum confinement effect.

Abstract

Results of a detailed study of the effects of high-temperature γ -ray and electron irradiation on the performance degradation of Si pin photodiodes are presented. The macroscopic device performance will be correlated with the radiation-induced defects, observed by DLTS. After irradiation, two majority electron capture levels with ($E_c - 0.22$ eV) and ($E_c - 0.40$ eV) were induced in the n-Si substrate, while one minority hole capture level with ($E_v + 0.37$ eV) was found. It was found that the dark current increases after irradiation, while the photo current decreases. Additionally, the degradation of the device performance and the introduction rate of the lattice defects decrease with increasing irradiation temperature. At 200°C irradiation, the reduction of the photocurrent is only 10% of the starting value. This result suggests that the creation and recovery of the radiation damage proceeds simultaneously at high temperatures. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Si photodiode; Radiation damage; High-temperature irradiation; γ -irradiation; Electron irradiation; Induced deep levels

For several reasons, interest in high-temperature electronics develops fast. If these components are to be used in a radiation environment, knowledge about the degradation under high-temperature irradiation conditions is highly desirable, as it is difficult to predict from device simulation only. For the same reason, the space community has also developed interest in electronics for extreme environments, ranging from low to high temperatures and for extreme radiation doses. In satellite systems devices can be exposed to irradiation for extended time periods at elevated temperatures. Military specifications also require devices to function over a temperature range of -55 – 125°C .

Some studies on the physical properties of defects in high-temperature electron-irradiated Si substrates have been reported [1,2]. The effect of the X-ray irradiation temperature on the MOS transistor behaviour has also been investigated [3]. However, not so much is known about the radiation response of microelectronic devices and circuits at high temperatures. There is still some uncertainty about the possible relationship between the induced lattice defects and the performance degradation. In this paper, results are presented of a detailed study of the effects of high-temperature γ -ray and electron irradiation on the device performance of silicon pin photodiodes. The macroscopic device performance will be correlated with the radiation-induced defects, observed by DLTS.

Si photodiodes were fabricated on floating-zone (FZ) n-type (111) Si substrates doped by phosphorus to a

VOLTAGE (V)

(b)

LIGHT POWER (mW/cm²)

Fig. 1. I/V (a) and I_L (b) characteristics after γ -ray irradiation at different high temperatures.

resistivity of 2–4 k Ω cm. The p-type region was boron doped. A SiN_x layer of 100 nm thickness formed by chemical vapor deposition was used as passivation and anti-reflection film. Al with 1.5 μ m thickness was evaporated and alloyed to the p contact. After dicing in chips of 1.5 \times 1.5 mm² size, the diodes were encapsulated in TO-18 packages with kovar glass windows of 0.3 mm thickness.

Diodes were irradiated by a 8150.1 TBq ⁶⁰Co source at the Takasaki JAERI. The total dose of the γ -rays was 1 \times 10⁷ rad(Si). Packaged diodes were also irradiated with 2 MeV electrons to a fluence of 1 \times 10¹⁵ ecm⁻² produced by the Dynamitron at Takasaki JAERI. The

sample temperature was fixed at 20°C, 100°C or 200°C and was controlled by a panel heater, mounted in a chamber for γ -ray irradiation. For electron exposures, irradiations at 30°C, 100°C or 200°C were also performed through a 50 μ m thick Ti window.

Before and after irradiation, the current/voltage (I/V) characteristics of the diodes were measured at room temperature to examine the change of the dark current (I_D) by the irradiation. The photocurrent (I_L), measured at room temperature, was also recorded as a function of the white light power (P_L). The deep levels in the Si photodiodes were studied by DLTS in the temperature range between 77 and 300 K. The emission rate window ranged from 1.18 to 26.51 ms and the filling pulse was -2 to 0 V to observe electron capture levels in the n-Si substrate, while it was -2 to 0.5 V to detect possible hole capture levels.

Fig. 1a and b show the typical result of I/V and I_L characteristics for γ -ray irradiation at different high temperatures, respectively. From these figures it can be found that after irradiation the dark current increases, while the photo current decreases. The degradation of the device performance decreases with increasing irradiation temperature as shown in Fig. 2. For a γ -ray irradiation at 200°C, the reduction of the photocurrent is only 10% of the starting value. The same tendency was observed for 2 MeV electron irradiated Si photodiodes. Fig. 3 shows typical I/V characteristics of Si photodiodes after 2 MeV electron irradiation at different temperatures.

To compare the degradation for different radiation sources, one can calculate the damage coefficient (K) of the dark and the photo current by the following

Fig. 2. Normalized dark and photo current as a function of the γ -ray irradiation temperature.

Fig. 3. I/V characteristics of 2 MeV electron irradiated Si photodiodes for different irradiation temperatures.

equation.

$$K = \partial I_{D,L} / \partial \Phi, \quad (1)$$

where Φ is the fluence. The γ -ray exposure to 10 Mrad (Si) is approximately equivalent to $1 \times 10^{14} \text{ cm}^{-2}$ at 1 MeV energy [4]. Table 1 shows the K values of the γ -ray and the 2 MeV electron irradiation. From this table, a contrasting behaviour is derived for K_D and K_L . This could point to a different origin of the degradation, i.e., bulk versus surface damage. In the first case, radiation-induced defects will affect the bulk generation/recombination lifetime, while in the second case, the creation of interface traps can increase the surface generation/recombination velocity. Therefore, a study of the microscopic damage is necessary for a better understanding of the device degradation.

Fig. 4a and b show typical DLTS spectra for electron and hole capture levels in γ -ray irradiated Si photodiodes, respectively. After irradiation, two majority electron capture levels with ($E_c - 0.22 \text{ eV}$) and ($E_c - 0.40 \text{ eV}$) were induced in the n-Si substrate, while one minority hole capture level with ($E_v + 0.37 \text{ eV}$) was found. Their concentration is smaller for increasing irradiation temperature. In addition, it is well known that the E-center disappears around 150°C [5], which could partly explain the reduction of the $E_c - 0.40 \text{ eV}$ peak. In principle, it is expected that the $E_c - 0.22$ and $E_c - 0.40 \text{ eV}$ peaks are associated with the di-vacancy. However, the 0.3 eV activation energy is quite low to correspond to the single acceptor state. In addition, the corresponding peak is much higher than the double acceptor at $E_c - 0.22 \text{ eV}$. Apparently, some other

Fig. 4. DLTS signal of electron (a) and hole (b) capture levels of γ -ray irradiated Si photodiodes.

unknown level contributes to the electron trap at around 200 K. The hole capture levels are related to a carbon related complex (presumable C_F-O_i). For an irradiation at 150°C , an additional unknown electron capture level is observed around 170 K. The same deep levels are induced for 2 MeV electron irradiated diodes, however, with one order higher introduction rate.

In agreement with the device performance, the introduction rate of the deep levels decreases with increasing irradiation temperature. For a 200°C irradiation temperature, the induced capture levels amount to 60% of the concentrations found after room temperature irradiation. This result suggests that the creation and recovery of the radiation damage proceeds

Table 1
Damage coefficient for γ -ray and 2 MeV electron irradiation

	K_D ($e^{-1} A cm^2$)	K_L ($e^{-1} A cm^2$)
γ -Rays (equivalent 1 MeV electrons)	3.2×10^{-24}	-7.8×10^{-14}
2 MeV electrons	1.1×10^{-22}	-1.6×10^{-14}

simultaneously at high temperatures. It is also shown that the hole capture levels are mainly responsible for the performance degradation.

In conclusion, after irradiation, two majority electron capture levels with ($E_c - 0.22$ eV) and ($E_c - 0.40$ eV) were induced in the n-Si substrate, while one minority hole capture level with ($E_v + 0.37$ eV) was found. The degradation of the device performance and the introduction rate of the lattice defect decrease with increasing irradiation temperature. This result suggests that the

creation and recovery of the radiation damage proceeds simultaneously at high temperatures.

INSTRUCTIONS TO AUTHORS

Submission of papers

Manuscripts (one original + two copies) should be sent to one of the following regular editors:

Prof. Dr. F.R. de Boer, Amsterdam
Prof. L. Degiorgi, Zürich
Dr. Z. Fisk, Tallahassee, FL
Dr. R. Jochemsen, Leiden
(Addresses: see p. 2 of cover)

Original material: Submission of a manuscript implies that it is not being simultaneously considered for publication elsewhere and that the authors have obtained the necessary authority for publication.

Types of contributions

Original research papers and letters to the editor are welcomed. Both should contain an Abstract (of up to 200 words) and a Conclusions section, which, particularly in the case of theoretical papers, translates the results into terms readily accessible to most readers.

Manuscript preparation

All manuscripts should be written in proper English. The paper copies of the text should be prepared with double line spacing and wide margins, on numbered sheets.

Structure: Please adhere to the following order of presentation: Article title, Author(s), Affiliation(s), Abstract, PACS codes and keywords, Main text, Acknowledgements, Appendices, References, Figure captions, Tables.

Corresponding author: The name, complete postal address, telephone and fax numbers and the E-mail address of the corresponding author should be given on the first page of the manuscript.

PACS codes / Keywords: Please supply one to four classification codes (PACS and/or MSC) and up to six keywords of your own choice that describe the content of your article in more detail.

References: References to other work should be consecutively numbered in the text using square brackets and listed by number in the Reference list.

Illustrations

Illustrations should also be submitted in triplicate: one master set and two sets of copies. The *line drawings* in the master set should be original laser printer or plotter output or drawn black india ink, with careful lettering, large enough (3–5 mm) to

remain legible after reduction for printing. The *photographs* should be originals, with somewhat more contrast than is required in the printed version. They should be unmounted unless part of a composite figure. Any scale markers should be inserted on the photograph itself, not drawn below it.

Colour plates: Figures may be published in colour, if this is judged essential by the editor. The publisher and the author will each bear part of the extra costs involved. Further information is available from the publisher.

After acceptance

Notification: You will be notified by the Editor of the journal of the acceptance of your article.

Copyright transfer: In the course of the production process you will be asked to transfer the copyright of the article to the publisher. This transfer will ensure the widest possible dissemination of information.

Electronic manuscripts

The publisher welcomes the receipt of an electronic version of your accepted manuscript. If there is not already a copy of this (on diskette) with the journal editor at the time the manuscript is being refereed, you are invited to send a file with the text of the accepted manuscript directly to the Publisher on diskette (allowed formats 3.5" or 5.25" MS-DOS, or 3.5" Macintosh) to the address given below. Please note that no deviations from the version accepted by the Editor of the journal are permissible without the prior and explicit approval of the Editor. Such changes should be clearly indicated on an accompanying printout of the file.

Author benefits

No page charges: Publishing in Physica B is free of charge.

Free offprints: The corresponding author will receive 25 offprints free of charge. An offprint order form will be supplied by the publisher for ordering any additional paid offprints.

Discount: Contributors to Elsevier Science journals are entitled to a 30% discount on all Elsevier Science books.

For specific enquiries on the preparation of electronic artwork, consult <http://www.elsevier.com/locate/authorartwork/>

Other enquiries

For enquiries relating to the status of accepted articles through our Online Article Status Information System (OASIS), author Frequently Asked Questions and any other enquiries relating to Elsevier Science, please consult <http://www.elsevier.com/locate/authors/>

Contact details for questions arising after acceptance of an article, especially those relating to proofs, are provided when an article is accepted for publication.
